In another case of constitutional syphilis examined by Moos, in which violent subjective noises, vertigo, and pain in the bones of the skull were followed later by a remarkably rapid destruction of the hearing power, he found the following condition: The osseous substance of the petrous bone was destroyed wherever it was examined. The middle ear was entirely normal in every part. The labyrinth alone showed pathological alterations. The periosteum of the vestibule was slightly thickened; the foot-plate of the stapes was also thickened and immovable. The connective-tissue supports between the bony walls of the vestibule and the vestibular membranous structure were hyperplastic and infiltrated with small cells. The connective-tissue membrane itself of the membranous vestibular structures was likewise hyperplastic and infiltrated with small cells. The periosteum of the lamina spiralis ossea, as well as all the zones of the lamina spiralis membranacea, exhibited the same small-cell infiltration. The exudation consisted of small round cells, with a few oval ones containing a single nucleus, which were placed with regularity very close to each other. With regard to the degree of dissemination of the infiltration, it remains to be mentioned that the periosteum of the lamina spiralis ossea and of the zona pectinata was much less infiltrated than the zona pectinata and Corti's arches; the two last-named regions were so densely infiltrated that but few of the teeth and of Corti's arches could be seen distinctly; on the other hand, the infiltration was more copious in the ampullæ and sacculi, and in the connective-tissue supports between them and the bony walls, than in the membranous circular canals. The trunk of the auditory nerve was intact.

According to Politzer,[80] recent investigations leave no doubt that in cases of long duration, a chronic inflammation of the lining membrane of the labyrinth may result in a periosteal bone proliferation in the cavity of the labyrinth. The following case occurred in his own practice: The patient was a man, fifty years of age, who had been totally deaf for ten years in consequence of syphilis. In the right drum-membrane two broad, ribbon-shaped stripes extended downward at an acute angle from the end of the handle of the hammer. Bone-conduction was destroyed. Death was caused by phthisis pulmonalis. Autopsy: The ribbon-shaped stripes on the drum-membrane proved to be ridges of horny, thickened epidermis. The lining membrane of the tympanic cavity and the ossicles were normal on both sides. In decalcified sections of the cochlea, pathological alterations were mainly found in the ganglion-cells in Rosenthal's canal. Within these cells were seen small, round, granular cells without a distinct nucleus, and also oval and angular bodies, in only a few of which a nucleus could be recognized. (Atrophy and degeneration of the ganglionic cells in the ganglion spirale.) The modiolus showed in spots a reticular structure. In the spiral membrane, in the vestibule, and in the semicircular canals no changes were visible which could be interpreted as pathological.

Pathological alterations in the blood-vessels of the inner ear, similar to those described by Heubner as occurring in syphilis of the brain, have thus far been observed only in a case examined by Baratoux.

The *prognosis* must be guarded as regards the recovery of hearing. In acute cases of recent date recovery has occasionally followed the energetic employment of mercury and iodide of potassium; but in cases of gradual loss of hearing or in those of long standing, the prognosis is decidedly unfavorable. Politzer is of the opinion that the degree of deafness is not always decisive for the recovery of normal hearing, since recovery from total deafness has been observed; while, on the other hand, in milder cases, active antisyphilitic treatment not only fails to produce an improvement, but is, moreover, sometimes followed by an increase in the deafness. This author has also seen patients in whom the deafness came on while they were under the influence of mercury.

Treatment.—If the ear disease occurs during the earlier stages of constitutional syphilis, mercury should be be used freely, preferably by inunctions, till the system is brought under its influence; after that the remedy must be continued in smaller doses for a long period. Mercurial baths, subcutaneous injections of corrosive sublimate, and the internal administration of calomel, blue pill, and other preparations of mercury, may be substituted for the inunctions when they are objected to. The iodide of potassium, alone or in combination with mercury, is especially useful in cases occurring during the intermediate or tertiary stage. Roosa has obtained very encouraging results from this remedy in very large doses (120 to 369 grains daily), in cases where smaller doses failed to produce any effect. He used, however, inunctions of the oleate of mercury at the same time. To avoid disturbance of digestion it will be found best to dilute the iodide largely with water, and to administer it in divided portions during meals. Tonics and a generous diet should be given with both the mercury and the iodide to patients in feeble health. Subcutaneous injections of the muriate of pilocarpine, in gradually increasing doses (4 to 12 drops of a two per cent. solution), have also proved useful in this disease in Politzer's hands. He is of the opinion that it should be tried for from eight to fourteen days in all recent cases, and that mercury and iodide of potassium should be given only if at the end of the above-stated period no improvement is manifest. Lucae, Moos, Barr, and others also speak highly of the effect of pilocarpine in these cases, and think it worthy of further trials. Lucae has also seen temporary improvement of hearing follow the application of the artificial leech.

In order to protect the diseased ears as much as possible against the injurious effect of noises, while undergoing treatment, the patient should be kept in a perfectly quiet room, away from the streets, and it may even be advisable to cover the ears and the side of the head with cotton batting. If disease of the middle ear is present, this must be treated in the manner already described. Care should, however, be exercised, that the force employed during inflation be not greater than is absolutely necessary.

AUDITORY NERVE.—Of the syphilitic diseases of the auditory nerve, beyond the labyrinth, little or nothing is known. An intracranial disease, involving some part of this nerve may be assumed, however, if in addition to the symptoms enumerated under the head of diseases of the labyrinth, positive symptoms of intracranial disease are present in a syphilitic individual. Foci of softening in the brain, gummata, circumscribed basilar meningitis or pachymeningitis, chronic periostitis ossificans of the petrous bone, with hyperostotic narrowing of the porus acusticus, and paralysis of the trunks of the nerves from compression, are mentioned by Schwartze as the morbid conditions probably present in such cases. Of the morbid changes in the trunk of the auditory nerve and in its nuclei, due to syphilis, we have no knowledge

B. INHERITED SYPHILIS.—Affections of the ear due to inherited syphilis are met with at two periods of life, during the first year and between the fifth and twenty-fifth year of age.

In Infants.—In infants suffering from syphilitic disease of the nose and pharynx, affections of the middle ear are of common occurrence. Both the catarrhal and the purulent inflammations of this part, occurring under these circumstances, present no features by which they can be distinguished from the non-syphilitic form of inflammation. Caries and necrosis of the ossicles and the walls of the tympanic cavity, may perhaps be developed more frequently, or more speedily, in the syphilitic than in the ordinary form, but no statistics are available by which this is proved. As in many of these cases the general health is seriously impaired by the constitutional disease, often but little attention is given to the ear affection by the parents or the medical attendant of the infant, and treatment is delayed until great destruction has already taken place. In a case of purulent inflammation of both middle ears, of two months' standing which was recently under the care of the writer, paralysis of the right facial nerve existed when the patient was first seen, and paralysis of the left facial, and exfoliation of the hammer and anvil of both ears occurred a few days later. The child was greatly emaciated, and although mercury was given at once and the usual local treatment pursued, the child died two weeks later, apparently from marasmus. The prognosis is probably less favorable in syphilitic cases than in otherwise healthy children, but under proper general and local treatment, begun shortly after the appearance of the disease, many cases make a good recovery. Concerning the pathological anatomy of the diseases of the ear in syphilitic infants, we know but little. Baratoux ("Transactions of International Medical Congress," held in Washington, D.C., September, 1887) who made autopsies of forty-three still-born or new-born infants with hereditary syphilis, found lesions of the middle ear twenty-three times, lesions of the labyrinth four times, and lesions of both parts twelve times. When the internal ear was affected simultaneously with the middle ear, without pus being formed in the labyrinth, the walls of the ampullæ and cochlea were reddened; the axis of the cochlea was injected and infiltrated with round cells, and the parts were bathed in a sero-sanguinolent fluid which had taken the place of the lymph. When the internal ear alone was affected, the blood-vessels were found dilated, the walls were thickened, and in some instances hæmorrhagic spots were found.

The local treatment of these diseases does not require any other measures than those usually employed in the non-syphilitic form. Local treatment will, however, accomplish but little so long as the constitutional disease is active. For this mercury must be given; ten grains of the mercurial ointment rubbed into the palms and soles twice daily, as recommended by Hutchinson, will usually make the symptoms disappear very rapidly. Iodide of potassium is rarely beneficial in these cases.

IN CHILDHOOD AND ADOLESCENCE.—*The Drum-membrane.*—Special affections of the external canal and drum-membrane are doubtless of very rare occurrence in connection with syphilis hereditaria tarda. The only case of such a disease on record, so far as the writer knows, has been described by Pomeroy ("The Diagnosis and Treatment of Diseases of the Ear," 2d ed., p. 350) under the heading Papillo-tubercular Affection of the Drum-membrane in a Subject of Hereditary Syphilis. In this case, a boy, eighteen years of age, with parenchymatous keratitis and considerable impairment of hearing, both drum-membranes, just behind and below the malleus handle, were the seat of a nodular, grayish mass of triangular form. Large blood-vessels traversed the region of the tumors. Efforts to remove the masses by wiping with cotton wool were unsuccessful. After a few days the color of the tumors changed from gray to a dark red, and after the tumors had disappeared vessels of large size remained. Under constitutional treatment and inflation of the tympanic cavity the drum-membrane regained its normal appearance in about six months. Pomeroy infers that the tumors were in the dermal layer of the drum-membrane, as the malleus handles and short processes were distinctly behind the tumor. The drum-membranes were not perforated. It is not denied that there was more extensive disease than this, there evidently being an inflammation of the drum cavity with exudation into the tympanal lining, including that covering the round and oval windows. The tuning-fork tests pointed to a suspicion of labyrinthine disease, but actual proof of that was not given.

Middle and Inner Ear.—In the offspring of syphilitic parents, and almost exclusively in those of the female sex, between five and twenty-five years of age, there occurs occasionally a disease of the ears producing in most cases great impairment of hearing or total deafness in a short space of time. The connection between the ear affection and inherited syphilis was first pointed out by Hutchinson, though Toynbee and others had previously mentioned the occurrence of hardness of hearing in the children of syphilitic parents. Wilde's (op. cit., 266) familiarity with the disease under consideration is shown by his remark: "It sometimes coexists with, sometimes alternating with, the ocular disease." "What is termed strumous ophthalmia and also corneitis are the forms which the eye affection assumes. Occasionally it is that of iridochoroiditis." Since the appearance of Hutchinson's paper numerous cases of this affection have been put on record by various authors, and the clinical history of the disease is now well known, but our knowledge of its pathology is still very meagre. This disease is by no means of as frequent occurrence as the eye affection of inherited syphilis, and is, as has already been observed, found chiefly in the female sex. The present writer has met with it (or rather has seen it associated with well-marked symptoms of inherited syphilis) but once in a male, while he has notes of over twenty cases occurring in females. Other physicians have had a similar experience. The disease seems to be, from all accounts, of less frequent occurrence in this country and in Germany than in England, where, according to Hinton, five per cent. of the aural patients treated at Guy's Hospital, London, suffered from it.

The subjects of this disease of the ears have, in many cases, manifested symptoms of hereditary syphilis during the first year of their lives, and usually have enjoyed good hearing during early childhood. The ear disease usually begins between the fifth and twenty-fifth years of age, and is commonly preceded by an attack of parenchymatous keratitis or of an inflammation of the uveal tract of one or both eyes. Not unfrequently the ear disease commences while the eyes are still inflamed, and occasionally it precedes the eye disease. Painless swellings of the larger joints, more particularly of the knees, which pass away without much treatment, are often present at the same time, or are developed later on. In most of the cases the patients or their guardians are unable to assign an immediate cause for the ear trouble, but occasionally, as in one of Gradenigo's cases, and in one of the writer's cases, both of which occurred in young women, the deafness was attributed by the patients to exposure, particularly of the head, to draughts of cold air while the hair was wet. The first symptom to attract the attention of the patient, or of those who are with her, to the ear affection, is a sudden and marked impairment of hearing. Pain in the ear is almost never complained of. Vertigo, unsteady and staggering gait, subjective noises, and headache accompany the hardness of hearing in most cases. In a number of cases seen by the writer, vertigo and headache preceded the impairment of hearing, while in others these symptoms developed afterward. Occasionally nausea, vomiting, and headache usher in the attack. The hardness of hearing, which at first perhaps may not be of the same degree in both ears, increases steadily, and often very rapidly, to total deafness. Sometimes total deafness is found to exist as early as the second or third day after the beginning of the attack, but more commonly from six to ten weeks elapse before this stage is reached. Occasionally the progress is still slower, and is then usually characterized by marked variations in the degree of deafness from day to day.

The vertigo and the staggering gait usually continue for months and then gradually pass away. The deafness, after it has once become total, nearly always remains so. In several of the cases seen by the writer a perforative purulent inflammation of the middle ear of one or both sides developed several years afterward.

In the beginning of the disease the patients can usually hear the tuning-fork (the writer uses tuning-forks which, when struck with moderate force, are heard for from thirty to forty seconds normally when vibrating in the air near the ears) longer and louder through the air than through the mastoid process. The tuning-fork C⁴ (2,048 vibrations a second) is often not heard at all. In some cases bone conduction for tuning-forks of small size, of high and low pitch, is entirely abolished, while massive forks (for instance Politzer's C fork, described and illustrated in his "Lehrbuch," 2d ed., p. 117) are still heard through the mastoid. In cases of complete deafness of both ears, seen by the writer, he found that the tuning-forks C (128 V. S.), C¹ (256 V. S.), C² (512 V. S.) were heard both through the air and through the mastoid only when they were struck with great force, and louder and longer through the mastoid than through the air. None of these forks was heard from the vertex or when placed between the teeth, but the large C fork of Politzer (which is two and three times larger than the others mentioned) was heard from vertex and teeth. The tuning-fork C^4 was not heard at all. The shrill whistle of a distant factory was heard. Their own voices the patients could scarcely hear. In other cases of total or nearly total deafness of both ears, in which also only the large tuning-fork C was heard, the writer found sometimes a preponderance of bone conduction over aërial in one ear, while the other ear gave an opposite result. Gradenigo (*op. cit.*), who used tuning-forks of the same size and make as the writer, obtained similar results from his experiments. The examination of children with tuning-forks is, however, in most cases, very unsatisfactory in its results, as many of them are apathetic and indifferent, and can rarely be induced to produce, by singing, the tone of the fork, and one is, therefore, never certain whether they hear the fork or simply feel its vibrations.

The objective examination of the ear may reveal a perfectly normal condition of the drum-membrane, the tympanic cavity, and the Eustachian tube, or evidence of present or past disease of these structures. Acute catarrh of the middle ear will be found present in an inconsiderable number of cases, and changes in the drum-membrane, evidently the remains of bygone disease, in many others. Symmetrically placed areas of redness (localized periosteitis) on the posterior and upper wall, in close proximity to the drum-membrane, in both external canals, were observed in a well-marked case of this disease by Buck ("Transactions of American Otological Society," 1889, p. 62). Disease of the naso-pharynx is as often present as it is not. Perforating ulcers of the hard and soft palate, caries and necrosis of the naso-cranial bones, and ulceration of the larynx will be found in a small percentage of the cases.

The diagnosis of the peculiar ear affection under notice presents no difficulty if, in addition to the aural symptoms previously described, other symptoms of syphilis hereditaria tarda are present or have preceded the ear trouble. In addition to the eye diseases already mentioned, these patients often suffer from chronic inflammation of the knees or other large joints. The knees are often very much enlarged and locomotion may be painful, but there is rarely spontaneous pain. The disease usually passes off in the course of a few weeks, leaving the joints apparently in as good a condition as they were before the attack. Nodes on the long bones are also not unfrequently present. With regard to the peculiarities of the teeth, Hutchinson says: "If the upper central incisors are dwarfed, too short and too narrow, and if they display a central cleft in their free edge, then the diagnosis of syphilis is almost certain. If the cleft is present and the dwarfing absent, or if the peculiar form of dwarfing is present without any conspicuous cleft, the diagnosis may still be made with much confidence." Perforating ulcers of the hard and soft palates, deep ulcers of the pharynx, caries and necrosis of the naso-cranial bones, and laryngitis are less often seen than the other affections above mentioned. The patients, moreover, often have withered and old man-like features, a peculiar square form of the forehead, prominent frontal eminences, a sunken nose, and scars about the angles of the mouth.

With regard to this disease Hinton [34] remarks that he knows of no other affection, except fever, which in a person under twenty years of age brings on a deafness so rapid and complete, and Hutchinson says that it may be broadly stated that if a child or young person, without either earache or otorrhœa, becomes quickly and completely deaf, the patient is almost certainly syphilitic. The writer has, however, recently met with two cases, both in vigorous boys, without the slightest sign of syphilis, in whom nearly total deafness was very rapidly developed while they were in excellent health. No disease of the middle ear could be discovered, and no febrile disturbance preceded or accompanied the onset of the deafness. Examination failed to reveal intracranial disease at the time, and none has developed since. The parents of these boys absolutely denied having had syphilis. Other otologists have doubtless met with similar cases, and have, like the writer, come to the conclusion that hereditary syphilis of the ear cannot be diagnosed from the symptoms presented by the ear affection alone.

From the ordinary catarrhal inflammation of the middle ear (from which syphilitic children are no more exempt than others) the disease here described can be readily distinguished by the clinical history and the results of the local treatment.

In the absence of post-mortem examinations of the organs of hearing of typical cases of this disease, the writers on this subject are divided in the opinion as to the seat of the lesion. Hutchinson thinks it tolerably certain that the internal ear or the nervous apparatus is the seat of the affection, but as to the exact site and the nature of the morbid process he is still in doubt, and most English writers are of the same opinion. Politzer and Schwartze do not hesitate to speak of the disease as inherited syphilis of the labyrinth, and Gradenigo calls it a syphilitic otitis interna. The view that both the conducting and nervous apparatus are liable to be involved in this disease is held by Hinton and others, and Roosa has come to the conclusion that the disease is one chiefly of the peripheric and not of the central part of the organ of hearing. The view expressed by the writer in another place,[64] that disease of the nuclei of the auditory nerves might be the cause of the deafness, he has now abandoned, and a larger experience and further study of the disease leaves but little doubt in his mind that the labyrinth is involved in all cases, and that in many, both it and the middle ear are the seat of the morbid process. The apparently normal state of the accessible parts of the middle ear found in acute cases, together with the total deafness for the voice with which the disease ends, must be regarded as strong evidence that the auditory nerve is the part affected, and the absence of other signs of cerebral disturbance makes it positively certain that its terminal apparatuses are chiefly affected. The results of tuning-fork tests cannot be utilized, as we have seen, in the settlement of the question as to the seat of the disease. That in many cases evidences of disease of the middle ear are not wanting is generally admitted, but they are rarely sufficiently marked to account for the profound deafness. The usual treatment for the middle-ear affection of children, moreover, is rarely followed by improvement in the hearing, even in the cases in which, under it, the objective signs of the disease disappear.

The purulent inflammation of the middle ear, with perforation of the drum-membrane, which was developed in several of the writer's cases years after the attack which destroyed the hearing, may have been due as well to a gradual increase in the inflammation of the lining membrane of the middle ear as to an extension of a purulent inflammation from the inner ear to the tympanic cavity.

Treatment is generally regarded as of no avail in any except very recent cases. Hutchinson thinks it more than justifiable, having regard to the terrible results in prospect, *in early* stages of ear disease of this type from inherited taint, to confine the child to bed and induce ptyalism quickly. Knapp has reported a case in which a cure occurred under the use of mercury; but the writer, who adopted Hutchinson's advice in a number of cases, has been unable to arrest the progress of the disease in a single one. The iodide of potassium has been given in such cases by the writer for many years, and sometimes with apparent benefit, which, however, was generally transient. Buck saw marked improvement follow the administration of this remedy in gradually increasing doses (5 to 38 grains three times a day). If middle-ear disease is present, it should be treated by inflation and other means, and even in cases presenting no marked evidence of a middle-ear affection it is best to give the patient the benefit of the doubt and treat him locally as well. Pritchard advises repeated blistering behind the ear for several months in all cases, and as it can do no harm it may be worth while to try it. Hinton has seen striking improvement follow in a severe case from scruple doses of hydrochlorate of ammonia, and has seen good effects produced by the injection of iodine vapor with the tympanum in less marked cases. Favorable hygienic surroundings and a sufficiency of good food are, of course, to be insisted on in the treatment of all cases of ear disease, but, if the writer may judge from his personal experience, they have little or no influence on the course of this disease.

Charles J. Kipp.

ENDOCARDITIS. *Definition.*—Accepting the definition of inflammation to be "the complex of changes occurring in tissues as the result of irritation," endocarditis becomes simply inflammation of the endocardium, the accepted definition. Many of the pathological processes, however, which constitute one form of the disease are evidently so closely allied to simple hyperplastic and hypertrophic changes, and are apparently so conservative in their purpose and protective character, that we are compelled to include in the class of irritants some causes which were more exactly regarded as only normal stimulants to nutritive processes. We cannot regard the connective-tissue development that occurs in valves subject to the strain of excessive blood tension, in either the ventricles or arteries, as any more "pathological," or any less conservative and protective in its intention, than the muscular hypertrophy, which finds its origin in exactly the same cause. Irritants, then, must be held to include all causes inducing reactionary processes which are potentially pathological. Under this acceptation of the term, the definition of endocarditis becomes exact.

History.—Bouillaud was the first to employ the term endocarditis, although Kreisig had previously recognized the relations between inflammatory changes in the endocardium and valvular disease of the heart. Vieussens, Lancisi, and some others following Harvey, described a few of the valvular lesions, but without assigning a direct relation to inflammation of the endocardium. Their studies represent the earliest contributions to the pathology of cardiac disease.

Laennec's discovery of auscultation gave an impetus to the study of cardiac disease, quite as important in its results in many ways as Harvey's discovery of the circulation. It was the clinical aspects of the disease, however, which were more especially developed by Laennec, Morgagni, Sénac, and earlier investigators. Sir Thomas Watson was among the first to describe the peculiar anatomical structure of the valvular tissues and point out its bearing upon the development of new tissue and influence in determining its distribution. Although his statements have been somewhat modified by later researches, the anatomical structure of the valves and their non-vascular character are still regarded as important elements in determining the nature of the inflammatory processes.

In the history of the pathology of endocarditis the investigations of Virchow, Luschka, Turner, Moxon, Wilkes, and, later, Cohnheim, upon the general subject of inflammation, found a direct application when the nature of the endocardial changes was considered, and tended to confirm the statement of Goodsir[1] that "an explanation of its phenomena is not to be looked for by referring them to actions of the extreme vessels, but to a disturbance of the forces which naturally exist in the extra-vascular portions of the inflamed part," a statement which finds special illustration in inflammations of non-vascular parts. In the more direct study of endocarditis Luschka developed more particularly the histological changes, and Virchow the sequelæ and complications. The history of infectious endocarditis does not cover a period of over twenty-five years, while researches within the past decade have made such radical changes in our ideas of its etiology as almost to render valueless all previous ideas.

Virchow, Kirk, Eberth, Lancereaux, and Moxon may be mentioned among the earlier investigators whose work was connected more especially with the pathological changes and etiology of the disease. The intimate clinical relations which ulcerative processes in the endocardium sustain to septic conditions had been clearly pointed out, but under the stimulus of Koch's discoveries pathologists sought to make clear the etiological relations, and to establish an unbroken chain of pathological elements starting in some specific cause.

Wyssokowitsch, Weichselbaum, Stern, Hirschler, Ribbert, and Prudden are among the more prominent of those to whom we are indebted for our knowledge of the relation of bacterial elements to the etiology of ulcerative endocarditis.

Much has been accomplished in this direction within a very recent period. Valuable contributions to the clinical history of the disease have been received from so many sources that an enumeration of authorities would include all the prominent clinicians of the past twenty years.

Classification.—From a pathological stand-point we recognize an entity of character in the various manifestations of this disease, with such variations only as may attend any inflammation. *Cellular infiltration*, the development of granulation or neoplastic tissue—which is the characteristic element of the pathological changes,—when rapid produces what is known as "simple or exudative endocarditis;" when associated with necrosis of the endocardial tissue it becomes "ulcerative;" while development of the cellular elements into fibrous tissue constitutes "interstitial" endocarditis.

It is evident that exudative must often develop into interstitial endocarditis, without any line of demarcation.

Upon an etiological basis we are compelled, by recent pathological studies, to recognize simple, or non-infectious, and infectious endocarditis; the former including, as a rule, the exudative and interstitial forms, and the latter corresponding to ulcerative endocarditis, although the non-infectious disease may possibly cause necrotic changes in the endocardium.

For descriptive purposes, a combined classification is not only more convenient, but also corresponds with three forms of the disease which can usually be recognized clinically, even when the transitional stages present no marked variations in the symptoms.

I shall therefore describe endocarditis under three heads:

1. Acute Non-Infectious Endocarditis.
2. Interstitial Endocarditis.
3. Infectious (or Ulcerative) Endocarditis.

Anatomy.—The endocardium is a non-vascular tissue composed of a connective-tissue layer with abundant elastic fibres. Its inner surface is made up of a single layer of flat endothelial cells. The membrane is connected to the muscular tissue of the heart by common fibrillated connective tissue which contains the nutrient vessels and a few muscular fibres. The valves are composed of prolongations of fibrous tissue from the fibrous rings surrounding the valvular openings. The endocardium passes over both surfaces of the auriculo-ventricular valves, and over the ventricular surfaces of the sigmoid valves, to their edges, where it joins the tunica intima of the arteries, of which it may practically be considered a continuation. The fibro-elastic body of the endocardium is thicker over the valves, and more abundant near their bases than at their apices. The auriculo-ventricular valves alone contain a few blood-vessels near their attached borders. Since the endocardial tissue is devoid of blood-vessels, it is evident that inflammatory processes must be attended by more or less extensive vascular changes in the subjacent connective and muscular tissue, and are thus prone to extend to these tissues.

NON-INFECTIOUS ENDOCARDITIS. — *Pathology.* — The vascular changes which form so prominent a part of many inflammatory processes are not marked in endocarditis, and are known to be present early in the connective-tissue vascular layer rather theoretically than from direct observation. As the exudative and hyperplastic changes progress, not only do the vessels become hyperæmic, but new capillaries are formed in the midst of the embryonic tissue, and this vascularization may extend deeply into the substance of the valves.

The essential and characteristic pathological process of acute endocarditis is found in a combination of exudative and parenchymatous changes. So far as we know, the exudation is composed almost entirely of white cells. If there is any free exudation upon the surface of the endocardium, it is washed away by the blood-current, leaving no anatomical indications of its occurrence. The cellular elements of the exudation, in connection with newly formed connective-tissue cells, become aggregated into nodular masses beneath the endocardium, causing irregular elevation and roughening of its surface.

These masses of granulation tissue, which are surrounded by a more or less diffuse infiltration of leucocytes, speedily become vascularized. The endothelium covering their apices disappears, leaving the new embryo-plastic cells exposed to the blood-current, and their roughened surface forms a favorable site for the deposition of thrombi. These thrombi are formed from the fibrin of the blood with entangled red and white blood corpuscles. When the granulation tissue develops about the bases of the valves and the outgrowths from adjacent valves come in contact, they become united and may form permanent adhesions between the valvular flaps or chordæ tendineæ.

Hyperplasia of the connective-tissue cells is an important element in the production of the new tissue. While the young connective-tissue cells are found most abundantly in the nodular masses, similar hyperplastic changes take place in the surrounding endocardium and in the areas where white-cell infiltration is most marked.

This cellular hyperplasia and infiltration is always attended by some softening of the intercellular tissue, with the development of a fluid within the endocardium which resembles mucin in some of its chemical properties. When the neoplastic tissue is developed with great rapidity or causes prolonged interference with endocardial nutrition, the softening may so weaken the endocardium as to allow of bulging and the formation of aneurisms, or even rupture of the membrane. The cellular masses, also, may either be torn from their bases, or undergo degenerative and necrotic changes which may extend to the surrounding infiltrated tissue.

In these degenerative changes pus is seldom formed, but granulo-fatty changes convert the entire vegetation into a débris of disintegrated cells, free fat globules, and blood pigment. A more rapid necrotic process may induce softening of the endocardial covering, with rupture and discharge of the contents into the blood-current.

Suppurative changes, when present, are most prominent in the masses of aggregated cells, and result in formation of minute abscesses, rupture of which leaves depressed ulcers. In connection with all grades of these inflammatory changes in the substance of the endocardium there occurs a more or less abundant deposition of fibrin from the blood upon the prominent, roughened, or ulcerated portions of the membrane and valves, forming thrombi. These deposits bear no special relation to the inflammation itself, but are such as occur on any roughened or inflamed endothelial vascular surface. They are formed more rapidly and abundantly in rheumatic and septic forms of endocarditis.

Morbid Anatomy.—In intra-uterine life endocarditis affects almost solely the right heart. After birth its seat is quite as invariably in the left heart.

Although any part of, or the entire endocardium may be involved, the inflammation most frequently begins in the valves, and seldom extends beyond the valvular orifices and the chordæ tendineæ. On the valvular surfaces the most abundant evidences of the inflammatory changes will be found at the bases of the valves and along the thickened line, a little distance from their edges, known as the line of closure. Upon the mitral valve, the points of insertion of the chordæ tendineæ will often be surrounded by the inflammatory processes, which also may have extended upon the chordæ. In the milder forms those areas near which the capillaries are abundant may present early a punctate or arborescent vascularity, only to become opaque as the exudation and hyperplastic changes occur. Generally there is little redness of the endocardium until the stage of vascularization of the new tissue. Before thrombi have formed on the endocardium, the affected surface presents a more or less granular appearance, being covered with small rounded or conical elevations corresponding to the points of cellular aggregation. When the exudative process is more extensive, these "granulations" become marked elevations, varying from the size of a hemp-seed to that of a pea, which either rest upon a broad firm base, or possibly have been drawn out until they are retained only by a mere pedicle. They are often so abundant as to form [illegible] masses along the base and edges of the valves, or fringed fringes about the attachments of the chordæ tendineæ. These vegetations are frequently seen projected along the thickened band which passes from the base of the valve to the Arantian body.

They become detached from the endocardium, and when forcibly removed, they bring away portions of the membrane, leaving a roughened line of attachment. It is seldom that the blood-current tears them away, but when this has occurred the remnants of the detached pedicle may be observed.

The thrombi which form upon the roughened vegetations vary greatly in thickness from a light film to a layer one or two, or even more, lines in thickness.

They are found on all the vegetations, but are most prominent upon those which are especially exposed to the blood-current, and are thickest on that part of the vegetation directly opposed to the impact of the blood. In appearance they are light in color, rather firm, and may be either conical caps, irregular raspberry-like masses, or attached bodies with filamentous prolongations. Detached portions of these thrombi, or crumbled bits of the vegetations, may form emboli that will pass into the general circulation, and initiate embolism and infarctions of the various organs. Pockets containing coagula or aneurisms of the endocardium will mark points of softening where aneurisms and valvular ruptures have been developed. Erosions and small irregular ulcers indicate detached vegetations or degenerative or necrotic processes. Such ulcers, however, are not frequent in simple endocarditis, and seldom present the dirty sloughing surfaces of ulcers found in the infectious form of the disease.

INTERSTITIAL ENDOCARDITIS.—*Pathology.*—The pathological changes of interstitial endocarditis not only may be, but often are, simply an advanced stage of acute endocarditis.

They consist essentially in the formation of new fibrous tissue, principally in the valves. As the intensity of the inflammation in the acute disease subsides the cellular elements of the vegetations become organized into a fibrillated connective tissue which passes on to the stages of maturation and contraction.

The vegetations shrink as contraction and obliteration of their capillaries take place, while the infiltration of the surrounding area assumes greater prominence, causing a more even thickening of the endocardium and less prominence of the vegetations. Adhesions between the edges of the valves, of the valves to the cardiac walls, or between the chordæ tendineæ, are even more frequent than in the acute disease. Acute necrotic changes are infrequent, but fatty degeneration of the neoplastic tissue and a subsequent calcareous deposit are of common occurrence. When the cellular infiltration and hyperplasia are not secondary to the acute process they are so gradual in their development as to escape notice, and the formation of the fully developed fibrous tissue goes on coincidently with cellular hyperplasia. In these cases the formation is in diffuse masses, more than in isolated nodules. Although the usual result is to strengthen the valves, points of softening may develop and be the cause of valvular aneurisms. This weakening of the endocardium and subsequent aneurismal formation is especially liable to occur when chronic endocarditis affects the wall of the ventricle.

When the inflammatory processes are an extension of an endarteritis of the aorta, the cellular exudation is at times more abundant, forming soft fleshy masses about the aortic orifice. This new tissue shows a marked tendency to become fibrillated, with a special liability to fatty and calcareous changes. As a rule it is confined largely to the aortic valves, although more typical interstitial processes may be going on in the endocardium. The development of new tissue is less closely confined to the endocardium in interstitial endocarditis, but extends to the adjacent tissue, and may involve the cardiac muscle quite extensively.

Deposits of fibrin from the blood are quite constant. They are most abundant and extensive on the auricular surface of the mitral and the ventricular surface of the aortic valves. When the free prolongations of these fibrinous masses reach from one valve to another they may cause adhesions, as between the mitral and aortic, which will produce most serious interference with the function of the valves.

Morbid Anatomy.—As in the acute disease, the marked changes are more commonly confined to the valves, or even to some portion of one valve; but any part of the endocardium may be affected, and that at the apex of the left ventricle is a frequent seat of chronic endocarditis. The endocardium will present all grades of change, from small opaque thickened spots scattered here and there over the walls of the heart and valvular surfaces, to the most extreme induration of the tissues.

The valves seldom present such prominent vegetations as in acute endocarditis, but are more uniformly thickened, in some cases to two or three times their normal thickness. This induration is generally most marked about their bases and edges, and gives the valves a firm, often almost cartilaginous and nodular consistency. They are inelastic, and often adherent for various distances from their bases toward the apices. Atheromatous and calcareous patches present yellowish chalky masses scattered throughout the valve substance, or appear as bead-like points strung along the free borders of the valves. Adhesions between the valvular leaves may result in the formation of a long funnel-shaped tube with a small opening at its apex, or a diaphragm with only a narrow slit through its centre. In many cases retraction is the most prominent change and the valves are curled up into rough, stiffened masses around the valvular opening, while less frequently extensive changes may have caused no disturbance of the valvular function. The chordæ tendineæ often share largely in the changes. They are found thickened, adherent, shortened, fused, or ruptured. When rupture occurs in those attached near the apex of the valve, the free end may be driven back through the valvular opening with each systole, causing sudden and extensive insufficiency. Aneurisms may rarely be found in the valves or interventricular septum, but are frequent when the endocarditis is of the ventricular wall or apex. The walls of such aneurisms are commonly smooth, and the cavity free from clots. When the wall is rough the cavity will be found with soft adherent clots.

INFECTIOUS ENDOCARDITIS.—*Pathology.*—Since the specific causes of infectious endocarditis induce their changes with far greater certainty in endocardial tissue which has undergone some form of injury, it often happens that the septic disease becomes engrafted upon either simple acute or chronic interstitial endocarditis.

In such cases the pathological changes and consequent morbid appearances of these conditions will be present.

Although pathological experiments upon the lower animals have seemed to show that some injury of the endocardium, however slight, is a necessary condition for the action of the specific cause of the disease, it certainly occurs in cases in which we are unable to state the nature of the injury causing that loss of endothelium which opens an avenue of entrance for the septic element. We are forced to the conclusion, which is not only rational but is supported by the facts in many analogous conditions, that defective vitality, incident to the constitutional poison of some precedent disease, has rendered the valvular endothelium unable to resist either the irritant action of the poisonous germs or the traumatism of the valvular action and the blood-current. Whether primary, or secondary to simple inflammation, the earliest changes of infectious endocarditis are probably associated with the entrance of bacteria within the substance of the endocardium. They enter from the free surface, where the endothelial covering has been removed, or rendered less resistant, and rapidly invade the connective-tissue layer, passing later to the deeper tissues and vessels.

Coincidently there is established an inflammation in which white-cell exudation is prominent. Necrotic changes develop rapidly in the affected areas, even before cellular infiltration is marked. The necrosed tissue is almost entirely devoid of nuclei, but the white-cell infiltration of the surrounding parts gradually extends to these necrotic foci.

The cellular exudation becomes purulent early, and both the ulcerated surfaces and the adjacent tissue are infiltrated with pus.

The affected tissue is more commonly thrown off by a process of disintegration, leaving ragged, irregular ulcers covered with shreds of sloughing tissue. Very rarely a granulation tissue may lift off the necrosed mass and form a healthy ulcer.

It is more than probable, however, that this occurs only when the ulceration is non-specific, since, as we shall have occasion to say later, specific ulceration of this tissue has resulted heretofore in death.

It is desirable to maintain a careful distinction between those ulcers in which necrosis is due to the specific action of bacteria, and those losses of tissue found in simple endocarditis which depend upon granular or fatty degeneration, consequent to a compression by rapid cellular exudation, causing defective nutrition.

When bacteria are found in such ulcers, or in the inflammatory products of an old endocarditis, they must be regarded as being accidental or consequent, and not an etiological relation, to the ulceration.

Softening of the endocardial and myocardial tissue, with the stretching and aneurismal developments already described, as well as rupture and perforation of valves, are more frequent than in the simple form of endocarditis. At times also the blood, entering on the floor of an ulcer, dissects a course between the valvular surfaces and underneath the endocardium in the heart muscle.

Thrombi, composed of fibrin, bacteria, red corpuscles, leucocytes, and blood-plates, form rapidly, both upon the ulcers and the necrosed areas, which, owing to their septic character, are specially liable to be torn off and form emboli.

Morbid Anatomy.—The areas of necrosis, which are most frequently found on the valves of the left heart, present an opaque, dirty-gray, or yellowish-white appearance of irregular outline. The surrounding endocardium is swollen, softened, lustreless, and opaque. After ulcers have been formed they appear as irregular but well-defined openings and depressions of the endocardial surface. Their edges are softened, thickened, and ragged, and their floor, which is formed of the muscular tissue of the heart, is covered with scraps of sloughing tissue and infiltrated with pus. Rarely it is covered with granulations. The thrombi which are adherent to the rough edges and necrosed tissue are of a reddish-gray color, soft, friable, and often strung out into long shreds. Within the endocardium may often be seen small abscesses, and lacerated valves and chordæ with aneurismal pouches give evidence of the extent and severity of the destructive changes. Under the microscope the edges and floors of the ulcers, with the adjacent endocardium and vessels, as well as the thrombi, are seen to be filled with bacteria, which are more frequently and constantly micrococci rather than bacilli. No single and constant bacterium has been observed. On the contrary, all observers agree that several different micrococci and bacilli have been found in the endocardial ulcers; although the staphylococcus pyogenes aureus and streptococcus pyogenes are the more constant and abundant.

Fränkel and Sänger found eight different micro-organisms in thirteen cases of endocarditis. Babes found (1) a coccus resembling that of erysipelas, (2) one similar to that known as Fränkel's pneumococcus, (3) tubercle bacilli, and (4) several spheroidal and oval micro-organisms, both single and in chains. Wyssokowitsch seems to have determined that the streptococus grows the faster, causing an anæmic necrosis, and the staphylococcus more slowly, with suppurative changes.

Prudden's investigations of ulcerative endocarditis, which seem to have been conducted with equal care and skill, give somewhat different results. In eight out of thirteen cases of ulcerative endocarditis he was unable to demonstrate the presence of bacteria, even by culture. Clinically, the bacterial and non-bacterial cases could not be distinguished. He also claims that only the streptococcus and staphylococcus have been found in man. These facts emphasize the point that septic and non-septic ulcerations cannot be differentiated by either the gross anatomy, the occurrence of emboli and infarctions, or by the clinical manifestations.

The infarctions in various organs and tissues, with their later developments into abscesses as well as petechiæ in the skin, all of which develop from occlusion of the arteries and capillaries by detached bits of cardiac thrombi and vegetations, may be considered part of the morbid anatomy. When a large vessel, as the popliteal or femoral, is obstructed, gangrenous processes may ensue. These all present the same pathological changes and morbid appearances as do septic infarctions in pyæmia, or from any other cause. Clinically, these manifestations become important parts of the symptomatology.

ETIOLOGY.—*Acute Non-Infectious Endocarditis.*—It is a well-established *belief* that the exciting cause of all forms of endocarditis is direct local irritation of the endocardium. It is an equally well-established fact that in non-infectious endocarditis we are unable to recognize any definite chemical element or physical body that is known to produce such irritation. The pathological characters of those diseases with which simple endocarditis is most frequently associated, render it extremely probable, nevertheless, that the chemical products of a perverted, retrograde metabolism are the offending elements and etiological factors in the disease.

It is not impossible, however, that a deficiency in some of the normal elements of nutrition, which have been consumed in excess by the unusual metabolic processes in the tissues, becomes an exciting cause of malnutrition, and secondarily of inflammation.

Certain cases of endocarditis suggest the possibility of central disease of the nervous system being the primary etiological factor in their development.

It has been proven that lesions of the nerve-centres may induce trophic disturbances in the endocardium as well as other tissues; but at present it seems probable that, in so far as nervous irritation is a cause of endocarditis, it acts secondarily through disturbances of systemic metabolism, rather than primarily upon the endocardium. We are, therefore, forced to confess ignorance of the ultimate or direct cause of the disease, and content ourselves with stating its clinical relations.

Acute non-infectious endocarditis is rarely a primary affection, but may be induced by traumatism. It is more frequently associated with acute articular rheumatism than with any other disease, and is not infrequently developed in connection with the subacute or even chronic rheumatic diathesis. Some statistics give the proportion of cases of acute rheumatism complicated by endocarditis, as from forty to fifty per cent. Others place it much lower. Previous attacks of acute, or the presence of chronic, inflammatory changes render the invasion of the acute process more probable in connection with rheumatism or any of the exciting diseases. Any one of the constitutional diseases in which the constituents of the blood are affected may be complicated by endocarditis. The exanthemata are especially liable to such complications. Scarlatina and measles head this class, and Wunderlich even places measles next to acute rheumatism as the most frequent cause. Bright's disease, gout, septicæmia, the essential fevers, and pneumonia are among the more common causes of simple endocarditis. Endocardial murmurs are frequently developed in cases of chorea, and it has been customary to regard this neurosis as a common cause of endocarditis. More careful observation seems to show that, while such a connection is both possible and not infrequent, many murmurs have been considered as due to inflammatory changes which were developed from other causes. It has also been supposed that a common cause was present in both rheumatism and chorea.

It is of the utmost importance to remember that endocarditis may develop, without the intervention of distinct rheumatic symptoms, after conditions favoring the perverted metabolism characteristic of rheumatism. That the irritant and [illegible] elements of exercise may induce endocardial sooner than arthritic inflammation, is entirely in accord with the clinical facts, viz., that we often find a fully developed endocarditis with the advent of articular symptoms, and that endocarditis rarely appears in connection with even the most severe cases of acute rheumatism after the ninth day.

The causes most constantly credited to produce the apparently idiopathic form of the disease may be classed generally as (1) an inherited rheumatic or gouty diathesis; (2) general malnutrition from improper or insufficient food; (3) exposure to changes of temperature, or prolonged and exhausting muscular strain; (4) exposure to septic influences.

Interstitial Endocarditis.—As already stated, interstitial endocarditis is frequently but the continuation of the acute process. But even when chronic from the outset, it depends in a very large proportion of cases upon the same causes. Next to chronic rheumatism, however, Bright's disease and gout assume the most prominent place in the etiology. In connection with these broad dyscrasiæ, we also remember a fibroid diathesis, which strongly predisposes, if nothing more, to the development of fibrous tissue in the cardiac valves as well as the arteries under trauma and other forms of irritation. It is in this form of the disease that we find that protective development of connective tissue, which has been referred to in our definition, under the persistent traumatism of the valves induced by high arterial tension and cardiac hypertrophy—a development which may eventually become distinctly inflammatory, and compel us to place high arterial tension and cardiac hypertrophy among the exciting causes of interstitial endocarditis.

Infectious Endocarditis.—It is a generally accepted fact that, under certain conditions, bacteria may be the exciting cause of necrotic and ulcerative processes in the endocardium, although cases having such an origin cannot always be differentiated either clinically or macroscopically. But we are inclined to doubt, while accepting the above as proven, that the presence of bacteria in endocardial ulcerations is indisputable proof of their having been the cause of such ulceration. Thus far, experimental proof goes to show that some lesion, either physical or nutritive, of the endocardial epithelium is a necessary precedent condition to entrance and pathological activity of the bacterial elements. Ribbert alone reports successful induction of ulcerative endocarditis by inoculation without previous injury of the valves, and that but infrequently. It is not difficult to believe, however, that many systemic conditions, or even the traumatism of the valves incident to high arterial tension and cardiac hypertrophy, aside from acute or chronic inflammation, may induce such depression of cellular vitality in the valvular endothelium as to deprive it of its natural protective power, and allow the invasion of bacteria found in the blood.

Clinically, infectious endocarditis occurs as a complication not only of the typically septic diseases, as pyæmia, diphtheria, scarlatina, puerperal fever, and osteomyelitis, but also with many of the specific forms of inflammation, as pneumonia and dysentery.

It does not seem necessary to suppose that the specific bacteria of these diseases become in turn the exciting cause of the endocarditis. On the contrary, it is more probable that they simply induce that degree of endocardial malnutrition which is necessary for the introduction of other forms of infective micro-organisms. Among the unique apparent sources of infection reported in infectious endocarditis, are osteomyelitis with suppuration, acute and chronic gonorrhœa, ulcer of the foot from an ill-fitting shoe, etc.

SYMPTOMS.—*Non-Infectious Endocarditis.*—Cases of simple endocarditis unattended by other disease, often present no symptoms of sufficient intensity to bring them to the notice of a physician. When developed in connection with some of the subacute manifestations of rheumatism, the cardiac symptoms may be less marked than is usually the case. Although often ill-defined and few in number, with no typical development either in order or intensity, they are characteristic and sufficient to call attention to more exact physical signs. Palpitation, which may be constant or induced by slight exertion, and which has occurred rather suddenly in patients before unconscious of their heart's action, is one of the most constant and important symptoms. It is often attended by a sense of constriction or discomfort in the cardiac area, which may become concentrated into a distinct localized pain, usually near the apex.

Dyspnœa usually accompanies the palpitation, or is developed upon slight exertion. The dyspnœa and palpitation may perhaps be recognized by the physician before the patient has become aware of their presence.

It is probable that an irritable action of the heart is all that can be ascribed to the endocarditis alone, and that severe palpitation with pain and dyspnœa indicate the presence of coincident myocarditis.

All other subjective, as well as many of the physical, symptoms depend upon the myocardial change. Of these, disturbances of the cerebral circulation are most common, as dizziness, vertigo, sleeplessness or delirium, syncope, and coma, with nausea and vomiting (see Myocarditis). The constitutional reaction is marked by a febrile condition in which the temperature seldom exceeds 102° F. Pain in the joints and organs, followed by nodular indurations which do not suppurate, are indicative of embolism and infarction. Embolisms of the cerebral or large vessels will be attended by characteristic symptoms.

Physical Signs.—Inspection.—In most cases the superficial evidences of endocarditis will be confined to the cardiac area. Early, the apex-beat is sharp and irregular but not displaced; later it becomes more diffuse and indistinct, but is seldom carried much to the left of its normal position. This change is never so marked or developed so suddenly as in pericarditis. When myocardial changes are extensive the heart's action is more tumultuous, and the patient's general appearance indicates deficient circulation.

The face is flushed at first, but soon becomes darker, or even livid; or it may become pale, gray, and cyanotic. These evidences of venous stasis develop earlier and more rapidly in children than in adults.

The surface becomes covered with a cold perspiration, and the dyspnœa, either constant or paroxysmal, causes most evident distress.

Palpation.—The sharp irritable action of the heart, as well as the increased force of the impulse in the earlier stages, is well appreciated by palpation. At this time the pulse is strong and forcible. Later, as the cardiac action becomes more irregular, the pulse decreases in force and volume, and may even become dicrotic, causing apparently a great disparity between the pulse and that tumultuous action of the heart, which is the excessive action of struggling weakness. As the disease progresses, the cardiac impulse is felt to be more irregular in rhythm and uneven in force. This unevenness varies from day to day, the heart at one time thumping heavily against the chest wall, and again giving hardly any perceptible impulse. When myocardial changes have taken place the weak impulse will be more constant, but it must be remembered that an intercurrent pericarditis is often the cause of sudden weakening of the apex-beat. The action is stronger when pain is present in the precordial area, and if this pain is due to pericarditis, it may be increased by pressure. An endocardial systolic thrill may be developed as the valves become roughened or thrombi form upon their surfaces.

Percussion.—The area of cardiac dulness is not usually increased. When incompetence or obstruction of the mitral valve induces pulmonary congestion and obstruction of the right heart circulation, there may be a slight increase in the area of dulness to the right. It is only when myocarditis leads to dilatation of the left ventricle that there is any marked increase in cardiac dulness. Sudden dilatation or distention of the cardiac cavities by blood, or coagula and fibrin, will produce such severe and characteristic symptoms as to render the percussion area of no importance.

Auscultation.—When the development of a case of acute endocarditis can be followed from its inception, the earliest auscultatory sign will often be the unusually clear, loud, ringing character of the cardiac sounds, most marked over the apex of the heart, and probably induced by the sharp, snapping cardiac contraction that is associated with the earliest irritation of the endocardium and intrinsic cardiac ganglia. Occasionally, in this early stage the heart-sounds are doubled by an irregular and inco-ordinate action of the ventricles. This doubling of the heart-sounds is more frequent, however, in the later stages, and is then often associated with a weak first sound and intensification of the second sound, most marked over the pulmonary valves. As vegetations and thrombi form upon the mitral valve, and before the characteristic murmur is audible, there is developed what many authors place as the earliest sign of endocarditis. It is prolongation of the first sound, so that it appears to run into the second sound. This is due to the loss of the valvular element of the sound. The swollen valves are not only softened but perhaps covered with thrombi, so that in this cushioned state they cannot close with the normal sharp impact. Loss of the valvular element alone, however, would not prolong the first sound, as stated by Sansom,[2] by leaving the muscular part to be heard alone. It occurs rather because there is already present a soft developing murmur so like, in its quality, the muscular part of the first sound, that when the valvular click is removed the ear is no longer able to distinguish the transition from the one into the other. When later this murmur has become louder and more characteristic in quality, the first sound is immediately shortened to its muscular part, and the ear readily separates the two without the aid of the valvular element. Endocarditis may develop one or several murmurs, and they may be located at the mitral or aortic openings. About half the cases of rheumatic endocarditis have a mitral murmur alone. Mitral and aortic murmurs are associated in about fifteen per cent. of cases. The characteristic murmur of endocarditis, as well as the most important and constant sign of the disease, is a systolic murmur which, beginning as a prolongation of the first sound, gradually develops a soft blowing quality of considerable intensity. It is heard most constantly at the apex, but does not of necessity indicate mitral incompetence, as it is often purely endocardial. This "bellows" murmur may change its point of maximum intensity with variations in roughening of the endocardium upon which it depends.

When cardiac hypertrophy and other evidences of pre-existing valvular disease are present, it is always difficult, and often impossible, to determine whether an existing murmur is recent or old. Some assistance may be found in the quality of the sound, but certainty depends upon watching the murmur as it increases. In such cases one may at times state definitely when a new endocarditis has become engrafted upon chronic interstitial processes. The mitral murmur of acute endocarditis is seldom conveyed to the back, as are the murmurs of chronic disease. Its point of maximum intensity is variable and its area of diffusion small.

The evidences of impeded pulmonary and right heart circulation are often prominent. Accentuation of the pulmonic second sound is quite constant, certainly when the heart begins to flag; and an increase of the normal leakage at the tricuspid develops into a distinct murmur in fully one-half the cases of mitral, and in over one-third the cases of acute aortic, endocarditis. These murmurs cease with the restoration of the circulation. The murmurs of aortic endocarditis are usually of the same soft blowing quality, but may be harsh or musical. The second sound is usually weak over the valves and entirely absent over the carotids in aortic endocarditis. The murmurs are always systolic, as incompetency of the valves does not occur unless they are lacerated or perforated by ulcerations.

In children the murmurs are generally confined to the mitral valve, and are often both obstructive and regurgitant.

Interstitial Endocarditis.—The symptoms and physical signs of interstitial endocarditis are all referable to lesions of the valves, and have been considered under Heart, Valvular Diseases of, to which the reader is referred.

Infectious Endocarditis.—Differences in the rational symptoms of infectious endocarditis from those already given for simple endocarditis, depend upon the greater severity of the endocardial changes, and the specific character of the constitutional infection.

All the symptoms given above may be found in the infectious form of the disease; a few additions only are necessary.

The subjective cardiac symptoms are, with perhaps greater frequency than in simple endocarditis, exceedingly obscure or entirely wanting; but the general systemic condition of the patient, even when the source of the infection is unrecognizable, or such as to forbid the suspicion of general primary pyæmic infection, presents such marked evidences of severe constitutional disturbance as to render it exceedingly improbable that the disease is ever entirely overlooked, as may happen in simple endocarditis.

The prominent symptoms are those of an acute infectious disease of an adynamic type. An initiatory chill, which may be repeated at irregular intervals, is followed by a febrile condition, whose chief peculiarity is its uncertainty and irregularity. Sometimes entirely absent or not exceeding 100° or 101° F., it is more commonly a sharp rise to 105°, 106°, or even 107° F. which continues, until the death of the patient, with irregular or distinctly periodic intermissions. Just before death supervenes, it may run very high or become subnormal. The patient, usually, passes very early into a typhoid condition with nausea and vomiting, and a rather persistent diarrhœa. A hæmatogenous jaundice is always slightly marked and may be extreme, or accompanied by a similar hepatogenous condition when infarctions in the liver obstruct the bile-ducts.

To these symptoms must be added all those dependent upon cardiac failure and embolic infarctions throughout the body.

Albuminuria and hæmaturia, however, may be present without renal infarctions.

Since myocarditis is quite invariably present, dyspnœa, palpitation, and cyanosis are usually prominent symptoms.

Of the cerebral, splenic, hepatic, arthritic, and pulmonary infarctions, it will suffice to say that some or all are almost always developed, and present the usual symptoms of such infarctions with a tendency to suppuration.

When infectious endocarditis complicates pyæmia or other severe infectious diseases, in which many of the foregoing symptoms have already appeared, the advent of the cardiac complication may be evidenced only by an intensification of the typhoid condition, and can be recognized with certainty only by the physical signs.

Physical Signs.—The physical evidences of an infectious endocarditis do not differ in kind from those given for the simple inflammation.

The evidences of cardiac failure are usually more prominent, and severe lesions of the valves, as rupture, and perforation, or rupture of the chordæ tendineæ, are not infrequent. These latter accidents are attended by rapid development of a typhoid condition which is speedily followed by the typhoid delirium and coma that always precede death in this disease. Finally, it must be admitted that cases of septic endocarditis complicating pyæmia, pneumonia, diphtheria, and similar diseases, may cause such slight change or increase in existing symptoms as to escape detection, although such a misfortune would hardly happen were the heart carefully examined from day to day in diseases liable to this complication.

DIFFERENTIAL DIAGNOSIS.—*Non-infectious Endocar-*

dium. Since the diagnosis rests mainly upon the physical signs, the differentiation is from other causes of cardiac murmurs, principally pericarditis, aortitis, functional and anæmic murmurs. Pericardial murmurs (friction sounds) are superficial in character, not necessarily synchronous with the heart-sounds, often double, with a to-and-fro sound and heard over only a limited area, which is usually at the base of the heart. They are often distinctly creaking, rubbing, or leathery in quality, are increased when the patient leans forward or takes a deep inspiration, and by pressure with the stethoscope over the præcordial area, and they disappear as the area of cardiac dulness is increased by fluid effusion. Pericardial sounds may obscure the cardiac sounds, but the murmur is there, and the valvular click can be distinguished so long as the cardiac sound is heard at all. On the contrary, the murmurs of acute endocarditis tend very early to obliterate this valvular element of the first sound, and cause an inseparable union of the cardiac sound and murmur. They are soft and blowing in quality, and when observed early are augmenting in intensity. They are more distant, are synchronous with the heart-sounds, and when double have the valvular sound between them.

Their point of maximum intensity is a predetermined point as a rule, and they are diffused beyond the præcordial area. Pressure does not increase their intensity, and they are often more distinct when the patient reclines upon the back. Endocarditis often gives a thrill, felt on palpation, which is not found in pericarditis.

Increased area of dulness is attended in pericarditis by cessation of pain, disappearance of the murmur and obscuration or loss of apex-beat; in endocarditis by increase of pain, often intensification of the murmur, and diffusion of the apex-beat.

Acute inflammation of the aorta is exceedingly rare—indeed some authorities doubt its existence. It is probably accompanied in most instances by similar changes in the aortic valve. Aside from the evidences of endocarditis there may be acute neuralgic pains which pierce the upper portions of the chest and shoot down the spine, or are reflected to other parts. The diagnosis is usually doubtful.

The diagnosis of functional and hæmic murmurs rests upon the recognition of a cause, their location at the base of the heart, the absence of evidences of change in the cardiac walls due to obstruction or regurgitation, their invariable systolic rhythm, and the absence of other signs of endocarditis.

It is often impossible to determine whether a cardiac murmur depends upon recent changes in the endocardium or chronic interstitial processes, and when a new murmur is added to one previously existing, it can be known only by repeated observations which display its development. Recent murmurs are usually soft and systolic, old ones harsh and often diastolic.

The myocardial changes of acute endocarditis tend to weakening and dilatation of the heart with weak sounds; those of interstitial change are hypertrophic, causing accentuation of not only the heart-sounds but their accompanying murmurs. (See Heart, Valvular Diseases of.)

Infectious Endocarditis.—The diverse manifestations of septic endocarditis have resulted in its being mistaken for several of the infectious diseases as well as some cerebral lesions. Hirschfeld recognizes two types of fever in this disease, corresponding to typhoid and the intermittent malarial fevers.

It has also been mistaken for acute phthisis. In many cases the diagnosis can be determined only by physical examination of the heart, and when a constant unchanging murmur is found at the first examination an immediate diagnosis may be impossible. The typical fever curve, abdominal pain and tenderness, and eruption of typhoid fever are wanting in endocarditis, while dyspnœa without physical signs of pulmonary disease, and embolic infarctions are not found in typhoid. In the acute severe forms of intermittent fever the liver as well as the spleen is enlarged and tender, which it is not in endocarditis unless infarctions have formed. In endocarditis the fever is remittent rather than fully intermitting, and quinine has little effect in controlling its exacerbations. During the intermissions of the malarial paroxysms the patient may be quite well, but in endocarditis the depressing effects of the disease do not abate.

A careful examination of heart and lungs can hardly fail to differentiate endocarditis from phthisis. When the endocarditis is of the right heart, pulmonary infarctions may produce all the physical signs of acute consolidation at the apex, with hæmoptysis. In such case an examination of the sputum for bacilli may be necessary for a diagnosis.

A meningitis of typhoid type following traumatism in a tuberculous subject may present all the symptoms of infectious endocarditis, except infarctions and the physical signs of valvular disease. Generally, however, the tension of the pulse is not lowered so quickly as in endocarditis, and dyspnœa without physical signs is absent.

It is evident that in all these conditions, as well as in some other general septic diseases, the diagnosis must rest mainly on the physical signs of endocarditis.

It is often a matter of importance to distinguish between ulceration in simple endocarditis and septic inflammation with ulceration. There are no physical signs of ulceration of the endocardium *per se*, and embolic infarctions do not of necessity imply ulceration.

Rupture or perforation of a valve will be attended by constant symptoms from whatever cause it may arise. The infectious or non-infectious character of endocarditis must be determined by the presence or absence of any suppurating source of infection or open wound, through which bacteria might gain access to the blood, by the number and course of infarctions, and by the general condition of the patient.

In simple endocarditis infarctions are rare, when developed are few in number, and produce simply mechanical effects without suppuration. In infectious endocarditis they are quite constant, affect numerous organs, and show suppurative inflammatory changes early. In the former the cardiac and constitutional symptoms are sthenic, and the signs of myocarditis are slight or develop late. In the latter all the symptoms become typhoid in character early; the mental depression and anxiety are out of proportion to the physical signs; the pulse becomes dicrotic or hyperdicrotic early, and a condition of mental torpor or typhoid delirium is rapidly developed. Cases of the infectious variety in which the symptoms are less severe, or in which remissions and intermissions are distinct and often prolonged, may remain uncertain until the end.

PROGNOSIS.—*Non-infectious Endocarditis.*—Death seldom results directly from simple acute endocarditis, although more or less extensive changes in the valves become permanent.

Nearly one-third of the cases of acute mitral endocarditis pass into the chronic interstitial form. When an acute inflammation attacks an already crippled heart, the sudden strain may cause a fatal myocarditis and acute dilatation, rupture or perforation of a valve, or rupture of one or more of the chordæ tendineæ.

The unfavorable symptoms indicating one of the above conditions are sharp pain over the region of the heart, sudden and intense dyspnœa, and cyanosis with rapid, fluttering, and dicrotic pulse.

When death does result from acute endocarditis, it is more commonly through a more slowly developed myocarditis with cardiac failure.

Infectious Endocarditis.—It is perhaps still true that recovery is not known ever to have followed infectious endocarditis. So true has this been that a favorable termination in any supposed case was regarded as proof of error in diagnosis.

Recently some cases have been reported which render it probable that recovery may occur in this disease. The percentage of recoveries, however, is still exceedingly small, although the diagnosis is never sufficiently exact to enable us to state this per cent. in figures. Unfavorable symptoms are those of myocarditis, valvular rupture, multiple infarctions, and the psychical indications of extreme systemic infection.

TREATMENT.—*Non-infectious Endocarditis.* Although perhaps not strictly included under the head of treatment, the question of prophylaxis, as applied to endocarditis, is of the utmost importance, and therefore strictly pertinent to our present discussion. Throwing out a small percentage of cases called idiopathic, which represent the extent of our complete ignorance as regards etiology, we find that all other cases of simple endocarditis are induced by diseases known to produce a perversion of the normal elements of the blood, or the development within the system of some new product which must pass off through the blood.

Of these diseases, one class, represented by rheumatism, is characterized by a simple perversion of metabolism; the other, of which measles is a type, possibly, if not probably, throws into the blood the products of bacterial growth. The fact that the endocardial changes induced by the poison of measles are often postponed for a long period, suggests at least that in this class, as in rheumatism, a weakened vitality has given way, and the etiological factor in the endocarditis is again the product of faulty metabolism, and not the direct result of bacterial action. In any event, however, we believe that the resistance which the endocardium, as well as the other tissues, offers to the irritant action of the *materies morbi* depends upon an inherent vitality, which in turn depends, not only upon present, but also upon previous and continuous conditions of healthy nutrition. Remembering, then, that the manifestations of the rheumatic diathesis are manifold, and that an acute endocarditis is often only the explosion following a prolonged stage of irritation, it becomes a matter of importance that children should be watched with care, more especially if descended from a stock with a rheumatic or gouty taint; and that the earliest evidences of malnutrition be met with prompt treatment by cod-liver oil and iron without waiting for "growing pains" and lame joints to confirm the diagnosis. The remarkable effects following the use of cod-liver oil and iron in these cases confirm the hypothesis upon which it is given. In cases of subacute endocarditis, or what often appears like a recurrent and intermittent acute inflammation in adults, characterized by increase of some cardiac symptoms that are only seldom entirely absent, the iron will often be found to give the most marked relief. In connection with these measures, the daily diet-list and clothing of children should be attended to with equal care, and always with the knowledge of any special inherited diathesis. It must suffice to say that the determination of an appropriate diet and clothing implies a consideration of all the conditions of gastric and intestinal digestion, hepatic activity, assimilation and excretion, either congenital or acquired. Upon the same basis we must urge a more careful and prolonged watchfulness of cases recovering from scarlatina, measles, and other specific diseases, or cases of chronic, suppurative, and ulcerative disease of the throat and tonsils, with a view to preventing possible endocardial complications.

No unquestionably effective measures have as yet been found for the arrest of an endocarditis once developed.

Absolute rest, so far as attainable, should be afforded the heart. The quieter action gained by the horizontal position is of the utmost value, and patients should be placed in bed and not allowed to indulge in even the most trifling exertion. Similarly, those remedies which tend to relieve arterial tension and quiet the heart's action, may assist in decreasing the inevitable irritation of valvular action. Very small doses of morphine, or preferably codeine, may be given, when the heart's action is very irritable, or when pain is prominent. Morphine cannot be given, however, with the same freedom as in pericarditis. In the earlier stages, when ventricular and arterial tension is high, $\frac{1}{100}$ ♏ doses of nitro-glycerine may be used tentatively. There are no other internal measures directed specifically to the inflammatory process. The use of mercury and potassium iodide, with a view to promoting absorption or lessening the deposit of inflammatory products and fibrinous thrombi, has been abandoned by the best authorities. The external application of ice-bags has been strongly recommended, and many German authorities uphold the practice. In this country the careful protection of the chest by cotton, or flannel, or the use of hot applications, either dry or moist, is the more common practice. The use of the cold coil, however, applied directly to the chest, or with an intervening layer of flannel, is gaining ground.

Stimulants are not desirable in the early stages of the disease. Their use is to be delayed until irregular heart action and the pulse tension indicate cardiac failure. Then they will be of decided value. The cardiac tonics, digitalis and strophanthus, may be indicated later, and when used should always be given in connection with alcoholic stimulants. Oxygen inhalations are occasionally of value when dyspnœa is excessive, but it must be remembered that defective circulation, rather than deficient oxygenation of blood already in the lung, is the cause of the distress.

Theoretically, every case of endocarditis presents a causal indication for treatment, but clinically, rheumatism, gout, and Bright's disease are about the only diseases in which we have any definite idea as to the nature of the etiological factor or the organ at fault in its production.

In gout and Bright's disease it is sufficient to say that we should use such remedies as stimulate the functions of the liver and kidney, especially mercury, colchicum, squill, or the milder diuretics. In that large class of cases, however, in which rheumatism is the cause of endocarditis, an accepted treatment is less definitely determined. Affirmatively, it may be stated as proven that the alkaline treatment pushed to the point of maintaining a complete and persistent alkaline reaction of the urine, is the most satisfactory as regards the endocardial inflammation. Negatively, it is equally well proven that salicylic acid and antipyrine do *not* decrease the danger of cardiac complications, while many, if not most, authorities hold that the prolonged use of the salicylates increases the frequency with which endocarditis develops.

As a result rheumatism is best treated, with a view to endocarditis, by the salicylates or antipyrine until the acute pain and the primary inflammation subside. Then the alkalies should be given throughout the course of the disease, and quite safely for some time after the subsidence of the acute manifestations. The salicylates should be withheld upon the slightest evidences of a developing myocarditis.

Infectious Endocarditis.—Flint's statement ("Practice of Med.," Ed. 1886), that "it is not known that recovery from acute ulcerative endocarditis ever takes place," has until quite recently been generally accepted. Within the past two years, however, several cases have been reported in which there was but little reason to doubt the diagnosis.

The most typical and valuable case, as offering hope of a more successful treatment, was reported by Sansom. This patient recovered from a condition that was typical of septic endocarditis. She left the hospital with a systolic apex murmur, but no hypertrophy, and otherwise apparently well. Some months later she returned with similar symptoms, and the post-mortem showed the lesions of infectious ulcerative endocarditis.

The treatment—under which this patient improved rapidly in the first attack, after having received no benefit from the usual treatment—consisted in the administration of thirty grains of the sulpho-carbolate of sodium three times a day, with free inunctions of carbolized oil (20 per cent.). With our present knowledge comment is valueless. We can simply hope that other cases may prove that the diagnosis was correct, and that the results were something more than coincident. The fact already alluded to under pathology, that the specific cause of the disease probably enters the valves from the surface and acts superficially rather than deeply, seems to offer some encouragement to the belief that the blood may be sufficiently loaded with an antiseptic to destroy the power of the infectious elements.

Beyond this the treatment is that of simple endocarditis. Since the septic condition is often present at the outset, antiphlogistic and sedative measures are seldom required, while the stimulant and tonic treatment must be employed from the first. Alcohol and the cardiac stimulants, with quinine and iron, will be tolerated in large quantities and very early. *Charles E. Quimby.*

HERNIA. It is not the object of this article to cover in its entirety the subject of Hernia. This has been done in a previous volume, and the work allotted to these pages is the much smaller one of giving a résumé of the latest and perhaps most generally accepted operations for attempting a radical cure of ruptures. At the same time, the writer has allowed himself the liberty of expressing his own personal views regarding strangulated hernia and its management.

Except otherwise specified, let it be understood that hernia of either the inguinal or the femoral type is under discussion. A strangulation here is but too common, and it behooves every practitioner to have, for his patient's sake as well as his own reputation, certain clear-cut ideas distinctly formulated as to these cases, so that an emergency shall not find him unprepared for the active treatment so often necessary in order to save life.

It is frequently impossible to say with certainty, whether in a given case simple incarceration exists—obstruction to the passage of fæces in an unreduced hernia; or actual strangulation—obstruction of fæces and also of intestinal circulation. I believe there is no positive guide in this matter. Pain and tenderness are no certain evidences for strangulation and against incarceration, though probable ones. Fæcal vomiting and hiccough may occur in both. Fortunately the treatment in either case is the same. A cathartic is best avoided. Give the patient morphine (gr. ¼) with a little atropine (gr. [illegible]) hypodermically. Atropine is a good preventive of shock in an operation that may be needed soon. The morphine enables taxis to be attempted without the local muscular contractions that might otherwise obstruct the endeavor to reduce parts that are in a state of considerable irritability, if nothing worse. It is a question, however, if we often have a tonic spasm here as a cause of the strangulation.

We should remember, in connection herewith, that morphine, by masking the symptoms and causing a lull, is apt to induce hopes from expectant treatment not justified by the event.

Should gentle taxis now fail, with the patient in the appropriate posture (flexion of the thigh, decided elevation of the foot of the bed), we may try for—say—one hour the application of either a hot poultice or ice, and then, gently, as before, repeat the attempt. Cold tends to contract the bulk of gas present in the gut, and may thus aid taxis. Just how poulticing (or the general hot bath) is of use, I cannot say—assuming that morphine has previously been employed to relieve any possible spasm. Very probably it is not of any use, although generally recommended, as poulticing often is elsewhere, when the attendant does not know what to do and feels the necessity of doing something.

The writer is decidedly of the opinion that an hour spent in this way is enough time to waste. If, after this period, another cautious attempt at reduction fail, then the attendant's duty is clear. It is to tell the patient that an operation is necessary in order to save life, and the sooner it is done the better the chances will be. Consent being obtained, and assistants procured, the surgeon should proceed to give relief.

This teaching may sound dogmatic, and the writer would not take such positive ground here as the result of a conviction that leaves no room for doubt. It is unquestionably true that many cases of strangulated hernia have been reduced and the patients have recovered, in consequence of prolonged and frequent taxis renewed at intervals during many hours, and at last successful. But many other cases are killed by just these means—the gut, either from the continued strangulation or from the taxis, rupturing or sloughing, with fatal consequences. On the other hand, herniotomy in careful and clean hands, performed with clean tools, is not an operation to be dreaded by either the surgeon or the patient. If done as it should be, and done early, and upon a patient not previously maltreated by taxis, there will be nearly one hundred per cent. of recoveries. To find dead gut in such early operations is a great rarity, and if found, the patient's general condition will be so much better and shock so much less that the prognosis from a kelotomy will not be a very bad one.

The writer was recently present at a meeting of the Surgical Section of the Academy of Medicine of New York, during which an eminent surgeon, greatly respected for his many successes, stated that in his judgment it would be a boon to the world if "taxis" and all attempts thereat were expunged from our text-books. This was, of course, putting the matter in a very vigorous way, for didactic purposes, and was not meant to be taken literally. But it shows clearly enough the drift of thought among surgeons at this day.

Yet it is seldom that the surgeon (as distinguished from the practitioner, who rarely sees the first phase) sees a case before twenty-four hours have elapsed since serious symptoms first made their appearance. During this time many attempts at reduction have been made—the more desperate ones none too gentle. Abrasion or actual rupture of the gut, with serious, perhaps fatal, peritonitis, is the frequent result. At last the surgeon is called in, operates, relieves the pressure upon the intestine, but the patient "dies cured," and the harmless operation, and not the previous malpractice, has to bear the odium in the minds of the family and their medical attendant.

The writer does not advocate any of the lame and halting measures so frequently suggested as an aid to taxis, neither Simon's method—the hand in the rectum to make use of traction upon the gut from within—for this is unsafe save with the smallest hand, and not entirely safe then; nor the passage of the finger (in the inguinal variety) up the scrotum or labium into the canal, trying with the finger-tip to stretch the constricting point, for this threatens rupture of the gut at the neck of the sac. The section of Poupart's ligament anywhere above the inguinal canal, recommended in order to relax the rings of the canal, to be followed after reduction by suturing of this ligament, seems to the writer also objectionable, because it is a blind method. All these, and the several other plans advocated by various authors in order to dodge a plain duty, have at least one fault in common. They do not open the sac and give the operator a view of the gut, which may be ruptured, ulcerated, dead, or dying.

It is not claimed that these and still other methods are never successful, but it is distinctly claimed that delay is very perilous; and the former teaching, that opening the sac increases the mortality, is not now, as it used to be, a statement of fact; not, at least, in the practice of men who know what the term *surgical cleanliness* means. The peritoneum is no longer the "sacred sac."

The advantages of opening the sac, on the other hand, are numerous. Reduction *en masse* is thereby avoided; a possible strangulation within the sac, or, more probably, such inflammatory adhesions of gut to gut as will prevent the passage of fæces, even though permitting circulation of blood, are relieved; dead or dying gut or omentum is seen and treated appropriately. In a word, it is daylight against darkness.

The question, how long can the gut live while strangulated, is one that never will be settled so that a limit of time can be formulated. The answer depends upon two factors, the tightness of constriction and the vitality of the patient. If constriction of circulation is absolute, probably an hour or two may suffice for death from [illegible] at the constriction, and passive congestion, with stagnation, beyond. If even a little blood can flow, the gut may retain vitality, as I have seen it do after forty-eight hours of strangulation, with apparently urgent local and constitutional symptoms. Vitality is a vague expression, but nevertheless stands for an entity that all must recognize, and which varies widely in degree among people apparently in equal physical vigor.

Not only should the sac invariably be opened, but it should be opened *before* relieving the constriction at its neck. This is because the gut is liable, if not adherent within the sac, and not prolapsed in large amount, to slip back into the peritoneal cavity as soon as the undue pressure upon the neck of the sac is removed. And then the operator, upon opening the sac and failing to find it, will be compelled to choose one of the horns of a dilemma—either to do nothing further and assume that the contents which slipped back were living, or else, if his conscience will not allow this, he must take the risk of a laparotomy and look up the missing bowel or omentum; which he can probably best do (if the hernia is inguinal) by an incision running up from the internal ring a sufficient distance.

The original incision in a herniotomy should be in length at least equal to that of the tumor, and in its direction the same as that of the long axis of the tumor. This I think to be the best rule, whether the hernia be of the femoral or the inguinal variety. Careful dissection with a light hand, and either the grooved director or two pairs of forceps for safety, will quickly expose the sac, which in recent cases will be smooth, tense, and shining, and apparently not fibrillated, but rather of homogeneous texture; in other words, presenting the usual peritoneal appearance. On opening this slightly, there will generally be an escape of colorless or dark fluid—not blood—and omental fat will probably force itself out at once from the great internal pressure, or else the more or less discolored gut will be seen, always darker in hue than the normal bright pink, and varying between a dark-red, in favorable cases, and absolute purple-black. Occasionally, however, especially in neglected cases, in which the sac is inflamed and adherent to surrounding structures, perhaps even gangrenous, there may be some little difficulty in distinguishing between this and the peritoneal coat of the gut. To differentiate, cut very lightly and superficially through the presenting membrane for half an inch or so. Then take a grooved director and gently introduce it. If the severed membrane be sac-wall, the director will easily pass within in various directions. If it be the peritoneal coating of the gut, the director will, of course, not pass with any degree of readiness between this and the muscular layer.

After ample incision, in order the more readily to examine the sac-contents, it is well to seize its cut edge at several points with artery forceps and draw it out into a funnel.

The sac being freely opened, the next step is to divide the constriction—first securing control of the gut by a loop of stout silk or catgut passed through the mesentery. The division should be free or not, depending upon the state of the gut. If this is in a condition allowing immediate return, then a few slight nicks in the classical directions may be all-sufficient, if they permit its return without much handling and friction. Before return, however, it should be sufficiently drawn out to make sure that there is no ulceration at the tightest point.

The treatment of the presenting omental masses, whether dead or not, is always the same. They are ligated at as high a point as possible, cut away, and the stumps, after irrigation, returned to the abdomen. If their bases are at all large it is well, for security against hæmorrhage, to transfix with a double ligature and tie off either side. They are more often adherent in the sac than is the intestine, probably on account of the constant vermicular movement of the latter.

All adhesions should be broken, save when a speedy end of the operation is a necessity, or when the gut must be left out for a time. Adhesions to the gut require careful dissecting away. For safety to the gut it is sometimes necessary to excise a little of the wall of the sac, leaving it adherent to the gut.

If the bowel be found in a doubtful state, or actually dead in any part, or if, though apparently sound, there be difficulty in returning it, then the division of the compressing tissues should be free indeed. And here I am inclined to advise an open dissection—not the usual nicking in the dark with a hernia knife, but daylight work—cutting not only Gimbernat's but Poupart's ligament, if necessary, in the femoral variety, and cutting upward from the deep ring freely, in the inguinal, the external oblique aponeurosis, forming the anterior wall of the inguinal canal, having, of course, first been slit its entire length—nearly two inches. By cutting down in this way cautiously, step by step, the deep epigastric artery will, if in danger, be seen and can be avoided; or, if very annoying, may be tied and cut. Provided the operator tie first, it is of little importance whether this rather small vessel is or is not cut, and it is not worth the worry devoted to it by the text-books; and if cut accidentally, it may be seized with a pair of artery forceps and tied with perfect ease, as it is in plain sight and in an open field; whereas if the surgeon follow the more usual plan of nicking in the dark, and happen to cut it while trying to make an opening of some size, there may be difficulty in controlling the spurting vessel which he cannot see.

In any case, it is rarely necessary to open the peritoneum farther than is done in opening the sac. We simply cut, down *to* the peritoneum, a sufficient distance to free absolutely the gut within the rupture from any pressure whatever.

Now comes the question, Is the doubtful gut dead or only threatened with death? If the former is the case, it will be very dark, probably lacking in lustre more or less, and when pinched will show no peristalsis. Neither will Nothnagel's test, with a piece of salt placed upon it, induce vermicular movement. If firmly pinched for a minute between the finger and thumb, the dark blood thus squeezed away from one spot will show no tendency whatever to return. In cases in which decomposition is beginning, it will be actually sticky, apparently shrunken somewhat, and thinner than normal to the feel. The offensive and peculiar odor of putrefaction can in these bad cases be detected; an odor differing from the merely fæcal smell.

If the bowel is wavering in the balance between life and death, it will be decidedly dark. But darkness alone does not necessarily mean death. I have seen a gut almost black resume its natural color within a few hours. Upon pinching such a gut there will probably be some slight peristalsis induced, and to the comparatively pale spot caused by prolonged firm pinching the blood will very gradually return, showing the existence of some little degree of circulation still.

Assuming, now, that the gut seems dying, but is not yet dead, or is at least doubtful, there is but one course open to the surgeon—he must await events; putting that gut meanwhile into a condition, as to its environment, as nearly normal regarding warmth, moisture, and asepsis, as possible. It would be entirely inexcusable to return a doubtful gut to the abdominal cavity and sew up the wound, trusting to luck that it may live. That course is sometimes pursued, but it is not good surgery; it is reckless surgery. Should it die, the first evidence thereof will be a septic peritonitis, in all probability fatal.

The surgeon can with propriety, after thorough irrigation with a warm, weak antiseptic solution (Thiersch's boro-salicylic, for instance), return the gut to the belly, controlling it, however, by means of an anchoring-thread of large-sized catgut through its mesentery; and can devote a quarter to half an hour in work, partly on the omentum, if present, ligating and cutting it away, and partly on the canal, dissecting up the sac, passing but not tying the stitches, and making all the preparations for the operation for radical cure. It is assumed, of course, that the general condition of the patient justifies such a prolonged operation. Finally the gut is drawn by the anchoring thread into view again. If it is distinctly better in color, the thread is removed and the radical operation completed. If the gut is still doubtful, the wound must be amply enlarged at its deepest part, the gut drawn forth so that the suspicious portion is, if possible, several inches from the peritoneal cavity, and moist iodoform gauze in several turns packed uniformly about the gut at its point of emergence so as to make sure of the prevention of any penetration to the peritoneal cavity in case of inter-partial rupture of more dead spot, with faecal escape. The retention thread is made fast to the skin, and finally, the bowel and hernial sac are wrapped in warm, soft aseptic cotton loosely laid on thin rubber tissue which is moistened with a very weak antiseptic solution. The steady temperature desired—100° to 105° F.—is best maintained by means of Leiter's coil—preferably of rubber tubing, as this is less heavy than the block tin. In default of a coil with running hot water the heat is maintained by siphonage from a bucket of very hot water placed on a shelf higher than the patient. The water trickles slowly, and the gut-temperature is regulated by the number and thickness of the cloths covering it. (See article Fomentations, Vol. III.)

The patient is, of course, now allowed to come out of anaesthesia. At intervals of an hour or two the gut is cautiously uncovered in a warm room as before, and examined. Whenever it seems safe to return it, the operation may be completed, and very probably without anaesthesia, especially if the stitches have been passed and are lying loosely, only awaiting tying. On the other hand, should the state of the bowel become worse and death overtake a small portion of it, or more, then the treatment to be adopted is the same as if this state of things were discovered when the sac was first opened.

Part of the gut being found unquestionably dead, there are three courses of action open to the surgeon:

(A) He can simply leave the gut and wound prepared as we have just described it and await events. These will be sloughing and the ultimate escape of faeces, contaminating the wound, but probably not its deeper parts, which have been protected by the thick layers of gauze. The gut, if not adherent to the sac at first, will become so within a few hours, and nature will make the artificial anus awaited further by the surgeon. Whenever the deeper dressing is changed—which must be very frequently—the new anus is carefully closed, the wound irrigated, dusted with iodoform, the iodoform gauze packing removed and replaced with fresh. Stitches may be taken to narrow, but not to close, the canal about the gut, which heals by granulation from the bottom. It would be unsafe to attempt an immediate closure by suture, as in method B, of a wound large, deep, and irregular in outline which has been poisoned with faeces.

While the method just detailed is allowable, it seems to the writer objectionable save in cases where sinking of the patient demands a hasty termination of the operation, or where the sac is putrid or septic to any extent. If a somewhat longer time can be permitted—say half an hour—then method B is preferable, and is the one actually employed in perhaps the greater number of cases.

(B.) Here the artificial anus is made by the surgeon, not by nature, and without waiting for spontaneous rupture of the dead gut. Under this head we have choice of three plans, and no fixed rule can be given as to which is always preferable.

I. Here the surgeon simply frees the constriction, draws the gut out and lifts it gently away from the wound, protects the wound by packing, excises the necrosed part, allows thorough fecal evacuation, cleanses the cut ends, and makes an immediate artificial anus. If an entire loop is dead, there will, of course, be two intestinal ends. It is commonly easy to recognize the proximal end as being that one which contained the most faeces and gas. But commonly both ends are kept open by sutures. The steps may now be as follows: The peritoneal coat of the gut is first stitched to the cut edges of the sac by one or two rows of sutures, and then the muscular-mucous coat to the skin. Finally, the rest of the cutaneous wound is closed, except for drainage; this may be provided for by a rubber drain, or better by some iodoform gauze packing, reaching to the bottom.

II. Here the constriction is freed as before. Then the peritoneal coat of the gut is sewn to the cut edges of the sac and tied, and may be to the skin. The remainder of the wound is sewn, loosely packed or dressed, as in I. Twenty-four hours are allowed to pass before the dead part is cut away (unless it ruptures spontaneously), when the faeces are allowed to escape. It is not necessary, but is sometimes done, to stitch the muscular-mucous coat to the skin after opening.

This mode of procedure (II.) allows time for firm adhesions to form, giving peritoneal protection from septic infection, and is identical with the technique used in the preliminary steps of gastrostomy, inguinal colostomy, cholecystostomy, etc.

III. Here the constricting point is not severed, but otherwise the steps are, as far as possible, as in I. It is a question of great interest whether this third mode is or is not justifiable. There are eminent authorities on both sides. Mitchell Banks has put his views very forcibly. He strongly disapproves of severing the constricting point, because emptying the prolapsed gut will relieve the constriction, and the more readily as the faeces in these cases are, he says, invariably quite liquid, and because "the only result of this [cutting the point of tension] is that the protecting barrier which isolates the still aseptic peritoneal cavity from the putrid sac is broken down, and putridity spreads upward into the abdomen and kills the patient by rapid septicaemic poisoning. Why break down this valuable wall?"

The writer must dissent from this view of the case, and prefers the first technique in method B for several reasons. First, it is entirely possible to prevent sepsis and peritoneal infection, if the wound is first carefully disinfected and then packed with iodoform gauze before the drawn-out gut is opened and allowed to empty itself. In fact, it seems to me more feasible by this means to escape infection than by leaving the constriction, which is not a perfect barrier at all points of its circumference, especially after the tension from retained faeces is removed. Second, if the constriction is not relieved, it is difficult, if not dangerous to the gut, to draw it out and away from the wound before emptying it; and if it is not so drawn out, the wound surely runs a greater risk of infection. Third, it is not a fair assumption that the constriction is always due to a "swelling of the loop of gut" (Banks); it is often caused by the straining of an *additional* and unusual hernial knuckle into the inner ring; therefore, simply to empty the prolapsed gut is not invariably to relieve tension at the neck of the sack; and a small, tightly nipped knuckle, deeply placed, could readily be overlooked and not relieved by the method advocated by Banks. Fourth, unless the gut could be easily drawn out, a serious ulceration caused by constriction, with threatened consequent perforation, would be likely to be overlooked.

By whatever method the surgeon makes an artificial anus, he should contemplate, in logical cases, a subsequent operation to close this opening and restore the continuity of the bowel; and this should be attempted just as soon as the patient's general condition will permit. Kocher has stated that every case under his care (seven in number) of artificial anus resulting from gangrene has come to an untimely end from some cause more or less directly due to its presence. Within a very few weeks the gut below the lesion shrinks and atrophies considerably. And if the small intestine be the part affected, this, reducing so closely the maintenance of the patient's nutrition, gives an additional reason for hastening the closure of the artificial anus, the technique of which operation does not come within the scope of this discussion; it is enough to say that the gradual methods, such as that of Dupuytren, are being less employed of late.

Although Kocher has had such unfortunate results with his patients, this has not always been the case. There might be allowed an exception to the rule of early obliteration of some artificial anus, in cases where only a small spot has sloughed, and where the large gut or the lower ileum is the part affected. Several cases have been reported in which a spontaneous cure has occurred, the gut being apparently drawn gradually back into the abdomen by continued vermicular motion, and the artificial anus becoming so gradually a mere fistula which has finally closed. Unless the patient's nutrition and strength seem satisfactory, however, it would be very unwise to wait for this rare occurrence.

We have considered two of the three methods whereby we may treat a case in which, on opening the sac, the gut is found dead ; or if doubtful, has subsequently died.

(C). There remains a third method which deserves attention, although rare of application and unsafe in the hands of those who have not had opportunity to practise it upon the cadaver, or upon the lower animals. This is the resection of the dead part, and the immediate restoration of the continuity of the gut by circular enterorrhaphy, or some plan similar in that it avoids an artificial anus.

The advantages of this mode of disposing of the case are great. At one stroke the patient is cured, and the annoyance and danger of an artificial anus, with the almost inevitable subsequent operation or operations for the abatement of this nuisance, are avoided. But, on the other hand, the operation is long and trying, and therefore one which extremely few cases of strangulated hernia can endure. They are generally relieved by surgery late in the case, unfortunately, and are more or less in shock at the time of operation, which must hence be as brief as possible. The actual treatment of the gut and mesentery alone, takes from one to two hours in accustomed hands. It requires more time to do properly, with not a stitch too tight or too loose, too deeply or too superficially placed, than anyone realizes who has not tried it. I have demonstrated this operation now about fifty times, upon as many subjects, in my operative surgery classes at the New York Polyclinic ; and it is always most tedious. Since speed is so tremendous a factor in the problem of success in bowel-work, we shall all heartily welcome any device which cuts short the duration of operation, and yet gives a perfect result. It may well be that in Dr. Robert Abbe's catgut rings (see Fig. 4892)—an improvement on Dr. N. Senn's decalcified bone plates, seeming at least as safe, and being always ready at hand—we have the means of saving many lives through point of time. I have not yet had an opportunity to invert the gut-ends, close each with Lembert stitches, point the overlapped ends in opposite directions (as Abbe has suggested, to get a continuous and not an opposing peristaltic wave in the two ends), and, opening the two sides, apply the rings. I should think that quite a little time might be saved by this method as compared with circular enterorrhaphy.

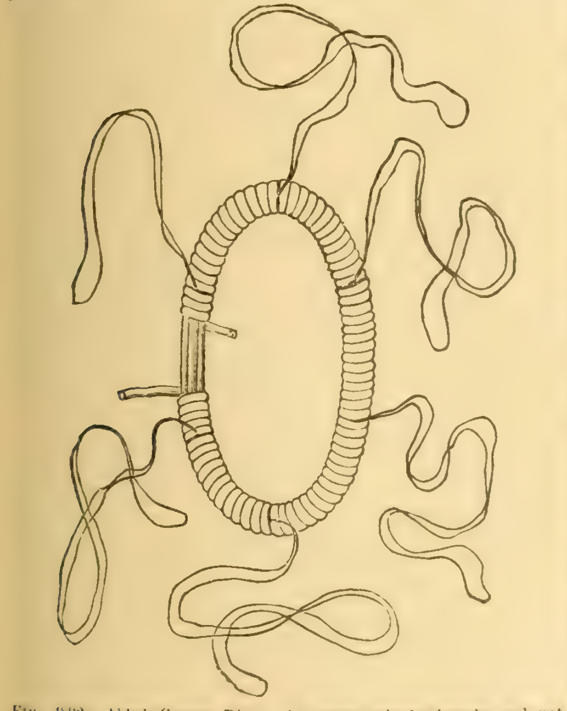

FIG. 4892.—Abbe's Catgut Ring. At present single threads, and not loops as in the cut, are used in uniting the two rings.

If the surgeon, however, deems it safer to suture the ends by the Czerny method, previous to inversion and the Lembert stitch, then nothing, it would seem, would be gained ; for twice the diameter is equal to two thirds of the circumference of the bowel ; and it would probably take no longer to put two tiers of sutures into the remaining third than to open the sides, insert the rings, fasten them by their threads, and then take the few Lembert stitches advised for security.

It might be a good plan—both with the idea of saving time and to avoid the formation of the cæcal pouches on either side of the new opening, caused by the occluded end of the intestine—to place the catgut rings within the ends of the gut, as an aid to ordinary circular enterorrhaphy. This I shall try at the first proper opportunity, provided the cadaveric test is satisfactory. (Dr. Abbe's article will be found in the *New York Medical Journal*, March 23, 1889.)

As has been stated, the treatment of dead gut by immediate resection and enterorrhaphy is a rarity ; so much so that many surgeons in a long and active practice have never had an opportunity to attempt this method. It will be of interest, therefore, to relate here the history of a case in which the writer performed this operation, and a very unusually large amount of the bowel was excised. At the same time, the conditions which made this step the proper one will be indicated.

I was called to see Mrs. M—— in the evening of March 23, 1889. She is, as her daughters say, "at least fifty-five years of age ;" has had a rupture twelve years, for which she has worn a truss. Twenty-four hours before my visit, while sweeping, she was taken with severe pain in the region of the rupture. The truss frequently allowed the gut to descend, and now she could not reduce it. Vomiting immediately set in. Her family physician now attempted taxis, failed, used morphine by needle, and ordered a poultice.

Four hours previous to my visit the vomiting, which had persisted and was frequent, became fæcal in odor ; and about that time, too, hiccough began and was very distressing. The local pain and tenderness continued.

On examination I found a hernia on the left side, about the size of a large fist, painful and tender, very tense, and without impulse on coughing. Gentle taxis failed. Poupart's ligament seemed to pass about to the middle of the tumor, and, the parts being quite fat, I was in doubt whether I had to deal with a femoral or an inguinal hernia. The most *fixed* point of the swelling seemed the lowest, which fact pointed toward femoral ; and its bulk seemed a little nearer the mid-point of Poupart's ligament—a little farther outward from the symphysis pubis—than would be the case with a complete inguinal rupture. Incision subsequently verified the assumption of a femoral hernia. The patient's general condition was fairly good. The temperature was 100.5° F. Her heart and kidneys seemed sound.

I advised immediate operation, to which she assented. The operation was begun two hours later, at 10 P.M. I was assisted by Drs. F. A. Manning, H. J. Kelly, J. H. Brower Browning, and two of my students, Messrs. Brickner and Van Deusen. I consider the good result obtained to have been largely due to the scrupulous care and attention of the surgeons named.

As the first step the bladder was emptied ; then the entire pubic and inguinal region and both labia majora were shaven, and the parts disinfected with ether and with a solution of bichloride of mercury, 1 to 2,000. A folded bichloride towel was packed into the slit of the vulva, and all the regions with which the hands of operator or assistants or instruments of any kind could possibly come in contact were covered with towels wrung from the bichloride ; so that the only exposed surface of skin was a space about the hernia six inches by four.

I considered it very important to have a high atmospheric temperature. There was no stove or other heating appliance, nor any atmospheric thermometer as a guide. I had the windows closed, and lit many lamps and swollen. The air was kept so warm that everyone present perspired freely.

An incision was made, in the long axis of the tumor, its entire length. The sac upon being exposed was of course freely incised, a grooved director being used to enlarge the original small point of incision.

The moment the sac was opened a considerable mass of omentum protruded, and a small quantity of fluid of offensive odor escaped also. A very loop of the small intestine was found strangulated, almost black in color, and tense with gaseous and semifluid contents. Its peritoneal coat was smooth in most places, but there were a few small ruptures of this coat, possibly due to taxis. As was subsequently discovered, a small ulcer at the point of constriction, of some depth, threatened perforation, and a deep groove in the gut separated the sound from the ulcerated portion.

The constriction was very great—it could scarcely have been greater. To relieve it I used, as the safest means that could be employed, the smaller blade of my French blunt-pointed scissors, curved on the flat and rather dull. This was cautiously introduced, the convexity toward the gut, and then, the edge being slightly turned toward Gimbernat's ligament, this was divided a sufficient distance to make circulation through the intestinal vessels entirely and easily possible.

Although the gut was not entirely lustreless, and was not sticky, I was convinced that it was dead. Upon pressing the gut sharply after freeing the constriction there was no peristalsis, and the very dark blood squeezed away by the finger and thumb did not return, even slowly. I determined to give it a chance, however, and nearly twenty minutes were spent awaiting a change in its color, the gut and the entire wound being meanwhile enveloped in soft cloths wrung out of warm bichloride solution, 1 to 10,000.

At the end of this time no change whatever was noticed, either in the gut or in the color of the mesenteric vessels supplying it.

Under ordinary circumstances I should now have considered excision and a temporary artificial anus the best of the several means at our disposal.

For three reasons I decided in this instance to follow my kelotomy by immediate circular enterorrhaphy. *First*, my patient was in excellent condition, and could, I thought, under the careful anæsthesia then being conducted, bear a much longer operation. *Second*, the appearance and feel of the gut, with which I have had many opportunities to familiarize myself, convinced me that it was a part of the jejunum and not the ileum, and hence nutrition with an artificial anus would not be well maintained. *Third*, the patient's bowel above the strangulation could not contain much fæces, as a thorough movement had occurred a little more than a day previously, and nothing had been retained in the stomach since then. Consequently, great pressure from retained gut contents would not be brought to bear against my intestinal sutures.

My first step was to ligate off with catgut the masses of omentum present, cut them away, irrigate carefully, and return the stumps to the abdomen. Next several inches of healthy gut at each end of the dead loop were drawn out of the abdomen. The gut, its mesentery, and the wound were thoroughly irrigated. In order to protect the peritoneal cavity from infection, a long strip of iodoform gauze was packed around the gut, in the bottom of the wound, as firmly as was thought safe for the vascular supply. Then the mesentery was stitched, with continuous sutures of catgut, a distance exactly equal to that of the gut about to be removed, and on a line about two-thirds of an inch from the gut. This suture puckers the mesentery so that it is greatly shortened. Then the gut was cut with scissors, which next divided the mesentery as close to the suture as seemed safe. Not only the dead bowel but an inch or more of that which seemed sound was removed from each end, the gut being really in the line of union rather than of [illegible]. The amount removed in this way measured [illegible] inches. This I have preserved, together with a part of the omentum excised. An additional small piece of the bowel was cut away at one end in order to make absolutely sure of perfect blood-supply from the mesentery there; so that a foot and about an inch of intestine were lost to the patient.

(This—if we accept as correct the lists of published cases, one hundred and fifteen in number, recently so carefully collected and classified by Dr. A. J. McCosh, of this city, and which specify death or recovery, giving details of the cases, including his own—is the largest amount of gut successfully removed at an herniotomy operation for strangulation on record in America, and though not by a few instances the largest in the world.)

This point regarding the blood-supply of the gut ends is of extreme importance. The severed gut must not project even a hair's-breadth beyond the cut edge of the mesentery, otherwise its life is threatened because of the peculiar anatomical distribution of the arterial supply.

One of the surgeons present now held the intestine firmly, so as to occlude it, about two inches from either end. These two inches were carefully emptied and irrigated, and then the ends were approximated. The sutures employed were of catgut, and interrupted. Two rows were used: a Czerny (embracing the muscular mucous coat) and a Lembert (covering and embracing the peritoneal coat). In sewing the muscular-mucous layer especial care was devoted to the intermesenteric margin. This, for ease of work, should be sewn first of all. I placed a mesenteric stitch tied but lightly across the gap above the gut, on each side, to reinforce this weak point. The Lembert sutures, following Sir William MacCormac's wise advice, were so drawn as not to press the peritoneal surfaces together, but barely to appose them. I remembered, too, Dr. J. A. Wyeth's report of a case of his own, demonstrating that within three hours and a half after the operation the line of contact was completely sealed, hidden, and protected by a thick layer of fibrinous exudate.

The stitches were placed ⅛ inch apart, and were not superimposed, so that a suture was present, of each alternate kind, for each $\frac{1}{16}$ inch. The needle used was a common small cambric needle which had been passed through a flame.

After a final irrigation with warm 1 to 4,000 bichloride solution, the gut was returned to the abdominal cavity. The hernial sac, in accordance with the method of Mitchell Banks in femoral cases, was now dissected clean away, clear up to Gimbernat's ligament; the freshly irrigated wound was dusted well with iodoform, and rather firmly packed with iodoform gauze, which was carried up as far as the peritoneum; and a stout bichloride-gauze dressing was applied. The duration of anæsthesia was two hours and three-quarters, of which nearly an hour and a half was devoted to work on the gut and mesentery.

The patient stood the operation remarkably well. There was very little shock, and the vomiting and hiccough ceased immediately, as also did the abdominal pain. A hypodermic injection of morphine with atropine was administered at once. No food whatever was allowed for twenty-four hours, and but little water; thereafter, but clam juice for the second twenty-four hours; then such as peptonized milk and Rudisch's sarco-peptones at the patient's option, for the first week, but no other food until after that period. The bowels moved spontaneously and painlessly the second day. (This was especially noted, for such cases.) I have since twice moved them freely by a glycerine enema; but usually she has a satisfactory daily movement without medication.

The temperature did not go above 101° F. (rectal), but remained between 100° and 101° for five days; after this it became normal. The dressing was first changed a week after the operation, because it had shifted a little, exposing the lower and inner angle of the wound. Under irrigation the packing, even the deepest, came away almost without pain. Her hips being elevated, the irrigating fluid still filled the wound and did not run into the abdominal cavity—showing that an exudation had covered and sealed the peritoneal opening. Probably it was this localized necessary and aseptic peritonitis which had caused the slight elevation of temperature mentioned.

The wound was completely healed about a month after the operation. Two weeks later the patient was allowed to get up, without a truss; which, it is hoped, may be permanently abandoned. The wound healed thus gradually, because of the repeated firm packings, preventing rapid filling. Thereby the cicatrix becomes denser and more resisting than would otherwise be the case.

It is not my intention to discuss the relative advantages of the dozen or more methods of suturing gut; these are elaborated in most systematic treatises on surgery, and are constantly receiving additions in recent writings. If simple circular enterorrhaphy is to be done without rings or other aids, it seems to me that no method combines speed with safety to a greater degree than the Czerny-Lembert, and yet its speed is all too little in most cases.

A word with regard to sutures and ligatures. I used catgut, and it has been used a number of times, notably in two recent instances reported by Dr. C. K. Briddon. But I think most surgeons advocate silk boiled in an antiseptic solution. My catgut was taken direct from the liquid which I have employed of late, and which I think keeps the gut aseptic and strong in a very satisfactory way: namely, a saturated solution of bichloride-washed iodoform in sulphuric ether. The raw commercial gut is first immersed in ether to remove its fat; and after a few days is put permanently in the iodoform-ether. Although the "iodoform question" is yet unsettled, still, because of Dr. G. de Ruyter's demonstration that a solution of iodoform in alcohol and ether is capable of penetrating tissues better than one in ether alone, I shall hereafter add alcohol to the iodoform-ether. I doubt, however, if it is much of an improvement on the simple ethereal solution, since the fact that ether can extract all the oil from the catgut shows its penetrating power in this instance; and because iodoform is much more soluble in ether (1 to 5.2) than in alcohol (1 to 80). Of course, the *solution* in either case does not reach the tissues to be sewn or ligated, as the gut taken out for use becomes dry almost at once.

Dr. Nicholas Senn's demonstration—that by the time forty-eight hours have elapsed after the gut is sutured, the cementing of the apposed serous surfaces is so great that even severe internal pressure will not part the lips of the wound—gives me confidence that there is no danger that the catgut will be absorbed too soon. And yet one has a greater feeling of security when aseptic silk is used.

In the case just related, the writer was bothered a little by the fact that so much intestine was removed that there was quite a noticeable difference in the calibre of the two ends. Beginning at the intermesenteric point and working round gradually with the sutures, there was a little wrinkle in the larger end to overcome before completing the circle. In a future case this would be avoided by putting the second stitch just half-way round the circumference, the third and fourth midway between these, and so on. In other words, it should be sewn according to the rule in other wounds—always dividing the spaces into halves, by our stitches. After doing this completely by the Czerny method, the peritoneal stitches could easily be placed in any order.

For microscopical purposes it is very proper to distinguish all the coats of the gut; to describe in their order the peritoneal, the longitudinal and circular muscular coats, the submucosa, the muscularis mucosæ, and the balance of the mucous layer. But it is as well to explain, for the benefit of those who have never worked on the gut, and who do not get a clear idea from their books on this point, that in the small intestine, at least, there are, for us as practical surgeons, only two layers which we can distinguish during operations: A thin outer layer, the peritoneum, which retracts quite a little when cut, and a thicker layer, including everything else. And in some portions of the small intestine—especially the lower part of the ileum—the entire thickness of the gut-wall is so trivial that the wall is quite translucent.

To prevent danger of tearing out, the Lembert sutures should pass a little into the layer beneath the peritoneum. We do not stitch directly through the intestinal walls for fear of fæcal material following the track of the thread, by capillarity, and infecting the peritoneum.

It is important to be able to recognize the region of the alimentary canal to which a given prolapsed and necrotic loop belongs, both for prognosis and because—as in the history just given—it may affect our choice in selecting the proper operation. The colon and the cæcum require no discussion; the bands of the former and the size of the latter settle the question at once. But in the small gut there are four points which guide us somewhat toward a correct conclusion: (*a*) The diameter of the jejunum averages ¼ inch more than that of the ileum—1½ inch for the former, 1¼ for the latter; (*b*) the jejunum feels decidedly thicker than the ileum, both because the former has an abundance of valvulæ conniventes and because its walls are actually somewhat thicker; (*c*) if the excised piece be split open the presence or absence, relatively speaking, of these valves will be a guide; (*d*) Peyer's patches being so much more numerous as we go down toward the distal end of the ileum, if the excised loop contain a patch, and if it be oval rather than round, this points to the ileum. The paler color of the ileum in the normal state is, of course, no guide in strangulated hernia, and the relative thickness to the feel would only be decisive to one familiar practically with the difference in this respect.

The points given can hardly help us *always* to distinguish different parts of the small intestine, but they mark quite sharply the characteristics of the duodenum and upper part of the jejunum as contrasted with the lower part of the ileum.

In the case under discussion the great length excised precluded the possibility of taking a V-shaped piece out of the mesentery; and, indeed, I cannot see the advantage of doing this in any case. The stitches might cut off some of the blood-supply to the gut-wound; moreover, the time spent in coaptating and suturing the edges is a needless prolongation of the operation; and so, I think, is the suturing of these mesenteric edges after cutting between the cobbler's sutures and the gut.

It seems best, by way of preventing bleeding, to make these latter stitches *before* dividing either the intestine or its mesentery.

There is a suggestion regarding irrigation which may perhaps not come amiss. This, I think, should be nearly continuous during the sewing, and of simple warm water, or better, because even less irritating, weak salt water—of a temperature of *at least* 100° F. If very distinctly warm to the hands, say 105° or 110°, the additional warmth will only have the soothing effect of a poultice; while, on the other hand, the slightest chilling or drying of the gut would tend toward shock. For the same reason, I think the heat of the operating room, previously mentioned, to be essential in cases demanding exposure of the bowels.

In another instance, perhaps, I should scratch lightly with my needle the peritoneal surfaces to be apposed, in order to hasten agglutination, as recommended by Senn. This I did not think of at the time.

Turning now to the question of radical cure of hernia—this naturally presents itself, following a discussion of the proper treatment of strangulation; for, whenever the patient's condition will permit it, an attempt should always be made to effect a complete cure, as a part of the same operation which relieves the constricted gut. It is hardly profitable to quibble over the question whether a "radical" cure is really possible. Most surgeons believe that it is possible in a majority of cases, and, at the worst, the truss which a returning rupture may necessitate will only need to be a light one. Whether or not it is wisest for the convalescent from a radical operation to go unsupported by a truss is still an undecided point. The greater number of surgeons approve of the truss here. Those who object to it think that the constant pressure of the pad tends to thin the walls and weaken the muscles about the inguinal canal. My own impression is that two factors should guide us. The question of strain ing, and the dangers of recumbency during convalescence. Those whose work does not demand muscular effort nor stooping, and who have not a chronic cough, nor obstinate constipation, and those who have been able to spend two or three weeks in bed after their wound has healed, thereby allowing a greater consolidation of newly healed tissues before they are subjected to tension—these are they who should be permitted to discard all support, whether of truss, pad, or simple bandage.

Several of the modern methods whereby radical cure is sometimes effected have been fully discussed in a preceding volume. Spanton's corkscrew and Wood's subcutaneous suturing have not found much favor in this country, perhaps because they are not daylight methods. Heaton's method, by astringent injections, is unscientific: it does not obliterate the sac, and merely condenses and shrinks the tissues about it, thereby narrowing its calibre. This scar tissue, under constant pressure from above, will probably not be permanent. In the hands of a surgeon, other methods will lead to much more brilliant results. Among those who fear the knife, Heaton's method will often palliate and sometimes cure. The cutting operations for this purpose, in careful and judicious hands, are not serious in prognosis. Dr. Macewen has reported a series of eighty-one cases without a death. In twenty-nine of these strangulation had been present.

Perhaps the following plans are at this day those most in vogue among surgeons, in attempting radical cure of inguinal hernia: *A.* The methods of Czerny, Banks, Nussbaum, and Socin. *B.* Those of Bassini and Barker. *C.* That of Ball. *D.* That of Macewen. *E.* That of McBurney.

In all of these and, in fact, in any modern scientific attempt to effect a cure here, the treatment of the sac is the essence of the whole matter. If this is not completely obliterated,—if any peritoneal depression or pouch, however small, is left at the deep ring,—then the method, whatever it may be, will probably prove an ultimate failure. The gut or omentum will descend again, little by little, pushing its pouch, the sac, before it.

Before describing individual methods, it may be well to say a word or two regarding the situation of the rings, and our anatomical guides thereto. The deep ring lies just above the middle of Poupart's ligament, and almost directly over the sheath of the external iliac or common femoral vessels; that is, a line at right angles with the ligament would cut the middle of both sheath and ring. This point is easily made out, as Poupart's ligament ends at a distinctly felt spinous process, above and below. The statement here made does not agree with that in the anatomical text-books, which puts the deep ring midway between the anterior superior spine of the ilium and the symphysis (not spine) of the pubes. A series of dissections, however, has convinced me that normally the middle of this ring is over the *middle* of Poupart's ligament. In old oblique hernia, however, this ring is so dragged down toward the superficial one, and the inguinal canal is thereby so shortened, that sometimes there is actually no lateral difference between the seat of the deep ring and that of the superficial one; and this fact, of course, renders a radical cure very difficult of accomplishment, as the path for passage of the gut would then be very short, direct, and easy.

To find the superficial ring, feel for Poupart's ligament, which can be rolled under the fingers and cannot be mistaken. Follow this downward and inward, and it will be found to end at a distinct spine—that of the pubes. In fat subjects if the spine is not readily felt at first, press very firmly and steadily, and the adipose tissue will melt away to either side of the finger, so that in a minute this bony point is easily recognized. The superficial ring is always found just above the spine, extending half an inch or so both outward and inward. And the inguinal canal connects the two rings, lying just above Poupart's ligament.

My reason for giving these latter and familiar facts in this way is, that in so many works on operative surgery a number of measurements are recommended to enable one to locate the superficial ring. If these are accurate it will be found, after the spot is carefully located thereby, that it exactly overlies the easily felt spine of the pubes. Therefore such rules are quite unnecessary.

It is assumed—if we are not operating for strangulation—that the patient's bowels have been moved, and preferably with calomel, which is most thorough and not irritating; also, that the bladder is emptied; and also the parts are shaven and disinfected. The thigh should be slightly flexed, and a free incision made, the mid-point of which is over and somewhat above the superficial abdominal ring. The skin is retracted downward. By this little point of Mr. Kendal Franks', the skin wound does not correspond with the line of buried sutures, and is somewhat further removed from the region of possible urinary or fecal contamination. So much for rules generally applicable.

A. The sac is now exposed, opened over a moderate extent to make sure that there are no adhesions within, for it must be completely empty. Should adhesions or omental masses be found, the treatment should follow the lines already formulated in discussing strangulation.

If the hernia be found to belong to the congenital type, so that the finger passed downward in the sac feels it to be a tunic of the testicle, then the sac should be severed a little above the testicle, the lower part being closed by sutures to make a tunica vaginalis.

For irrigation within the sac, warm Thiersch's solution—the boro-salicylic—is excellent, being unirritating. Care should be taken, if work upon the sac contents is necessary, to prevent blood and irrigating fluid from entering the abdominal cavity, by packing a small aseptic sponge, controlled by a catgut or silk cord, into the neck of the sac, for the time being.

By careful blunt dissection the sac should now be detached completely from its surroundings, and cleared up to the deep ring, being pulled as far as possible out of the inguinal canal. The hard feel of the vas deferens is a guide in separating the cord from the sac. Sometimes, even with exercise of the greatest care, where firm adhesions exist between the cord and sac, the vas has been cut. Dr. A. G. Gerster has reported such a case. Recognizing the nature of the accident, he adopted, as an ingenious expedient, an attempt at restoration of continuity. "A short piece of stout catgut was introduced into the patent ends of its lumen, and the duct was united by four fine catgut sutures."

The detached sac is now ligated firmly—with chromic gut, aseptic silk, or simple stout aseptic catgut—at the highest point at which the ligature can be applied; the fundus is divided about half an inch below this point and removed, and the stump is pushed well up into the deep ring. To prevent slipping of the ligature, some surgeons when tying transfix the sac with a double thread, ligating off the two halves separately.

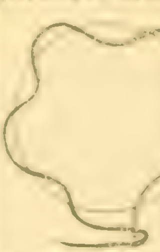

FIG. 2596.—Purse-string Suture employed for closing the neck of the hernial sac. (After Gerster.)

Dr. Gerster has suggested and practises, instead of the ordinary method, the purse-string suture. The technique of its application is clearly seen in Fig. 2596, taken from his work on Surgery. This suture, while completely shutting off the peritoneal cavity, does not entirely prevent circulation of blood in the short stump left after section of the sac. That this shall live is an obvious advantage.

The subsequent steps of method *A*, after dissecting out, tying off, and cutting away the sac, have for their object the narrowing of the inguinal canal. The surgeon has to pass a suture through (1) the conjoined tendon and external oblique aponeurosis on the one hand, and the mid-point of Poupart's ligament on the other, or as near the middle as possible. This stitch, bringing outward the conjoined tendon, is a very important one in helping to restore the normal valve-like action here. In passing it, avoid including the deep epigastric or external iliac vessels, or the spermatic cord. (2) A suture a little lower, through the conjoined tendon and external pillar of the superficial ring. (3) A stitch through both pillars of this ring—and so on. The stitches are placed at intervals of about one-third of an inch, and usually from four to seven are used. The material employed by Mitchell

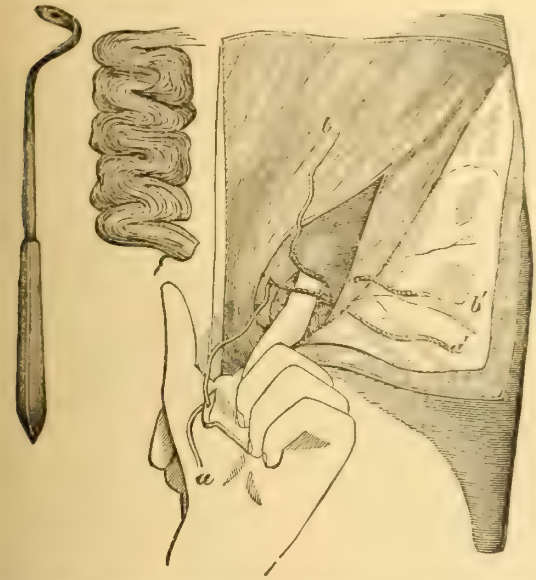

FIG. 4894.—On the left is one of Dr. Macewen's needles; they are made of one piece of steel. In the middle is the folded sac. The right-hand figure (modified from those of Dr. Macewen) is intended to show his mode of suturing the internal ring. The index-finger in front of the folded sac is separating the peritoneum round the internal ring. The suture *a*, *b*, has penetrated the conjoined tendon at two places, first from without inward near its lower border, and secondly from within outward, as high up as possible, a loop being thus left on the abdominal aspect of the conjoined tendon. At *a'* and *b'* the two ends of the above suture have been passed, separately threaded on needles, from within outward, through Poupart's ligament below, and through the transversalis and obliquus above. (Copied from W. H. A. Jacobson's "The Operations of Surgery.")

Banks, preferably, is silver wire, so thick that a single knot will hold, with the ends cut close, and without any twisting or any second knot; silk is his second choice. Czerny differs only in that he prefers silk for his sutures. Macewen advocates the chromic acid gut so prepared as not to be absorbed short of from fourteen to twenty-one days. The stitches should all be introduced before tying any of them. Finally tie them, beginning with the highest and going downward in order. Before tying each and every stitch, the cord should be examined and left free. Drainage is accomplished by means of a small rubber tube (Czerny), or a bundle of horse-hair (Banks), or a decalcified chicken-bone tube (Macewen); and finally the skin-wound is coaptated and sutured.

B. The method of Riesel and of Barker. Here the incision, as before, exposes the superficial ring freely, and Riesel also splits the anterior wall of the canal clear up to the deep ring. He then ties the neck of the sac at as high a point as possible. The fundus of the sac is left *in situ*, helping to make a resisting mass here, its cavity being obliterated. Part of the anterior wall of the canal is cut away; transverse deep sutures are introduced, in much the same manner as in method *A*, but beginning high up, at the deep ring; and finally the skin is sutured.

Barker does not split the anterior wall of the canal. The sac is separated at its neck, and tied opposite the superficial ring. Its neck and the stump are drawn up the canal and against the deep ring by means of threading needles on the ends of the ligature about the sac, and passing these, guided by the finger, each along the canal, and then through the aponeurosis of the external oblique at points opposite the borders of the deep ring, where they are tied. Three or four more deep sutures, again of silk, are passed across the walls of the canal, high up, and across the borders of the superficial ring, all sutures being superficial to the spermatic cord. This method resembles that of Riesel in that both, after tying off the sac, leave the lower portion of it in the canal permanently.

C. The method of Mr. C. B. Ball consists in stitching the twisted stump of the sac to the pillars of the superficial ring. The sac is, as in Czerny's method, isolated clear up to the deep ring, is ascertained to be empty, is seized by a pair of wide-jawed forceps at its neck, and gradually and gently twisted. On the average, four or five entire revolutions are enough; but his rule is to continue torsion until it seems as if further attempts would cause a rupture. By this time the peritoneum beyond the deep ring will probably have been included somewhat, and a laparotomy would show curved lines of peritoneum radiating from the internal ring.

The twist is now maintained while the neck of the sac is ligated with stout catgut, and while two strong silk sutures are passed through it distally to the ligature. These stitches are each made to include the inner and outer pillar of the superficial ring, and come out through the skin half an inch from the wound. The sac cannot now untwist, and it is cut away distally to the sutures just named, which are next tied over lead plates, so placed as to relieve the skin tension.

Objections to this method would seem to be the possibility of twisting in a small knuckle of gut adherent at or near the deep ring, and a possible peritoneal rupture from slight excess of twisting.

D. The method of Dr. William Macewen is the one which is now most employed, at least in this city. Of all the longer lists of published cases reported by various operators, his statistics as to success have been the most brilliant. Stated briefly, his method consists in retaining the entire sac, detached as far as to its neck, and crumpling it into a wad which is forced against the deep ring and left there; the canal and the superficial ring being at the same operation narrowed by suture.

Dr. Macewen freely exposes the superficial ring and the sac below this. He dissects out and examines the sac as described in method *A*, but any adherent connective or adipose tissue is carefully preserved as a part of the sac mass, which makes therefore a larger plug than would otherwise be the case. The sac is not only stripped up to the deep ring, but the peritoneum around that ring is also separated for about half an inch.

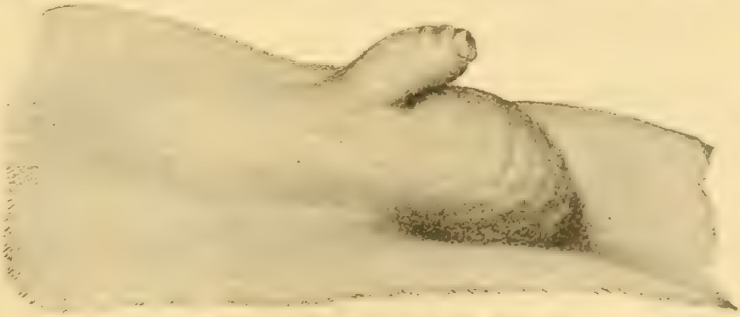

FIG. 4895.—Copied, by permission, from McBurney.

A stitch is now secured firmly into the distal extremity of the sac, and then passed, in a proximal direction, several times through and through the sac (backward and forward, like a shuttle); so that, when pulled upon, the sac becomes folded on itself like a curtain, constituting a pad (see Fig. 4894). The thread is now attached to a hernia needle, or any long, slightly curved needle,

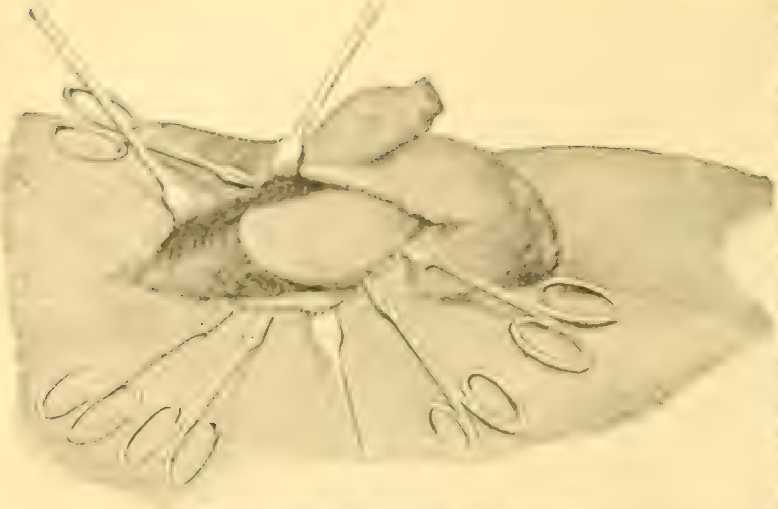

Fig. 4896.—Copied, by permission, from McBurney.

which is carried up the canal and brought out through the abdominal muscles at a point one inch above the deep ring. By pulling up the sac the point of the needle comes out of the muscles just below it—that is, without penetrating the skin.

By pulling on this suture the folded sac is drawn up the canal and through the deep ring, forming "a boss or bulwark" on its peritoneal aspect, which projection is intended to shed to either side the intestinal waves of peristalsis.

Next, the thread is secured by a few stitches taken in the external-oblique aponeurosis, or else by tying over a bit of decalcified bone drainage-tube.

Finally, the freshened canal is narrowed, and the action of the conjoint tendon as an obturator restored as much as may be, by sewing this to Poupart's ligament at a point on the latter as far out toward the anterior superior spine of the ilium as is possible, and also to the transversalis and oblique muscles here. The rest of the canal and the pillars of the superficial ring are also sewn, as detailed in method A. The peculiar method of inserting these first stitches is illustrated in the cut, which also shows one of Macewen's needles for this purpose. These are made with the curve turned either to the right or to the left. While a convenience, they are not a necessity for the proper performance of the operation.

Macewen applies a sublimate gauze and wood wool dressing. "As a rule a portion of elastic webbing is placed over the margin of the pad and stretched to secure it firmly." The patient, in bed, has the shoulders and knees slightly raised to relax the tissues about the canal. The dressings are not disturbed until two or three weeks later, unless stained, or when the patient shows an abnormally high temperature.

When they are removed the wound is found healed; but a fresh pad is applied to continue pressure. The patient is allowed to get up in from four to six weeks after the operation, but does no work until the end of the eighth week. Lifting or straining is permitted only after the third month. Adults engaged in laborious occupations are advised to wear a belt; and elsewise, only in the case of those "of very lax build."

The writer has used this surgeon's exact language in several parts of the foregoing description.

In children, and occasionally in other cases, the sac may be so thin that it is impossible to make a clean and unbroken dissection of it as above. It may be gangrenous, or otherwise unfit to use. Sometimes, too, the entire bulk of the folded sac is quite too small to plug at all effectively the internal ring. In cases of congenital hernia this is apt to be true, as the lower part of the sac must remain to form a tunica vaginalis.

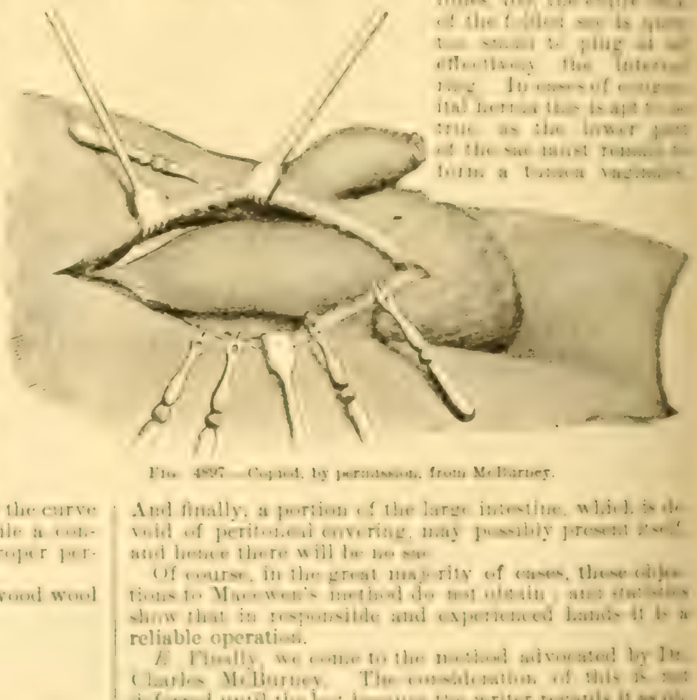

Fig. 4897.—Copied, by permission, from McBurney.

And finally, a portion of the large intestine, which is devoid of peritoneal covering, may possibly present itself, and hence there will be no sac.

Of course, in the great majority of cases, these objections to Macewen's method do not obtain; and statistics show that in responsible and experienced hands it is a reliable operation.

E. Finally, we come to the method advocated by Dr. Charles McBurney. The consideration of this is not deferred until the last because the writer regards it as objectionable. Quite the reverse is the case; and it is discussed later for the reason that it is of more recent date than any of those named heretofore. It has now had a fairly sufficient length of time in which to demonstrate its qualities, so that surgeons can better form a verdict. Dr. McBurney first devised and used it in 1888. Briefly stated, the steps are, entire removal of the sac at the peritoneal level, and open treatment of the wound, which after healing presents a thick scar to oppose return of the rupture.

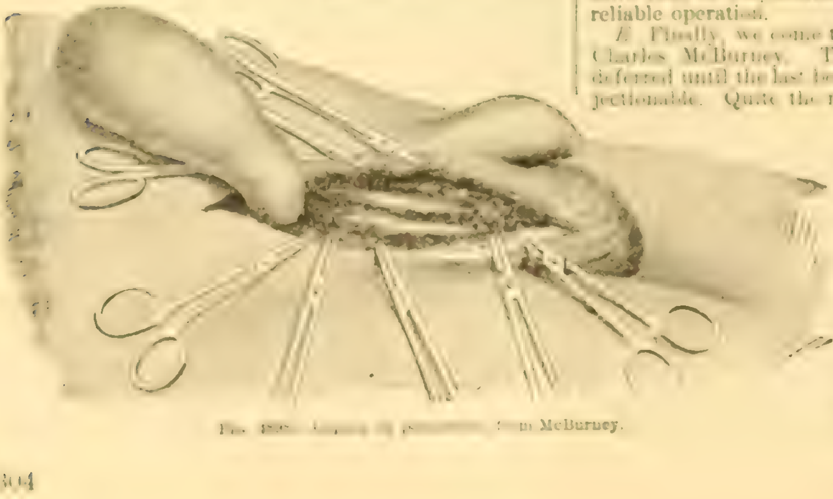

Fig. 4898.—Copied, by permission, from McBurney.

Dr. McBurney calls attention to the objections just mentioned regarding operations which we have discussed, and further points out the absurdity of attempting permanently to unite the pillars of the superficial ring by means of sutures. These pillars were never meant by nature to lie in contact; their edges also are too thin to readily unite. Permanent stitches holding them together are bound ultimately, if gradually, to cut through, allowing separation of the edges, and this will be hastened by every motion of the flat muscles of the abdomen. Further, such suturing offers no resistance at all against descent of a hernia through the deeper ring and the canal. Therefore, suturing, to be of any value, should mainly be of a nature to obstruct the pathway of the gut at its beginning; and Dr. McBurney claims that, by the blunt dissection of the sac always advocated, such surfaces as are coaptated by the buried sutures (the conjoint tendon and Poupart's ligament, for example), are not very likely to unite firmly. Further, assuming that they have so united, there is still a space above and to the outer side of the conjoint tendon which can offer no resistance beyond that of loose areolar tissue to a commencing new sac, caused by repeated impact from within. He thinks, too, that the great success of Macewen is due to perfect obliteration of the sac, rather than to successful obstruction from his sewing.

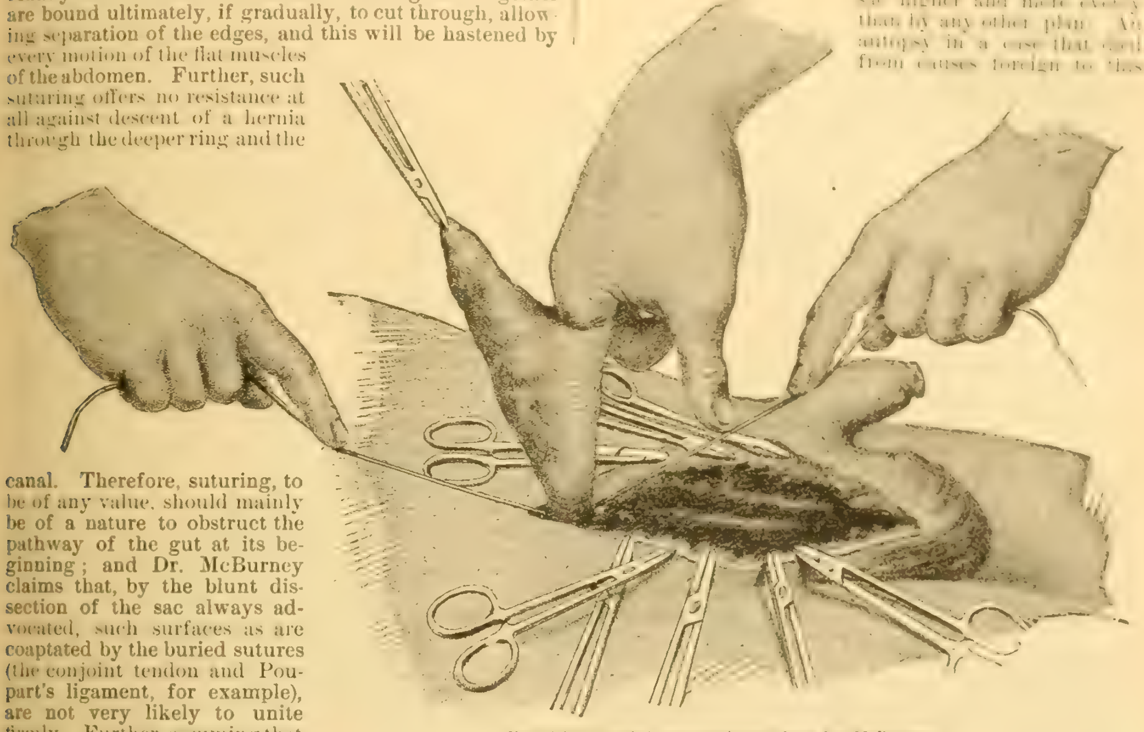

FIG. 4899.—Copied, by permission, from Dr. McBurney.

McBurney's incision begins a little *outside* of the deep ring, and is carried across the canal, the superficial ring, and a sufficient distance below (Figs. 4895 and 4896. These and the following cuts are used by permission).

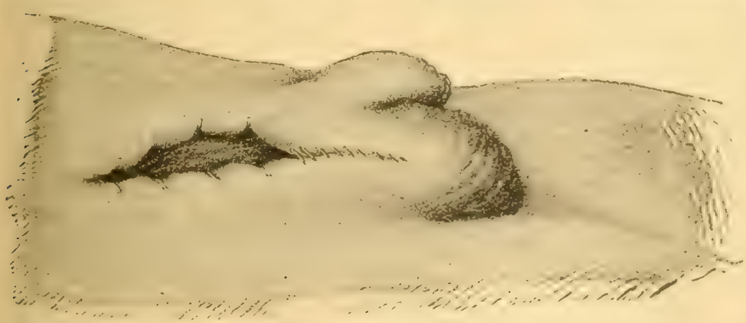

FIG. 4900.—Copied, by permission, from Dr. McBurney.

Following the method of Riesel, the aponeurosis of the external oblique muscle is cut, beginning at the superficial ring and running parallel with Poupart's ligament and a little above it, up to and slightly beyond the outer border of the deep ring, thereby opening the front of the canal from end to end (Fig. 4897.) This enables the operator to separate the cord from the sac with comparative ease, and the sac from its environment; and these steps should be begun high up and continued downward. It also enables the surgeon to strip with ease and safety the neck of the sac away from the abdominal walls for a short distance inside the deep ring (Fig. 4898), and to tie off the sac higher and more evenly than by any other plan. An autopsy in a case that died from causes foreign to this subject, some time after being subjected to this operation, showed, according to Dr. Abbe, who was present, a perfectly smooth peritoneum opposite the deep ring, marked by a punctate cicatrix only.

Prior to ligation—which is done with either stout silk or catgut—the sac is opened for examination of its contents, as heretofore described; and during ligation it is held vertically while the index-finger of an assistant is kept deeply in its neck, to prevent a nipping of the gut or omentum. The ligature is tightened over the tip of his finger, and flush with the general peritoneum (Fig. 4899), after which the sac is cut away as close to the ligature as safety will permit.

Dr. McBurney believes that a firm, deep, and solid cicatrix will offer the greatest resistance to return of the gut, and judging by analogy, there is no reason why it should not be permanent when once formed. He makes the two walls of his wound as nearly solid and homogeneous as possible, by from four to eight stout catgut or silk stitches placed on each side (Fig. 4900). These should invert the skin and go through *all* the abdominal layers down to the transversalis fascia, on their own side of the wound. Now, the wound must heal from the bottom. But it is too wide, and therefore two or more heavy sutures are placed across it, drawing the edges so that the average width of the space between the lips of the wound shall be from one-fifth to one-fourth inch. These last sutures pass down to, but not through the abdominal muscles, and are tied over pledgets of iodoform gauze, in order to prevent their cutting. The wound is now irrigated, dusted with iodoform, and packed firmly with absolutely gauze to the very bottom. This firm packing prevents an oedema, which otherwise occurs, and interferes with granulation. Fig. 2902 shows the wound packed and ready for the external dressing. The scrotal or labial wound is sewn without packing, and may be drained from below if thought advisable.

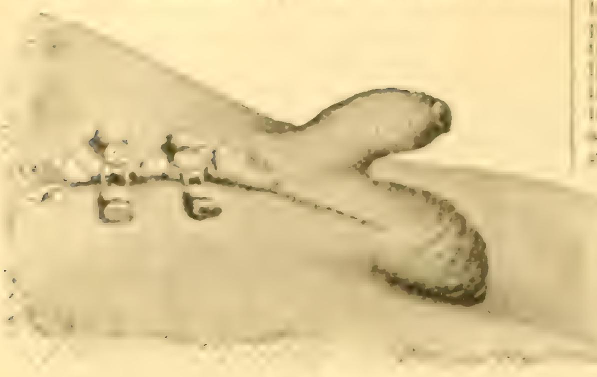

Fig. 2902.

An ample bichloride gauze dressing is applied and bound securely in place. A large square of rubber tissue, having a hole for the penis in its centre, is put in place just beneath the bandage. In women, especially, it is well to catheterize for some days to avoid risk of wetting the wound. In children, for the same reason, a shellac-coated plaster of Paris dressing is advisable. The dressing is changed and renewed as before, at the end of five or six days; subsequently every four to six days. The average time required for complete healing is from five to six weeks; at the expiration of which time the patient will have a very strong cicatrix; hence the delay for this length of time in bed is advantageous, enabling the subject to discard the truss altogether. In fact, Dr. McBurney strongly disapproves of the truss, believing that its constant pressure tends to cause weakness of the scar.

A theoretical objection to the operation under discussion would be that the spermatic cord might become constricted by pressure from the inevitable contraction of the scar tissue with which it lies in contact. As an actual fact, however, this has never occurred, and the cord takes care of itself.

The advantages claimed for this method are:

1. That in inguinal hernia one is able, after laying open the canal, very evenly and completely to tie off the sac, and so obliterate it.

2. That the wound being open, no drainage is required, and the risk of abscess and septic complications is reduced to a minimum. Since the great majority of deaths from attempted radical cure have occurred either from septic troubles or from hemorrhages, and since many men attempt cutting operations who are not entirely familiar with aseptic technique, this is undoubtedly the safest of the true radical operations.

3. That the walls of the canal are united throughout by strong cicatricial tissue.

4. That it is rapid, and applicable to every form of inguinal hernia.

I have gone much into detail here, giving often Dr. McBurney's exact language, believing that the method warrants it. Surgeons generally are regarding it at present with growing favor. And if used at all, it is simple justice to the method and to its author to employ it as he has directed.

Robert H. M. Dawbarn.

INTUSSUSCEPTION. History.—Obstruction of the intestine was known to the ancients, who grouped it with peritonitis and other affections giving similar symptoms under the name "Ileus." Thus Hippocrates speaks of εἰλεός, literally the Latin volvulus; but it is evident from his description that this name was suggested not by the anatomical displacement known to us as volvulus, or twisting of the bowel, but rather by the supposition that the disease was situated in the intestine, the peristaltic movements of which were already known. It may be, however, that the twisting character of the pain, or perhaps the visible peristalsis sometimes noticed in intestinal obstruction, gave the reason for the name. Aretæus limited the term εἰλεός to cases in which only the small intestine was involved, the similar affections of the large intestine being called by him χόρδαψος (χορδή, a string, and ἕψω, to boil, or ἅπτω, to bind). Galen, however, gave the latter name to those cases of εἰλεός in which a tumor could be felt in the region of the small intestine.

Intussusception was the first form of intestinal obstruction to be recognized pathologically, being first found by autopsy as early as the sixteenth century. We are indebted to Peyer,[1] Ruysch,[2] and Haller[3] for the first descriptions; and Peyer, at least, investigated the subject by experiments upon animals. Before their time, ileus had been considered a nervous affection, and this view is actually clung to by Hilliard as late as 1811.[4]

The form of intussusception which occurs in the death-agony, the "intussusception of the dying," was first recognized and distinguished from the clinical form by Louis,[5] Baillie,[6] and his translator, Soemmering,[7] and also to Voigtel,[8] who saw it in animals.

Laparotomy was performed for this form of obstruction at a very early date. In 1692 Nuck, a Dutch physician, caused a surgeon to open the abdomen of a patient and reduce an intussusception, with a successful result. In 1700 Bonetus also had a successful case of laparotomy for intestinal obstruction; but whether the form of obstruction found was intussusception is not beyond question. In 1810 Otto had a fatal case of laparotomy for intussusception, and in 1824 Fuchsius was able to save the life of a patient by operation. After that time the operation became much more common, and the writer of this article found seventy-one operations for intussusception among the 528 cases of laparotomy for acute intestinal obstruction performed from 1873 to 1887 inclusive.

In modern times the statistical analyses of Leichtenstern, Rafinesque, Treves, and Braun, and the monumental work of Nothnagel, are the most noteworthy contributions to our knowledge of this disease. These and others will be referred to in the course of the article.

Definition.—Intussusception has been variously defined, but to get a clear idea of all its aspects it is necessary to combine the different points of view taken by the numerous definitions. The old physician, Velse, defines intussusception as the disappearance of one part of the bowel into its adjacent part when it is driven into the latter ("Quum [illegible] impulsa [illegible] absconditur"). Gay describes it as, anatomically, an invagination; surgically, an internal hernia. Treves defines it as the prolapse of one part of the bowel into the lumen of an immediately adjoining part. Cruveilhier very happily compares it to a partial inversion of a finger of a glove.

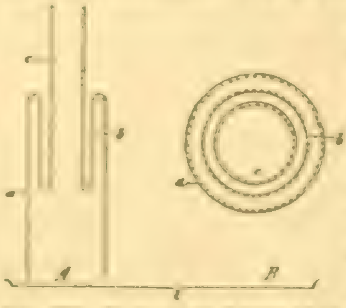

Fig. 2903.—Diagrammatic Section of an Intussusception. A, Intussusceptum; B, intussuscipiens; a, external layer; b, middle layer; c, internal layer.

The characteristics of the lesion can best be made clear by describing the way in which it can be produced in the intestine of a cadaver. One hand compresses the bowel so as to reduce it to the smallest possible bulk, and then thrusts it into the next adjacent part, held by the other hand in such a way as not to diminish its lumen. The compressed part is forced into the other as one would insert the fingers into a tight glove. An intussusception consists of three layers of intestinal wall (see Fig. 4902): the internal layer, continuous with the normal intestine at one end of the intussusception; the middle layer, where the wall of the intestine returns upon itself, being bent back outside of the internal layer; and the external layer, forming the sheath of the whole, and continuous with the normal bowel at the other end of the intussusception. The middle layer is continuous with the internal layer at one end, and with the external layer at the other. The peritoneal surfaces of the internal and middle layers are in contact, and the mucous surfaces of the middle and external layers, the middle layer being turned inside out, while the other two preserve their normal position in this respect.

The external layer or sheath is called the intussuscipiens; the two other layers, being contained within the external layer, are together called the intussusceptum. The apex is the free extremity of the intussusceptum which projects into the cavity of the intussuscipiens, and the neck is that part of the intussusceptum which is constricted by the edge of the intussuscipiens at the point where the middle layer turns back again to form the external layer or sheath. By some authors the constricting edge of the intussuscipiens is also included in the term neck, but if it is necessary to give a name to this part it should rather be called the collar.

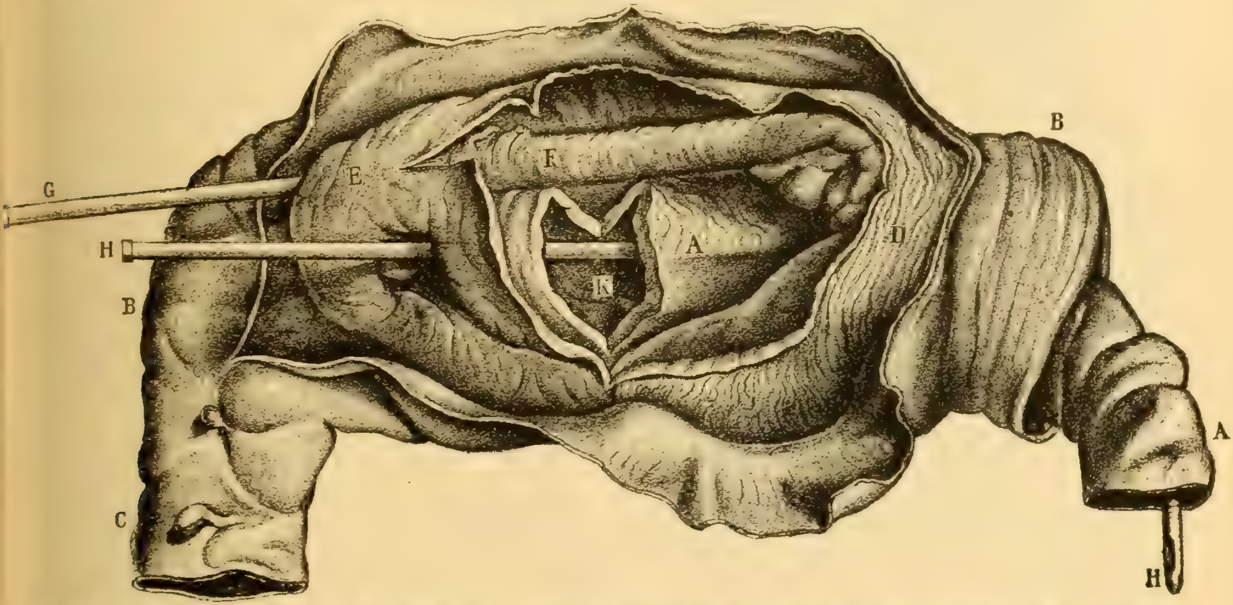

Fig. 4903.—Ileo-cæcal Intussusception. (From Rafinesque.) A, ileum; B, transverse colon; C, descending colon; D, ascending colon (mucous surface); E, cæcum (mucous surface); F, vermiform appendix; G, sound passed into the vermiform appendix; H, H, sound passed through the ileocæcal valve and the ileum; K, ileum, mucous surface exposed by incisions in the walls of the bowel.

It follows from this formation that there are two cylindrical spaces between the layers of the intussusception, one between the external and middle layers, lined with mucous membrane and continuous with the cavity of the bowel; the other between the internal and middle layers, lined with peritoneum, and continuous with the peritoneal cavity. In the space between the internal and middle layers lies the mesentery belonging to the loop of intestine that forms the intussusceptum, folded upon itself, and dragged in by the traction of the intussusceptum in its efforts to pass on down the bowel, and thus moulded into the shape of a cone, being thickest at the neck.

Frequency.—According to Leichtenstern, in 1,152 cases of intestinal obstruction, excluding congenital obstruction, stenosis of the rectum, and the various forms of hernia, there were 442 cases of intussusception, about thirty-eight per cent., so that this is one of the most frequent forms of occlusion of the bowels.

Varieties.—One of the important distinctions to be made in the classification of intussusceptions is that between the clinical or inflammatory intussusceptions and the intussusceptions of the dying, which form just as life is passing away. The clinical intussusceptions are also called inflammatory, because they almost invariably show some inflammatory changes when examined at autopsy, while the intussusceptions which form in the death-agony are entirely free from them. The intussusceptions of the dying are, of course, without clinical importance, but from an anatomical stand-point no difference can be found between them and the clinical form; and as the mechanism of their formation must be the same, they should be carefully studied for the sake of the light which they throw upon the etiology of the disease. The characteristics which serve to identify the intussusceptions of the dying at autopsy are their retrograde direction, the apex being turned toward the stomach-end of the intestine, their small size, their ready reducibility, as no adhesions are found, and their occurrence in considerable numbers. It is the rule to find several in one body, and exceptionally ten, or even more. As we shall presently see, the clinical intussusception is usually single, almost invariably directed toward the anus-end of the intestine, shows more or less marked changes from disturbed circulation, which render it difficult of reduction, and it may attain a considerable size.

The varieties of intussusception may be classified according to the part of the intestine which is involved. This anatomical classification divides them into those in the small intestine, enteric; those in the colon, colic; those in the rectum, rectal; and two forms which are found at the ileo-cæcal valve. If the valve retains its integrity, and is pushed forward into the colon at the head of the intussusception, we have the ileo-cæcal form, two subvarieties of which can be distinguished. In the more common of these subvarieties the cæcum becomes inverted with the valve, and assists in the formation of the middle layer (see Fig. 4903). In the rarer subvariety the inversion begins at the junction of the colon and cæcum, and the latter forms part of the internal layer, being advanced parallel with the ileum, and at the apex of the intussusception two openings can then be found, one being the ileo-cæcal valve, and the other leading into the cavity of the cæcum. This latter subvariety is so rare that it might almost be omitted from the list.

In the other form of intussusception, which occurs at the ileocæcal valve, the valve itself gives way, and the lower part of the ileum is inverted or prolapsed through it into the colon; hence it has received the name "ileo-colic" (see Fig. 3004). Leichtenstern and Treves suppose that the mechanism of the ileo-colic intussusception is the same as that of the prolapse of the rectum at the anus; but it is not clear why it might not also take place by the growth of an intussusception in the lower part of the ileum in the ordinary method—by simple advance of the apex of the intussusception already formed, forcing its way through the ileo-cæcal valve. But we shall return to this question when we consider the mechanism of intussusceptions in general.

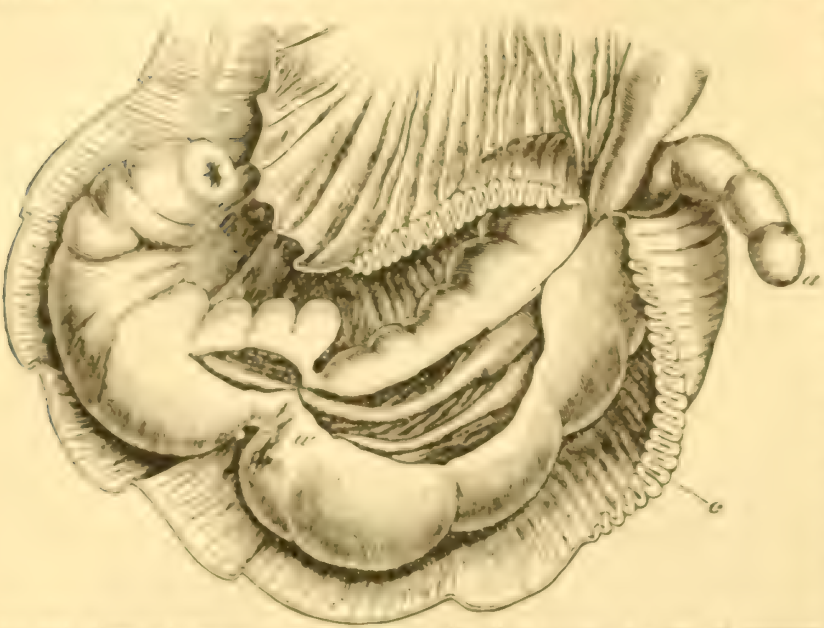

FIG. 3004.—Ileo-colic Intussusception. (From Treves, after Von Rokitansky.) a, colon; b, vermiform appendix; [illegible]

In the small intestine, intussusception is almost entirely confined to the ileum and the last part of the jejunum, being most frequent in the latter situation, according to Treves. According to Leichtenstern, they are most frequent in the lower ileum, and next at the ileo-jejunal junction. From the latter author we obtain the following table:

Relative Frequency of the Various Forms of Intussusception.

	Cases.	Per cent.
Ileo-cæcal	212	44
Enteric	[illegible]	30
Colic	90	18
Ileo-colic	39	8

These figures show that while nearly one-half of the cases are ileo-cæcal, and nearly a third are in the small intestine, but eight per cent. are of the ileo-colic variety. It is important to note that one case in twelve or thirteen is of the ileo-colic form, for the very existence of this variety was denied by many writers upon the subject before Leichtenstern's time. There are a few rare cases of intussusception of the duodenum on record.

FREQUENCY.—Among the predisposing causes of intussusception, its frequency in infants and in the male sex must be noticed. The statistics as to sex vary in their exact proportions, but the greater frequency of the disease in the male cannot be disputed. Thus Leichtenstern found it to occur 1.8 times in the male to once in the female, calculating upon [illegible] cases. Cox, in 1,280 cases, found the proportion 1.11 in the male to 1 in the female; but during the first year of life the proportion was 1.8 to 1, the figures growing gradually more equal as adult age was approached. Rafinesque, in his collection of fifty-one chronic cases, found intussusception to occur in males three times as frequently as in females, which is all the more remarkable as the proportion of adults is so great in this class of cases. It need scarcely be said that no reason is known for the greater liability to intussusception upon the part of the male sex.

Age is a still more important factor in the predisposition to intussusception. During the first three months of life intussusception is extremely rare, but in the second three months it is more common than at any other period of life. Leichtenstern found that twenty-nine per cent. of his cases occurred before the first year of life had passed, and forty-six per cent. before the eleventh year, while thirty-six per cent. of the entire number of cases were between eleven and forty years of age, and only sixteen per cent. over that age. Treves gives some figures of the relative occurrence of the acute form at various ages, obtained by a comparison of the results of various statisticians; and adding to them Rafinesque's figures for the chronic variety of intussusception, calculated upon 51 cases, we obtain the following:

Frequency of Intussusception at Various Ages.

Age.	Acute cases.	Chronic cases.
	Per cent.	Per cent.
Before 11 years	[illegible]	[illegible]
Between 11 and 20 years	12	[illegible]
Between 21 and 40 years	[illegible]	[illegible]
Between 41 and 60 years	[illegible]	19
Over 60 years	[illegible]	[illegible]

From this table it can be seen at a glance that children under ten years of age are most liable to acute intussusception, while the chronic form is more likely to attack the adult. From 598* cases in which both the age of the patient and the location of the intussusception were given, Leichtenstern constructed the following table:

Relation of the Age to the Situation of the Intussusception.

Age.	Total cases.	Ileo-cæcal.	Enteric.	Colic.	Ileo-colic.
		Per cent.	Per cent.	Per cent.	Per cent.
Under one year	153	[illegible]	6	19	[illegible]
2 to 5 years	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
6 to 10 years	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
11 to 40 years	[illegible]	[illegible]	42	[illegible]	[illegible]
Over 40 years	[illegible]	[illegible]	42	[illegible]	[illegible]

We are at once struck by the fact that in children not over one year of age (who furnish, as we have seen, twenty-nine per cent. of the cases of intussusception), the ileo-cæcal variety occurs in nearly three-fourths of the cases, and the ileo-colic and enteric forms are very rare. Moreover, in children under eleven years, although the proportion of ileo-cæcal cases diminishes steadily up to that age, the percentage of colic cases remains very high, being from a fifth to a fourth of the whole number. Accordingly, the number of enteric intussusceptions does not greatly increase until the sixth year of life is reached. The well known fact that the mobility of the cæcum and the entire colon is so much greater in early childhood than later in life, readily explains the greater frequency of intussusceptions involving the large intestine at that period; for, as will soon be shown, mobility of the gut is a prerequisite of intussusception.

---

* By an arithmetical error Leichtenstern's total in the table is made [illegible] in the original.

But little is known of the exciting causes of intussusception, the following table, altered from a similar one of Leichtenstern, showing all that can be extracted from the histories of reported cases upon this point. In a total of 587 cases, the history was sufficiently complete in 320 to allow conclusions to be drawn as to the cause.

Causes of Intussusception.

		Cases.	Per cent.
Taken suddenly ill while in good health		111	35
Mechanical causes (polypi [30 cases], cancer, stricture, undigested food, and foreign bodies)		64	20
Falls, blows upon the abdomen, violent exertion		26	8
Irregularities of the bowels, viz.:			
Diarrhœa	21	46	14
Dysentery	5		
Rectal gonorrhœa	4		
Colic from "taking cold"	6		
Constipation	4		
Simply "irregularities"	6		
Various complicating diseases (hernia, cholera, pregnancy, and childbed, etc.)		73	23
Total		320	

From these figures a third of the cases are seen to begin without warning, and without apparent cause, and probably this proportion is below what it should be, for some of the other assumed causes are far from being proven. According to many authors, including Treves, the disease appears to be more frequent in those who are in delicate health (anæmia, cardiac disease, phthisis), or convalescing from severe disease. But Leichtenstern expressly states that in his collected cases the contrary is the rule, for it more frequently attacked robust individuals. Rafinesque's small collection is about equally divided among the weakly and the strong. Many cases had some previous irregularity of the bowels, such as diarrhœa, dysentery,—and even constipation in a few instances. This agrees with what we shall presently see to be the result of experiments, that intussusception is most readily produced by spasmodic action of the intestinal muscle.

A few cases are reported to have been caused by "taking cold" by exposure, or by drinking cold water while heated, such being common causes of ordinary intestinal "colic." It has been a favorite supposition with writers upon this subject that all attacks of colic are intussusceptions, which reduce themselves spontaneously, or under the influence of narcotics. The name of Cruveilhier is especially associated with this idea. It is not at all likely that this theory can ever be proven, but it should be considered in the treatment of these attacks of colic, and it is a strong argument for the use of opiates, and the avoidance of purgatives in their treatment. In fact, the intussusception formed immediately after the giving of a purgative medicine (for intestinal worms, for instance), in two of Leichtenstern's cases. In this connection must be mentioned the fact that intussusceptions of the dying are said to be most common in children dying of meningitis and nervous affections, although no convincing evidence upon this point has yet been published.

A considerable number of cases have some definite mechanical cause, such as a polypus of the intestine, a narrowing of the canal by cancer or simple stricture, or the inversion of a Meckel's diverticulum. When a polypus is the exciting cause, it is generally small, attached opposite to the mesenteric border of the gut, and usually in the lower ileum (see Fig. 4905). But these polypi have been found as large as an egg or a pear, and they may occur in all parts of the intestine. The polypus generally forms the apex of the intussusceptum, although in some cases it has been attached to the bowel below. In the latter case it is probable that it has been only indirectly the cause of the invagination by exciting violent peristalsis; but, as a rule, the polypi act in a purely mechanical way by dragging upon the wall of the bowel at their point of attachment, and when they are urged on by the peristaltic movements, they turn it in at that point first, and then in the whole circumference. Whether Cruveilhier's case, elsewhere referred to, in which the polypus was attached to the middle layer of the intussusception, is to be interpreted as an accidental coincidence, or whether it is to be taken as proof of an unusual shifting of the layers of the intussusception after its formation, is uncertain, but probability inclines to the latter supposition. In a remarkable case reported by Homolle,[9] there were three intussusceptions, each caused by a polypus.

Becker[10] records a case in which an inverted Meckel's diverticulum, hanging into the lumen of the intestine, caused an intussusception by dragging upon the wall of the bowel in the same way as a polypus. A few similar cases are known to literature, and Treves describes a specimen in the Guy's Hospital museum, in London, which exhibits the same causation.

Masses of undigested food and foreign bodies are not infrequently the cause of intussusception, and appear to act by the increased peristalsis induced by the obstruction which they cause. Leichtenstern found twenty-eight cases of intussusception due to these foreign bodies, and Rafinesque found two such instances among his chronic cases. The foreign bodies in these cases have included, among others, apple-cores, pits of cherries or plums, beans, gall-stones, and portions of raw carrots. Treves describes a specimen in the museum of the University College, in London, in which an intussusception has formed, in the intestine of one of the lower animals, about a large piece of undigested tendon.

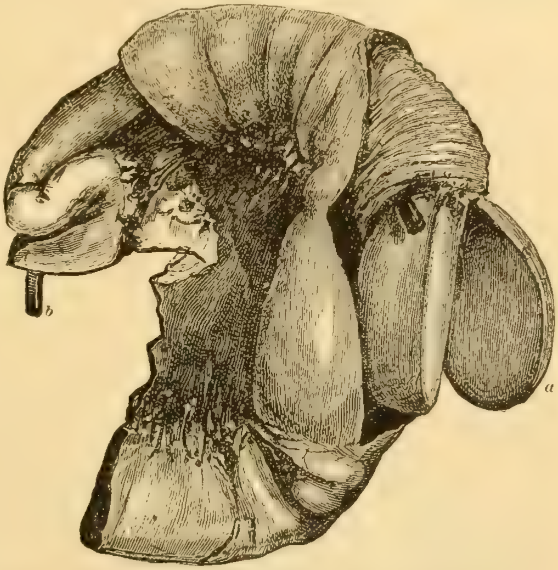

FIG. 4905.—Intussusception caused by a Polypus. (From Treves.) *a*, Polypus; *b*, bougie in the lumen of the gut.

In a certain number of cases the symptoms of intussusception have begun immediately after a blow upon the abdomen, a shock to the whole body received by falling from a height, or some unusual muscular exertion, and it is not difficult to believe that such traumatisms might cause irregular and spasmodic action of the intestinal muscles. In fact, it is easier to understand how such agents could cause an intussusception, than how they could produce some of the other forms of obstruction, in which such an injury not infrequently appears to be the cause.

MECHANISM.—There has always been much dispute as to the mechanism by which the intussusception is formed in the ordinary cases, in which there is no polypus or other evident mechanical cause. In ancient times it was regarded as the result of some sort of spasmodic action of the intestinal muscular coats, while later opinion favored the idea of a paralysis of these coats for a limited portion of the bowel. Leichtenstern is the most emphatic believer in the paralytic theory. There were three explanations possible under the theory of paralysis. The first of these supposed that the paralyzed part was drawn in by the part immediately below it—in fact, that it was swallowed by it, just as any body within the intestine would be passed on by the peristaltic movement. The second claimed that when the part immediately above the paralyzed loop was in contraction, the latter, offering no resistance, allowed the contracted part to force itself into the lumen of the paralyzed loop. The last and most plausible explanation was that the contracting part above propelled itself through the paralyzed loop into the part just beyond, inverting the paralyzed segment, and making it the middle layer of the intussusception. Leichtenstern and his followers overcame the objection that in a considerable number of cases there was colic, diarrhœa, dysentery, or some other derangement which would be more likely to be accompanied by spasm than by paralysis, with the supposition that in these cases paralysis came on as a natural consequence of the spasm, when the contractile power of the muscle was exhausted.

But, since Nothnagel's experiments upon peristalsis and intussusception, there can no longer be any doubt that the majority of intussusceptions, if not all, are the result of spasm. He opened the abdomen of etherized animals, most frequently rabbits, in a bath containing a half of one per cent. solution of salt, at the temperature of the blood, thus preserving the natural surroundings of the intestines as far as possible, and then applied faradic electricity to the bowel, and succeeded in producing intussusceptions at will. The writer has repeated these experiments and is able to verify Nothnagel's conclusions.

In some cases, when the abdomen was opened, active peristalsis was observed, especially in the duodenum, but as a rule the intestines lay quiet or waved gently to and fro in the "swinging" movements described by Van Braam Houckgeest, who first studied peristalsis with this method—movements which are supposed to be caused by contractions of the longitudinal fibres. In some cases the peristalsis was so violent as to produce spontaneous descending intussusception. In such cases a limited portion of the bowel was closely contracted, and the part next to it appeared to be drawn up over it, probably by the action of the longitudinal fibres. It might be mentioned here that Eichstädt (quoted by Leichtenstern) saw an intussusception form in a rabbit to which he had administered rhubarb, the contracting loop moving downward while the loop destined to form the sheath pushed itself from below upward over the first loop in an antiperistaltic direction. Therefore, this observer also saw a drawing up of the relaxed part, and not a moving down of the contracted. These spontaneous intussusceptions were always small, and reduced themselves generally at the end of ten minutes.

Having established the fact that mere mechanical irritation of the bowel by the electrode, without an electric current, produced only a local contraction, Nothnagel applied a faradic current to the intestine. The electrodes were held close together, so that the current passed only for a short distance through the intestinal wall. The writer employed a single electrode of the form designed by Ludwig for stimulation of the nerves, which passed the current in the long axis of the bowel for about a fourth of an inch. If the current is very weak only the part through which the current passes contracts.

As the strength of the current is increased, a contraction is seen to run upward toward the stomach for a couple of inches, and downward, for less than half that distance, being most intense beneath the electrodes, successive waves of contraction appearing to start from this point and to die out after reaching a certain length. The upper limit of this contraction is usually sharply marked, and occasionally a small ascending intussusception forms at that point, but this intussusception does not exceed a fourth of an inch in length, and soon reduces itself spontaneously, even before the contraction has entirely ceased. Even when there is active peristalsis just above it, the intussusception never grows larger. But this is not difficult to understand, for the direction of the invagination is opposed to that of the normal wave of peristalsis. The strong current produces more marked effects below the electrode. After an interval of some seconds, sometimes as much as two or three minutes, a descending intussusception appears at the end of the contracted portion of bowel below the electrodes. Sometimes an antiperistaltic wave seems to come up against this contracted part from below, and to force the relaxed portion over the contracted; but, as a rule, the relaxed part appears to be drawn over the contracted by the action of the longitudinal fibres, and this is probably the fact in every case, whatever the appearance may be. The receiving layer travels upward until it reaches the electrode, and then the growth ceases for a while. Then new contractions set in and the intestine below is seen to be drawn upward toward the electrode, where it turns in and disappears into the middle layer. Meanwhile the apex of the intussusception can be seen to be continually advancing downward, even for a distance of three or four inches. This advance of the apex evidently takes place by the constant turning in of fresh portions from the middle layer, to be added to the internal, for the external layer is firmly held by the electrode, and cannot move downward. This fact can be verified by watching the small vessels disappear in turn at the neck of the intussusception. Or two threads can be passed transversely under the serous coat of the gut a short distance apart and cut off short (see Fig. 2906). When the electrodes are applied at the upper thread, a, and the intussusception forms below it, the lower thread will be seen to pass up and disappear at the neck of the intussusception. If the latter is cut open longitudinally soon afterward, the lower thread will be found situated in the middle layer b, half-way between the neck and the apex.

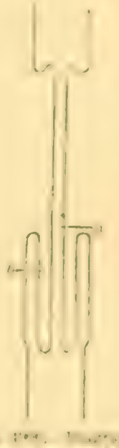

FIG. 2906.—Diagram Illustrating Intussusception Produced by Electricity. (From Nothnagel.)

If the electrodes are removed when the intussusception has been produced, the latter will remain quiescent for long periods, but exactly how long has not been ascertained, although Nothnagel saw the spontaneous intussusceptions mentioned above remain for ten minutes and then reduce themselves. He observed a large descending intussusception, which had been made under the electric stimulus, reduced by a downward movement of gas and fluid contents of the bowel in violent peristalsis. This would indicate that a purgative might cause the reduction of an intussusception, but clinical experience has shown that it is not safe to employ purgatives. He also observed an antiperistaltic wave, due to an enema of strong salt solution, reduce a spontaneous intussusception.

Nothnagel found that applying the electrodes directly to the intussusception produced an energetic contraction of its layers as a whole, and no reduction took place. Applying the electrodes below the intussusception, the ascending wave of contraction which spread over it gradually drew off the receiving layer and so reduced the intussusception. If the electrodes were reapplied above the intussusception, after having been removed, Nothnagel states that no result was obtained. The writer, however, found that such an application often reduced the intussusception, apparently by sending a wave of contraction through it which overcame the displacement, instead of causing all the layers to contract at once, as when the electrodes were applied directly to the intussusception itself. In fact, if the current was cut off and then suddenly reapplied, without removing the electrodes, the intussusception not infrequently reduced itself, and occasionally a sudden great increase in the strength of the current had the same effect. Sometimes, too, while the current was being tained without variations in strength, and even when the intussusception had reached a length of an inch or more, it would suddenly reduce itself, and then form again without any apparent reason. These unusual occurrences are probably to be explained by the variations in the waves of contraction running through the muscular fibres, for the contractions are never constant either in extent or in degree.

Nothnagel attempted to produce paralytic intussusceptions by crushing a portion of the bowel between forceps and then applying the electricity. When the electrodes were applied, just below the paralyzed loop, an intussusception formed below them, while the paralyzed part lay motionless above. When they were applied above the paralyzed portion, an anti-peristaltic wave swept upward as before, while below there was no contraction of any kind. The warm salt solution maintained the flexibility of the crushed loop, in spite of the extravasated blood, so that the presence of the latter could not account for the failure to produce an intussusception. Moreover, Nothnagel in one instance observed a spontaneous peristaltic wave come down upon the crushed loop, ceasing just above it, without producing an intussusception. This cessation was evidently due to the fact that the intestinal contents were arrested at the paralyzed part and distended the gut above, and that the contraction died out when it reached this distended portion. Active spontaneous peristalsis of the bowel, just below a paralyzed loop, also failed to produce an intussusception.

Leubuscher[11] made over a dozen experiments upon dogs by crushing a loop of the intestine until it was paralyzed, and then closing the abdomen, hoping to produce an intussusception. In only one case was an intussusception formed, and this was supposed by him to be an accidental coincidence, and not due to the paralysis.

The result of these experiments is to make the existence of a paralytic form of intussusception doubtful, while it is certain that intussusceptions are easily produced by spasm of the intestinal muscle, and may even occur spontaneously in consequence of strong contractions. Nothnagel's experiments make it probable, also, that the statement usually accepted heretofore, that a contracted part of the bowel was driven down into the part below, is incorrect. It appears to the eye as if the non-contracted portion were pulled up over the contracted, in the formation of the intussusception, and it seems reasonable to refer this movement to the longitudinal muscular coat. A good theoretical discussion of the mechanism of this movement has been made by Exner,[12] whose views are about as follows:

If the intestine is cut across, the edges of the wound are everted, owing to the contraction of the longitudinal muscular fibres which form the external layer of the intestinal cylinder, and, as they shorten, compel the internal layer to roll out. This action may frequently be observed to be preceded by a momentary inversion of the edges by a contraction of the circular fibres immediately at the edge of the wound. If we represent these actions in a diagrammatic section of the two layers of muscular fibres, as in Fig. 4907, A and B, *L* representing the longitudinal muscle, and *C* the circular, the longitudinal fibres contracting at the shaded part would produce an eversion of the intestinal wall as in A. B represents the circular fibres contracted in the shaded portion, with a consequent inversion of the wall of the bowel. The circular fibres could never produce eversion in a transverse wound of the bowel; consequently, when they alone contract in the normal bowel, no matter how sharply limited the contraction might be, the uncontracted portion of the gut would never be drawn over the contracted, and there would never be a tendency toward intussusception. The nearest possible approach to this displacement would be that shown in a section of the muscular layers of both walls of the intestine, as in C, in which the shaded part, *a b*, marks the limit of the contraction of the circular coat, and it is evident that an advance of the contraction toward *c* can do nothing more than reduce the calibre of the bowel at that point, as it did from *a* to *b*. But imagine that the longitudinal muscular fibres were also contracted, as in D, from *a′* to *b′*, a little in advance of *b*, bearing in mind the effect of such a contraction, as just shown in A. The curve *a′ b′* would at once become more concave, the curve *b c* remaining the same. If the circular coat at *b* be not very strongly contracted, it would be unable to oppose the longitudinal fibres and would be slightly everted. If the contracting wave should advance in the longitudinal coat, the curve *b c* would be constantly reversed, and a concave curve would be produced as at *a′ b′*, new portions of the intestinal wall being turned in all the time. If the contracting wave in the circular coat advanced at an equal rate of speed, but always keeping a little behind that in the longitudinal coat, the convex curve *a b* would constantly be reduced to the straight level of maximum contraction as at *a*. But if the contraction in the circular coat should at any moment outrun that in the longitudinal coat, so that it advanced from *b* to *c* before the latter had passed beyond *b′*, it will be seen (Fig. E) that an intussusception would at once begin to form, for the contracting circular fibres at *c* could not slip over the projecting curve *a b c*, and the intestinal wall would be sharply bent at that point, and would form the neck of the intussusception. When the intussusception had once formed, the further action of the longitudinal muscular fibres, even if its contraction should again run before that of the circular, would only tend to drag fresh portions of the intestinal wall around the convex curve *b′ c′*, and add them to the middle layer of the intussusception. If, however, the contraction wave in the circular fibres should continue in advance of that in the longitudinal, it would sweep around the curve beyond *c* to *d* as in F, and would fix that curve also. This would limit the extent

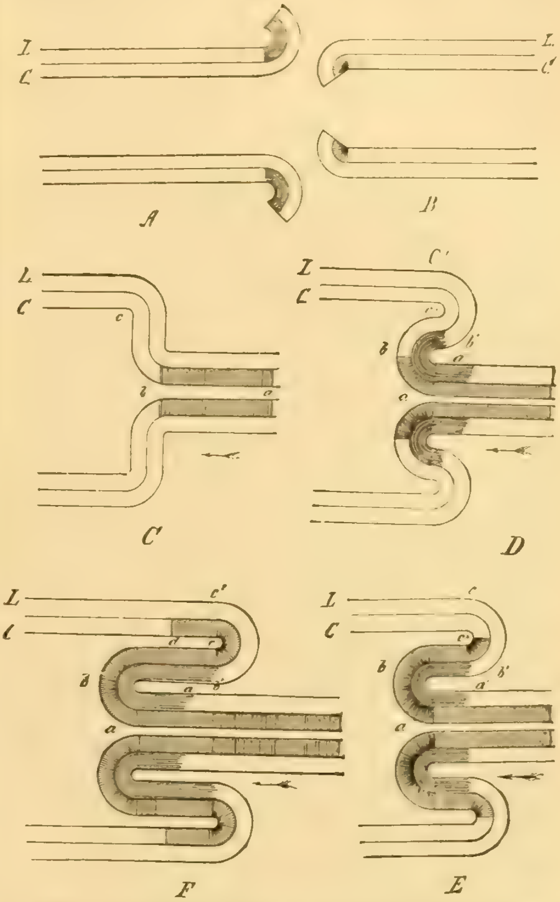

Fig. 4907.—Diagrams showing the Mode of Production of an Intussusception.

of the intussusceptum, unless the longitudinal fibres were strong enough to stretch the circular fibres at *d*, and to make the parts slip over one another, for the growth of the intussusception depends upon the constant advance of fresh portions of the wall of the bowel around the apex *b c*. But, practically, the increase of the intussusception is limited by the mass of included mesentery, and by the pathological changes which take place in the intestinal coats, and not by this contraction of the circular muscular coat.

A reversal of the above process would explain the mechanism of spontaneous reduction. In such a case the muscle in the included loop of bowel must be more or less relaxed, and then the advance of an antiperistaltic wave, in which the contraction of the longitudinal fibres predominates over that of the circular, would reduce the intussusception. For our theory it is unimportant whether the longitudinal fibres are in contraction or at rest when the contraction of the circular fibres be at its maximum, if we are allowed to suppose that the latter are the stronger of the two. But Ehrmann's experiments upon the innervation of the small intestine, "according with those of Fellner upon the rectum," indicate a crossed innervation of the two coats, the splanchnic nerve being the excitant nerve for the longitudinal fibres and inhibitory for the circular fibres, and the pneumogastric being the excitant nerve for the circular muscle and inhibitory for the longitudinal. If these results should be confirmed, both muscles would act to the greatest advantage, as in normal peristalsis the contraction of the two would not be simultaneous, and it would also give additional ground for our assumption that the contraction of the longitudinal fibres precedes that of the circular.

Some of Fellner's experiments just alluded to indicate that under certain circumstances a negative pressure, and consequent aspirating power, is developed in the rectum. Von Basch reasons from this that a similar aspirating mechanism might explain the occurrence of intussusception, the intussusceptum being actually sucked into the sheath. But this explanation is entirely theoretical and seems not a little fanciful.

Although Leichtenstern rejects the possibility of spasmodic intussusception in general, he claims that spasm of the ileo-cæcal valve is the cause of ileo-cæcal intussusceptions, comparing them with prolapse of the rectum, and Treves accepts this comparison. But even if we grant the existence of a strong sphincter muscle at the ileo-cæcal valve, there appears to be a very great difference between the two regions. On the one hand, we have a prolapse of the rectum through a sphincter attached to immovable structures, and with only the outer atmosphere beyond, the expulsive force of the abdominal muscles furnishing the motive power. On the other hand, in the supposed prolapse of the ileum into the cæcum the sphincter itself must, in the ileo-cæcal intussusceptions, be carried forward into a visceral cavity which is usually not immovably fixed—and in children, in whom this form of intussusception is most common, the cæcum is very freely movable. Besides being movable, the cæcum is folded up by the pressure of the viscera around it, or distended by gas or fæces. But, most important of all, there is no force driving the ileum into the cæcum, for the abdominal pressure is also acting upon the latter, whether collapsed or distended. The "peristaltic pressure" of which Leichtenstern speaks does not exist, for we have just seen that there is no propulsion of a contracted loop into a relaxed one in the production of intussusception. The only available force in this case is to be obtained by the contraction of the longitudinal muscular bands, and it seems quite reasonable to explain intussusception at this point by the same mechanism as elsewhere. The longitudinal muscular bands pass directly across from the ileum to the cæcum, and as the latter is so much the larger of the two, it ought theoretically to be much easier to produce an invagination here than elsewhere—certainly it would not demand such extreme circular contraction of the receiving layer. This explanation gains additional confirmation from the fact of the greater frequency of this form of intussusception in children, in whom the cæcum is often almost as freely movable as the small intestine. In the adult, however, the ileo-cæcal intussusceptions are not more frequent than those of the small intestine, for although the larger size of the cæcum renders intussusception liable to occur, the comparative fixity of its position in the adult would counterbalance this advantage.

The comparison of ileo-cæcal intussusception to prolapse of the rectum is also made by Leichtenstern, and is more exact, although he considers both as a result of tenesmus, whereas the cause should be sought in a relaxation of the sphincter muscle. Even in this case, however, the same theory serves to explain the mode of formation of the intussusception, and at the most we should have to depend upon the relative sufficiency of the valve to decide whether the intussusception in a given case would be ileo-cæcal or ileo-colic. If the valve were present the ileo-cæcal form would occur; if the valve were relaxed, the ileo-colic.

It can readily be shown by manipulation of the intestine in the cadaver that even moderate distention of the bowel by gas or fluid contents hinders the production of intussusception, and it is altogether doubtful whether a partial distention by either would favor it, although Leichtenstern claims the latter, clinging to his theory of prolapse.

Gay states that an adhesion of the intestine at any point, to the parietal surface of the abdomen, would increase the liability to intussusception, by giving a fixed point for the intestinal muscle to act upon. This theory was doubtless adduced to assist in the explanation of intussusception under the old idea that a contracted loop forced its way into a relaxed loop, and because the contracted portion of the intestine attains a certain rigidity it was imagined that if it was fixed at one end it could better thrust itself forward. From Nothnagel's experiments, however, we have learned that the apex of the intussusceptum is always directed away from the electrode, which may be considered a fixed point. The presence of the latter, indeed, seemed rather to hinder than to assist in the production of the intussusception, which would probably have formed with much greater ease if the entering layer could have been as free to move toward the receiving layer as the latter was to draw itself toward the former. The cases in which intussusception was associated with adhesions and upon which Gay's supposition was based, are far more easily explained as due to the increased peristalsis excited by the obstruction to the intestinal contents offered by the adhesions. Thus intussusceptions are frequently found associated with other forms of intestinal obstruction—tumors, internal incarceration in apertures, and volvulus—in all of which violent peristalsis must have been caused by the obstruction.

ANATOMY.—We have already seen that an intussusception is formed of three layers of the intestinal wall, and have explained their various names. Let us look a little more in detail at the structure of the intussusception tumor. We have already seen that the mesentery is dragged into the space between the internal and middle layers, forming a cone-shaped mass. The greatest thickness of the folded and wrinkled mesentery lies at the neck of the intussusception, and its pointed extremity is at the apex of the latter. Into this same interval a loop of intestine sometimes slips by the side of the mesentery, thus making one of the rare varieties of internal incarceration.

The mesentery in this new position has a very important influence upon the form of the tumor. When the mesentery is drawn into the intussusception there is more or less resistance, due to its increasing bulk and also to the traction upon its attachments, and this resistance produces a curving of the intussusception toward its attached border. The apex is consequently turned toward that side, and does not look directly forward into the lumen of the bowel, and the whole tumor is given a curved shape like a comma, or a curved link of sausage. The orifice at the apex of the intussusceptum also loses its originally circular form and becomes elongated into a slit, with its long diameter directed toward the mesenteric side. The intussusceptum is always more curved than the intussuscipiens. Treves claims that the axis of the former lies eccentrically nearer the mesenteric border than does that of the intussuscipiens. It is true that the axes of the two do not coincide, but as the mass of mesentery lies between the internal and middle layers it must certainly displace the axis of the intussusceptum away from the mesenteric border for the first part of its length, although, as has already been shown, the apex is directed toward that border. Probably Treves founded his statement upon the observation of specimens with inflammatory and œdematous changes, which are always most marked upon the free or convex border, and would cause a displacement of the axis of the intussusceptum toward the concave mesenteric border.

In the colon, intussusceptions are frequently straight, probably because the larger calibre of the bowel allows the mesocolon to enter with less traction.

The lumen of the bowel is not entirely obstructed at first, although it is diminished to a greater or less extent. This diminution is least in the ileo-cæcal intussusceptions, for here the sheath is formed by the colon, and there is much more space for the intussusception. The obliteration of the lumen is due to the changes which subsequently take place in the invaginated gut, but even in the chronic forms these changes may be absent, or very slight. In some cases the lumen of the intussusceptum admits the little finger when examined at the autopsy; in others it is almost entirely obliterated.

The direction of an intussusception may be either descending or ascending. The ascending intussusception, so called because the intussusceptum has its apex directed toward the stomach, thus ascending the stream of intestinal contents, would perhaps be better named *retrograde*, as suggested by Gay. Ascending intussusceptions are rare in the clinical forms, Leichtenstern having found only eight instances of primary ascending intussusceptions in his 593 cases, both the large and small intestine being represented in this group. But they are common in the intussusceptions which take place during the death-agony, and are not infrequently found associated with descending intussusceptions, probably owing to the disordered peristalsis caused by the obstruction to the intestinal contents, and they may lie below the obstruction (case of Power, "Path. Trans.," 1886, xxxvii., p. 240). These facts show that that there is no mechanical reason why the ascending intussusception does not occur as often as the descending, and the explanation of their infrequency must be sought elsewhere. Perhaps it is due to the fact that they are opposed to the direction of the normal peristaltic wave in the intestinal muscle; perhaps the continual downward pressure of the intestinal contents reduces them at once when they form. Both these circumstances may be altered in the death agony, for antiperistaltic movement appears to be not uncommon at that time, and the intestinal contents may not have time to reduce the intussusception before death takes place.

Besnier has reported a case of ascending intussusception which ran a chronic course. Senn,[16] in his experiments, produced an ascending intussusception two or three inches long in the colon of a cat, and it was found only partially reduced at the animal's death some days later. These facts show that in exceptional instances the ascending may have the same clinical history as the descending intussusceptions, and warrant us in using them to study the mechanical production of the displacement.

Lateral or *partial intussusception* has been described, being caused by the dimpling or drawing in of the wall of the bowel at the seat of attachment of a polypus, or by the inversion of a diverticulum. They are as rare as the so-called lateral hernias, but serve to show the mechanism of the beginning of intussusception from that cause.

In the *growth* of intussusceptions, when once formed, it is supposed that the peritoneal surfaces of the internal and middle layers remain stationary and do not glide upon each other, the intussusceptum moving as a whole into the sheath and the latter sliding upward over the middle layer, and being converted into it by turning in at the point of reflection. The mucous surfaces slip over each other with less friction than the serous. Thus fresh portions of the entering bowel are continually being covered in by fresh portions of the receiving bowel, and the apex of the intussusceptum is always constituted by the same portion of the gut. It is only in this way that growth is conceivable when adhesions have formed between the middle and internal layers. Cruveilhier, however, has recorded one instance in which a polypus was found attached to the middle layer, some distance behind the apex, and the supposition is that the polypus caused the intussusception, and that its attachment at first formed the apex of the intussusceptum in the usual way, but subsequently fresh portions of the internal layer slipped down and through the opening in the apex, these fresh portions then forming the apex, and the point of attachment of the polypus becoming part of the middle layer higher up. This is the only evidence extant for this mode of growth, and is not in itself sufficiently convincing to compel its admission. But the experiments of Nothnagel have shown that the different layers can slide upon each other, and render this supposition more tenable than was formerly thought. In these experiments the possibility of another mode of growth was clearly demonstrated, although the conditions were quite different from those which obtain in nature. This third method consisted in the constant turning in of a fresh portion of the external layer at the neck, so that it became the middle layer, and passed on until it reached the apex, where it was again turned upon itself and became transformed into the lowest part of the internal layer. In this mode of growth the other layers gained in length at the expense of the receiving bowel alone.

The *length* of an intussusception varies according to its position and variety. The rate of growth may be very rapid, especially in children, for the apex of an ileo-cæcal intussusception can be felt in the rectum a few hours after its first formation, as indicated by the symptoms. Leichtenstern found that in adults the enteric intussusceptions were the longest on the average, although the longest one in his cases was of the ileo-cæcal variety, the form which had always been supposed before his time to furnish the most extensive invaginations. In children the ileo-cæcal intussusceptions are the longest, being, according to Leichtenstern, longer in proportion than the same form in adults. The ileo-colic intussusceptions are the shortest, probably because of the very acute course and early strangulation common in them. It is self-evident that enteric invaginations in the lower ileum will be limited by the ileo-cæcal valve, and intussusceptions of the colon by the anus (although either of these may be forced and passed by the tumor), so that the possible length of an intussusception will depend in the first place upon its anatomical situation. It will also depend upon the movability of the portion of gut involved, for if the mesentery is long and at the same time thin, so as not to make too great bulk when invaginated, growth will be easy. But in the case of the large intestine it does not follow that the ascending colon must have a meso-colon long enough to reach up to the liver, across the abdomen to the splenic flexure, and then down upon the left side; for, although the invaginated bowel may take that course, the length of meso-colon required by the ascending colon in following it, will be indicated by a straight line from the situation of the ascending colon to the situation of the tumor at any given point of its progress, that progress following the circumference of a circle with the attached point of the meso-colon as a centre. A very important factor in determining the length which can be attained by an intussusception is the acuteness of the course, for in some varieties, and in some individuals, strangulation occurs so early that death takes place within a very few hours, or at most a few days.

Double and triple intussusceptions are sometimes found, the former being naturally not so rare as the latter, although seldom to occur. Like the ascending invaginations, they are frequently seen in the intussusceptions of the dying. The mechanism is the same as in the original formation of the intussusception. When the intussusception has been formed, the sheath becomes folded upon itself once or twice more, and thus an intussusception of five or even seven layers is produced (see Fig. 1889). More than seven layers has never been observed, and this perhaps indicates the extreme capacity of the gut as a sheath. Hodgson has reported a case of a triple intussusception, occurring in the jejunum measuring six inches in circumference. These cases are apt to have a chronic course, at least at first, and the secondary layers are not infrequently free from adhesions, showing that their formation is more recent than that of the original tumor. The mechanism of these forms is not definitely settled. The former supposition was that an ascending and a descending intussusception met and penetrated each other, and this explanation may be true of some cases. But it is rare to find these two forms within a short distance and with their apices directed toward each other.

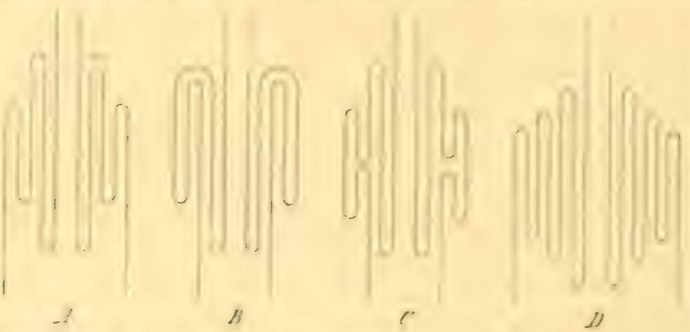

FIG. 1889.—A, B, C, Various forms of triple intussusception; D, quintuple intussusception.

An intussusception of five layers may be produced in another manner, and although this is not strictly a double intussusception, it affords a more probable explanation of their mechanism than that just alluded to. The five layers in this form are produced by the projection and secondary turning down of a transverse fold of the external layer of the intussusception outside of the original sheath, and this displacement is easily understood when it is noticed how marked is the transverse folding and wrinkling of the sheath in many instances. Treves quotes a case of this kind occurring in a child six months old dying with symptoms of intussusception. The autopsy revealed an intussusception of the colon in which the primary invagination was descending, five inches long, with adherent and congested layers. Outside of this was a double fold of sheath resembling a retrograde intussusception, formed in the manner just described, half the length of the primary tumor and without adhesions. Thus there were three layers of bowel at the upper end of the tumor, five in the middle, and three again at the lower end.

Multiple intussusceptions, that is, the simultaneous occurrence of two or more intussusceptions at once, are rare, except in those which take place in the death agony. In the latter variety, indeed, it is the rule to find several in one subject. When they do occur in the clinical form, there is usually one primary intussusception, to which the others are secondary, and not infrequently the latter are of the ascending variety. Sainz describes a very complicated case in which there was an ileocolic intussusception, and higher up also an intussusception of the ascending into the transverse colon. At the latter point a double intussusception had been produced, it is said, by the occurrence of an ascending intussusception which had passed outside and become fused with a descending one. But more probably this appearance was caused by the mechanism just described, a fold having been raised and folded over the original sheath.

PATHOLOGICAL CHANGES.—When an intussusception has existed for some time it undergoes certain changes in its various tissues, all of which owe their origin to the disturbance of circulation caused by the strangulation at the neck. This strangulation may be very slight, and in some cases there even seems to be no strangulation at all, and then the subsequent changes will be correspondingly slight, or they may be entirely absent. Among the chronic intussusceptions recorded by Rafinesque there are many cases in which there was no strangulation, and extraordinary as some of them appear, the evidence in their favor seems too strong to permit the rejection of even the cases of Léger, Brinton, and Fauquy. The first of these cases was in a woman sixty-five years of age who had been ill with vomiting, abdominal pain and tenderness, and constipation alternating with diarrhœa, for twelve months, but no tumor was ever discovered in the abdomen. The autopsy showed some old peritoneal adhesions, and an intussusception of the jejunum eighteen centimetres in length, but without any alterations in its tissues. Brinton's case occurred in a man who had been ill for six months, and the autopsy revealed an ileocæcal intussusception six inches long, in which a slight thickening of the coats of the intestine was the only pathological change. The last of these cases was also in a man who had been ill nearly a year, and after death a double intussusception of the jejunum was found, with only slight thickening of the intestine.

The very important question, from a clinical point of view, as to the time when adhesions take place, cannot be definitely answered. Extreme changes may take place in the tissues involved and yet no adhesions may form, as in the case reported by Lauer, in which a man, forty-three years of age, died after an illness of seventeen days, which had been supposed to be dysentery, and the post-mortem examination revealed a gangrenous intussusception in the sigmoid flexure, with rupture of the sheath and protrusion of the gangrenous intussusceptum, but without adhesions either at the neck or elsewhere. Quite as striking is the case in which Hutchinson found no adhesions or trace of peritonitis when he performed laparotomy and successfully reduced an ileocæcal intussusception in a girl, two years of age, in whom the symptoms had lasted for a month, and two inches of the cæcum had prolapsed from the anus for two weeks. If adhesions did not take place in an intussusception of a month's duration, subject to such violence as this must have received, it appears quite possible that they should be absent from cases of much longer duration, but not exposed to violence outside of the abdominal cavity. In fact, Hutchinson made the statement, in connection with this case, that adhesions are the exception in chronic intussusception. This is not a correct view, for it is certainly unusual for an intussusception to persist for any length of time without presenting at least some adhesions between the peritoneal surfaces. Rafinesque found in 23 cases of chronic intussusception, in which the point is noticed in the reports, that adhesions were present in 19, in 10 of which they were described as old and strong, while in only 4 cases were there no adhesions. The duration in these four cases was twenty days, three, ten, and thirteen months. In sixty cases of acute intussusception collected by Treves, there were adhesions in about forty-five per cent., but he thinks this figure below the reality.

In acute cases adhesions may be present, and even firm, in two or three days. Their formation depends chiefly upon the amount of strangulation in any case, for if the latter is slight there is nothing to excite even the slight peritonitis which gives rise to the exudation of lymph. The strangulation must at least be sufficient to obstruct the circulation in the implicated bowel. The adhesions may be confined to the neck of the intussusception, and this is the usual form, but occasionally they are limited to the apex, while the neck is free, and in such cases we may assume that the part of the intussusception where the adhesions are found was formed some time before the upper part, where there are no adhesions.

In rare cases they are seen in the form of bands at various points between the serous surfaces, or the serous surfaces are fused together throughout their entire extent. If there has been any inflammation or gangrene in the invaginated bowel, adhesions surround the whole tumor, and encapsulate it with the aid of surrounding coils of intestine, or other organs.

As we have already stated, the changes in the intussusception are the result of strangulation, and this primarily affects the intussusception alone, but the sheath is also altered secondarily by the great pressure exerted upon it by the swollen mass within. When the strangulation is limited in degree, the venous return of blood in the intussusceptum is interfered with in the first place, and venous congestion and œdema occur, with interstitial hæmorrhages into the tissues. All the tissues are affected in the same way, and the congestion of the peritoneal coat causes exudation of plastic material, and the formation of adhesions. The mucous membrane becomes œdematous, and if the strangulation is severe or long continued, ulceration takes place. A few rare cases have been reported in which the internal and middle layers have become fused, in consequence of this ulceration, by the union of the raw surfaces which have been produced. Meantime the muscular coats and cellular tissue of the intestinal wall have swollen, and if a moderate degree of constriction has existed for a long time without being so intense as to produce gangrene, these tissues become enormously hypertrophied. Probably this hypertrophy does not affect the muscular coat, although it is true that Lettsom[23] mentions a case in which there appeared to be a true hypertrophy of the muscular layer, even allowing for the fact that an intense degree of contraction would naturally result in a thickening of the walls of any hollow muscular viscus. Cruveilhier also[24] found an increase of muscular tissue.

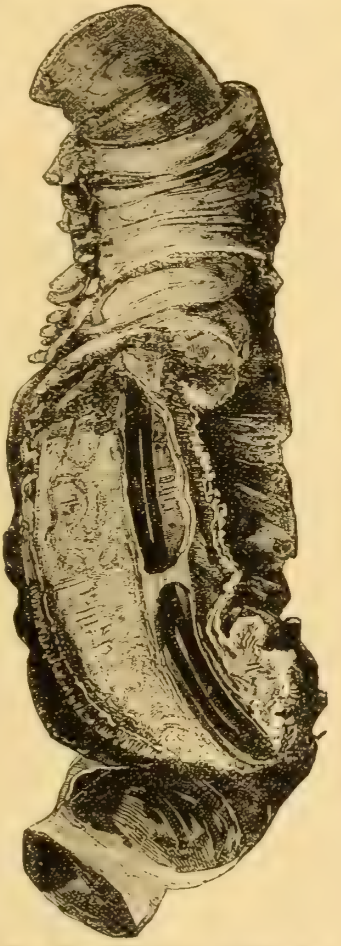

FIG. 4909.—Epithelioma growing in a Chronic Intussusception. (From Treves.) A bougie indicates the lumen of the intussusceptum.

The increase in the thickness of the intestinal wall is most marked in the middle layer, and the sheath is but very seldom affected. The wall of the middle layer has been found as thick as a third, or even half an inch, and the two layers of the intussusceptum have been found to measure seventeen millimetres. In one case the thickness of all three layers together is given as one inch. The swelling and increase in thickness is naturally greatest at the apex and on the convex side of the tumor, for here there is the least resistance. On the concave side the pressure caused by the folding due to the traction of the mesentery is very great, and it is increased by the crowding in of the mesentery itself at that point. This eccentric hypertrophy of the layers results in a displacement of the axis of the intussusceptum toward the mesenteric border. Treves describes a remarkable specimen in which an annular epithelioma appeared to have been the cause of the intussusception, which ran a chronic course for twelve months before death, when it was found that the later growth of the epithelioma had followed the law just stated in regard to œdema and hypertrophy, and had chiefly extended upon the convex side of the intussusceptum (Fig. 4909).

On the other hand, the great pressure to which the internal layers are subjected may cause atrophy, as in a case of acute intussusception in a child thirteen years of age,[25] in which the internal layer was reduced to the size of the iliac artery. It has even been claimed that recovery could take place in this way by a complete atrophy and disappearance of the intussusceptum, with a return of the bowel to its normal calibre; but, as Leichtenstern points out, it is much easier to explain these cases by assuming them to have been examples of a molecular gangrene of the intussusceptum, in which it passed away in such small pieces that no traces of the slough were discovered in the stools.

Close upon the heels of the congestion, œdema, and interstitial hæmorrhages comes the fatal change of gangrene. But the time of its appearance is very variable, being entirely dependent upon the amount of strangulation in the tumor. Judson[26] has reported a case in which gangrene was found twelve hours after the beginning of the symptoms. If strangulation is absent, there can be no gangrene. If it is slight, gangrene is long delayed, and it may be entirely absent in this case also, especially in intussusceptions with a chronic course. But even if the strangulation remains for a long time very slight in a chronic intussusception, it may develop very suddenly later, and terminate life even more quickly than in the ordinary acute cases, for the patient is already weakened by the long-continued ailment. If the strangulation is severe from the first, early gangrene is inevitable, unless death should ensue before it has time to develop fully, being caused by the severe nervous shock due to the strangulation.

Gangrene may attack various parts of the intussusception. Usually in this, as in other alterations to which the tumor is subject, it is the middle layer which suffers earliest and most frequently, and the sheath is generally exempt. Thus in Rafinesque's fifty-five cases the sheath was perforated in eight cases, friable or nearly gangrenous in three others, and probably healthy in the rest. In every case in which perforation of the sheath had taken place, the inner and middle layers were also gangrenous. When the sheath becomes gangrenous, the intussusceptum very frequently projects through the opening into the peritoneal cavity (see Fig. 4910), and in one case, reported by Reydellet,[27] the sigmoid flexure was found entirely divided "by suppuration," and the apex of a strangulated intussusception of the colon projected from the upper end. Sometimes the perforation consists of a small opening involving the sheath alone.

Although strangulation is much more common in acute cases than in chronic, gangrene is not. Leichtenstern found perforation at the affected loop, or above it, in sixteen per cent. of 175 cases, including both acute and chronic, while Rafinesque found it in twenty-two per cent. in 55 cases of chronic intussusception.

It is owing to this common exemption of the sheath from destructive changes, and the comparative rarity of perforation, that spontaneous cure of an intussusception is possible without reduction of the invaginated bowel. A considerable number of instances of spontaneous cure by elimination of the sloughing intussusceptum are known. Leichtenstern found 125 instances of this elimination of the invaginated gut in his series of 593 cases; but Rafinesque found only 6 in his 55 cases of chronic intussusception. It will generally be shown that the process of sloughing is dangerous, and only a small proportion of these cases made an ultimate recovery.

Occasionally the elimination is gradual, the gangrene beginning at the apex of the intussusception and extending gradually toward the neck; but this is an unusual process, and not likely to occur except in chronic cases. Generally the sloughing begins at the neck, just as in the case of a tumor surrounded by a ligature, and the intussusceptum is thrown off in a mass. As the changes are generally most advanced in the middle layer this layer may be unrecognizable in the fragments of eliminated bowel, while the internal layer appears tolerably well preserved. If peritoneal adhesions have formed, the two layers are passed from the anus in the same position that they occupied in the intussusception. But if there are no adhesions between their serous surfaces, as separation is generally first completed in one layer, the other holding a while longer, the invaginated gut becomes unfolded, and is passed in a long continuous piece. Usually the middle layer gives way first, and, as will be seen by Fig. 2911, B, it slips down over the internal layer, turning its mucous surface inward to its natural position, so that the whole length of bowel hangs down in the lumen of the intestine below, dependent from the neck of the internal layer; and when this finally gives way the slough passes off with the mucous surface internal and the serous surface external. But if the reverse should occur, and the internal layer should first separate at the neck, the internal layer would slip down inside of the middle (Fig. 2911, C), and turn inside out to correspond with the latter, its mucous surface becoming external, so that when passed the strip of bowel would be found turned inside out in its entire length.

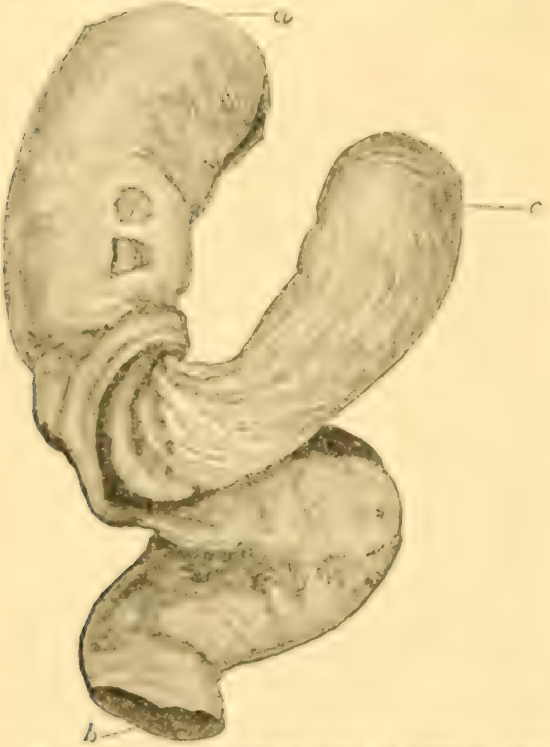

Fig. 2910.—Intussusception protruding through a gangrenous sheath. (From Treves.) a, [illegible]; b, [illegible]; c, [illegible].

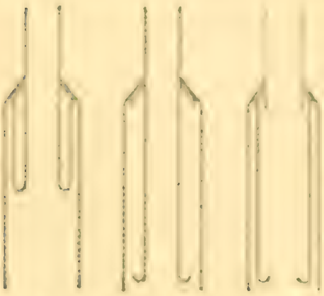

Fig. 2911.—Diagrammatic section of an Intussusception with adhesions. B, separation of middle layer; C, separation of internal layer.

The length of intestine thus thrown off varies from a few inches to several feet. It usually includes the whole length of the intussusception, but the recorded cases where several separate pieces are said to have been passed are more easily understood by supposing repeated progressive invaginations of the gut at the same point, with elimination of each in turn, than to imagine that several lines of demarcation would be formed in the intussusceptum. Such a case is recorded by [illegible] in which eight pieces of gut were rejected in three years, making a total length of twelve feet, with final recovery; the history being verified by an autopsy two years later showing slight stricture of the gut at the point where the ileum joined the colon.

A very few cases have been observed in which the gangrene attacked a limited part of one side of the intussusceptum, including both layers, and an opening was thus established between the lumen of the bowel above the apex and that below, without opening the general peritoneal cavity. Temporary recovery was the result. This termination would not be possible except in cases with a chronic course.

From what has preceded it is evident that intestinal obstruction, irreducibility of the intussusception, and strangulation of the latter, are not all equivalent terms, nor are they all present in every case of intussusception. We have already seen that in the majority of cases the lumen of the gut is not entirely obstructed, and this is also shown by the alternation of constipation and diarrhoea. In fact, the passage is sometimes large enough to admit the little finger. But fæcal obstruction may occur when the lumen of the bowel is not entirely closed, and it may even result simply from paralysis of the muscular coats of the bowel without any mechanical obstruction. In one curious case reported, laparotomy was performed after symptoms of intestinal obstruction had existed for some months, and the only cause found was a reduction of the calibre of the bowel, for a space of some inches, to the diameter of the little finger, by an "inflammatory stricture." The functional obstruction so often observed in peritonitis is an example of what may result from simple paralysis of the intestinal muscle. On the other hand, a very small opening in the lumen of the bowel will sometimes transmit the intestinal contents so readily as to give no symptoms for a long time, until some hard body becomes engaged in the opening and causes total obstruction and death, with the most acute symptoms. Thus Stimson has reported a case of acute intestinal obstruction resulting fatally, in which autopsy revealed an annular cancer of the large intestine which had never been suspected, although the opening through it was so small that an apple-seed had blocked it and caused death. Probably the length of the strictured part bears some relation to the amount of obstruction, a long comparatively slight stricture being the equivalent of a narrow stricture involving only a short length of the bowel. The amount of intestinal obstruction caused by an intussusception will depend, then, upon the calibre of the canal through the affected loop of bowel and the length of implicated intestine; upon the power of the intestinal muscle to overcome the increased resistance to the passage of the fæces; and upon the freedom of the latter from hard objects of a size sufficient to block the passage. The experiments of Nothnagel have demonstrated that complete intestinal obstruction by intussusception, or by any other cause, does not in itself produce antiperistalsis as it was supposed to do, by reflex nervous action; consequently we cannot look to this for an explanation of the obstructive symptoms in these cases. In the early stages of an intussusception there is no serious obstruction, but it may develop later in consequence of the changes in the parts caused by strangulation or by surrounding inflammation. Thus Senn found in two experimental intussusceptions, made in the intestine of cats, that bending and fixation of the gut by surrounding peritonitis had caused the complete obstruction which resulted in the death of the animals.

The irreducibility of an intussusception also depends upon several factors, but all of these factors depend in turn upon the degree of obstruction to the circulation of the blood. The commonest cause for the irreducibility of an intussusception is its increase in bulk by œdema in acute cases, and by œdema and hypertrophy in chronic cases. The formation of adhesions is also, probably, in most cases due to the stagnation of the blood. It would be supposed that adhesions must form at once if there were any gangrene of the bowel, but we have already quoted a case which proves that they may be absent even when the strangulation is so intense as to cause gangrene —in fact, the very intensity of the process explains why adhesions are not formed in some cases, death of the tissues taking place before the lymph necessary for the formation of adhesions can be thrown out. Thus, if the strangulation simply causes congestion, or if it gives rise to inflammatory processes by partial gangrene, adhesions are formed. But if it result in the immediate death of the tissues in the intussusceptum, there may be no adhesions. We must also recollect that the impeded circulation in the intestinal wall, due to the strangulation, will allow micro-organisms to penetrate to the peritoneal coat, and either adhesive or purulent peritonitis may be caused without any actual gangrene or perforation.

We cannot divide the course of an intussusception into reducibility, irreducibility, and strangulation; for all intussusceptions which are strangulated are not irreducible, and some may even be reduced with a certain degree of ease. In many chronic intussusceptions the adhesions have grown so strong as to render reduction impossible, and yet their long course and the slight alterations found in the walls of the implicated bowel show that they are not strangulated, in the clinical sense of the term, although there is an obstruction to the circulation of the blood. In such cases an acute strangulation may suddenly cause the death of the patient, after he has borne his intussusception for some time without severe symptoms.

Strangulation may or may not be present in any case; it may be present later on when not found at first, and it may occur in every grade of intensity. It is most frequent in the acute cases, and is generally due simply to the mechanical pressure of the mesentery, where it passes through the neck of the intussusception. At a later stage it may be caused by the pressure of the intestinal contents above the intussusception, when their passage has been obstructed in some way in the progress of a chronic or subacute case. Once having been set up by any cause, the strangulation continues, unless the swelling of the tissues at the neck of the intussusception is relieved by hemorrhage from the intussusceptum, when spontaneous reduction becomes possible. We have already seen that the various grades of changes in the tissues correspond to the varying intensity of the strangulation. To appreciate these differences, it is only necessary to recall the resemblance between hernia and intussusception, which has been insisted upon by so many writers upon the subject. In hernia we have the reducible, irreducible, and strangulated forms—that is, forms without any change and easily replaced, forms with changes which render them irreducible, but which are not incompatible with the life of the parts; and finally, forms in which death of the parts must surely follow. We might even carry the comparison further, and associate the spontaneous cure of strangulated hernia by the formation of an external fæcal fistula, with the spontaneous cure of intussusception by sloughing. But it must be borne in mind that the similarity is not exact in all respects, and mainly because of the difference in the use of the word reducible. Applied to hernia, this means only reducibility by the taxis; but applied to intussusceptions, it includes those reducible spontaneously, by such means as enemata, and also by direct manipulation and traction upon the gut with the fingers after the abdomen has been opened. In the latter sense of the term it will be acknowledged that many strangulated herniæ would prove reducible, even without enlarging the neck of the sac.

Symptoms and Course.—In order to understand the proper value of the various symptoms in intussusception we must first divide it into its different clinical forms, as indicated by the course of the disease. There are four different types—the peracute, acute, subacute, and chronic. While in the main it is easy to separate all cases into these four classes, some artificial distinctions must be made, and the principal of these is the limitation of the chronic cases to all those which run for a month or more.

1. The peracute cases are those in which death occurs very early, often in a few hours, and in which death is probably due to the shock caused by the strangulation of the gut. These cases are very rare, for in Leichtenstern's two hundred and sixty-nine fatal cases, in which the time of death was given, there are only five which perished in the first twenty-four hours.

2. The acute cases represent the great majority, nearly one-half of all the fatal cases, and yet in intussusception their proportion is less than in many other forms of intestinal obstruction.

3. The subacute cases are those in which the duration of the disease is more than a week, but less than a month; and this is the most artificial of all the classes. Nevertheless it includes a large number of cases, and a larger number than the thirty-one per cent. assigned to it in the following table; for that proportion is calculated only upon the fatal cases, whereas nearly all the cases of intussusception which recover are of the subacute variety. From a clinical stand-point the cases included in this class are of two sorts—first, those acute cases in which, in spite of the very violent symptoms, the powers of resistance of the patient are so great as to postpone the end beyond the usual term of seven days; and secondly, the cases which are much milder in their symptoms, and present a true subacute course.

4. Finally, there are the chronic cases, which last longer than a month. Here, also, there are two varieties of cases—the true chronic cases with very mild symptoms from the first, or, at least, after the first two or three days; and subacute cases, which are prolonged into the second month simply by the endurance of the patient.

From one of Leichtenstern's tables we deduce the following figures, showing the relative frequency of the different forms in the fatal cases:

Relative Frequency of the Clinical Varieties.

Variety.	Time of death.	Total cases.	Percentage.
Peracute	First day.	5	1.8
Acute	2 to 7 days.	129	47.9
Subacute	7 to 30 days.	84	31.2
Chronic	Over 30 days.	51	18.9

The course which the disease will run cannot be predicted from the mode of its onset, for the latter may be very violent, and yet, after a few hours or days, the first symptoms may subside, and the disease may assume a chronic type, lasting for months or even years. Conversely, a case may begin as a chronic intussusception, and yet the symptoms of acute internal strangulation may set in suddenly at any time, and terminate the life of the patient in a few hours. Chronic cases frequently have more or less acute exacerbations.

The order of the appearance of the symptoms may also vary. Thus, while pain is usually the first sign of the disease, in other cases an alternation of diarrhœa and constipation, tenesmus of the rectum and anus, or even the discovery of a tumor in the abdomen, may give the first indication.

As a rule, however, the attack begins with a sudden and very violent pain in the abdomen, usually without any previous injury or illness, even in the midst of sleep, lasting for some time, and then diminishing or even passing away altogether. After a varying interval it returns, sometimes with increased vigor. There may be vomiting, but this is often absent. Some of the signs of internal strangulation, such as shock, and diminution of the urine, are frequently present. In the intervals, and also during the paroxysms, some tenderness of the abdomen will be noticed, and this will increase as the case progresses. After a time a sausage-shaped tumor will be found in the abdomen. There will be frequent small passages of blood and mucus. The attacks of pain come more and more frequently, vomiting may set in with complete intestinal obstruction. The patient finally dies of exhaustion, or of peritonitis caused by perforation of the gut. Let us now study each symptom in detail.

Shock, Collapse.—In the peracute cases the onset of the disease may be so violent that very great shock is caused by the strangulation of the parts. But we have seen that these cases are very rare, and in Leichtenstern's five cases four occurred in children under one year of age. As a rule, there is little shock in the ordinary cases, and the general condition of the patient remains good until his sufferings and want of food produce exhaustion, which generally sets in from the third to the seventh day; but in subacute cases it may be delayed until the third week, and in chronic cases even for months. When shock is present it gives the usual picture of pallor, relaxation, cold sweating, superficial respiration, feeble pulse, subnormal temperature, and diminished urine.

Temperature.—In acute strangulation from bands, a subnormal temperature is the rule. But even in uncomplicated cases of intussusception the temperature is usually slightly above normal, 99° to 100° F., although it may sink below if the shock is pronounced. Fever is more marked in the later stages of the disease, when peritonitis has begun or some other complication is developing. But as septic peritonitis not infrequently runs its course without fever, there may be no decided elevation of temperature throughout the disease, even in these cases, except perhaps just before death. A rise of temperature, however, does not necessarily imply the presence of peritonitis, especially as so many cases of intussusception occur in children, in whom the liability to fever from slight causes is so well known. Thus, [illegible] has reported a case in a girl, eleven years of age, in which the temperature was over 101° F. on the seventh and eighth days. Forced enemata reduced the intussusception, and on the next day the temperature dropped to normal.

Urine.—If shock is present the urine may be diminished in quantity; but, as a rule, there will be no perceptible change. The theory that the diminution of urine is much greater when the lesion is situated very high up in the intestinal tract is not supported by facts. It has, on the contrary, been proven that diminution of the urine is as likely to occur in intussusception at a distance from the stomach as when it is close to the pylorus, allowance being made for the relative severity of the symptoms in each case; for the amount of the urine depends more upon the severity of the symptoms than upon any other one factor. In chronic cases of some days' duration it may well be that (as Barlow and Leichtenstern claim) the considerable loss of fluids by diarrhœa, and the difficult introduction of fluids on account of vomiting, may reduce the quantity of the urine, just as in stenosis of the pylorus. But it is difficult to believe that this effect would make itself noticeable in the acute form of the disease, and whenever the urine is diminished in such cases it must be referred to the shock, which might diminish the urine either by the reduction of the blood pressure, or by the reflex nervous action of the strangulation, as is so frequently seen in hernia and abdominal injury. Leichtenstern expressly says that shock was present in all his cases in which the urine was lessened in quantity.

Physical Examination. Attitude.—During the paroxysms of pain the patient will be seen to twist himself into various positions, but generally with trunk and limbs flexed to relax the abdominal muscles. Sometimes he will discover that the pain is lessened by lying always upon one side; sometimes pressure upon the abdomen will relieve the pain. In a few cases the position of opisthotonos has been assumed, and this has not only been observed in young children, in whom it might be taken to be the result of convulsive nervous action, but in the case of adults, who assumed it voluntarily because the pain seemed to be less in that position. Between the paroxysms the attitude may be natural and entirely unconstrained, but, even before any abdominal tenderness has developed, a more or less flexed position is often maintained; and in chronic cases the patient often walks about bent forward in a very characteristic attitude. But all these positions of the body only indicate the fact that an abdominal lesion of some kind is present. So, also, the anxious, haggard look of the face is simply indicative of pain and exhaustion, and the later emaciation merely shows the lack of rest and nutrition.

Appearance of the Abdomen.—The abdomen is generally flat, but it is sometimes slightly distended. Occasionally the muscles are rigid and retracted, but as a rule they are soft. The percussion sounds are usually normal, although there is sometimes a slight dulness over the tumor, especially if it be of large size. Dance described a depression in the right iliac region, when compared with that of the other side, as pathognomonic of intussusception with displacement of the cæcum. But this appearance is rarely seen, and chiefly when the intussusception has reached the left side, so that the fulness of that region makes more evident the depression upon the right. Leichtenstern remarks, however, upon the value of the artificial production of the "sign of Dance" by the injection of large quantities of water or air, which distend the colon upon the left side of the abdomen below the intussusception, while the other side remains flat. When peritonitis begins all the conditions are altered, and tympanites develops; but owing to the rarity of complete obstruction of the bowel in intussusception, the distention is seldom so extreme as in other forms of intestinal obstruction. The patient is generally so exhausted by the time that peritonitis sets in, that death terminates the scene before tympanites can fully develop. If perforation of the bowel should occur very suddenly, before adhesions had time to form, tympanites might appear at once, with loss of liver dulness. On the other hand, in some cases of septic peritonitis, tympanites and abdominal tenderness are absent throughout, and the disease runs a concealed course, presenting only the symptoms of sepsis.

Tumor.—But the most important of all the points to be ascertained by physical examination is the presence of a tumor in the abdomen, and its peculiar characteristics. If the typical form of tumor can be found, it is sufficiently pathognomonic to base a diagnosis upon, even without the aid of other symptoms. Leichtenstern in four hundred and thirty-three cases of all kinds, and Rafinesque in fifty-three cases of chronic intussusception, found that a tumor was present in about fifty per cent. of the cases. It is probable that, as Rafinesque observes, a more careful examination of the patients would have resulted in the discovery of the tumor in many more, especially with the aid of an anæsthetic. The frequency of a recognizable tumor varies a little with the different kinds of intussusception, and its position is also somewhat dependent upon the seat of the lesion. According to Leichtenstern, the figures as to frequency are as follows:

In [illegible] cases of [illegible] intussusception a tumor was found in [illegible] per ct.
" [illegible] " " [illegible] " " [illegible] "
" [illegible] " " [illegible] " " [illegible] "
" [illegible] " " [illegible] " " [illegible] "

This table shows that the tumor is more often found when the intussusception involves the large intestine, as is natural, because of its larger size in this situation, and because it can be reached by a rectal examination. On the other hand, the tumors of intussusception of the small intestine are small, and often lie in regions which are not accessible to exploration.

---

* According to [illegible] and R[illegible] [illegible].

Contrary to the statement of Rilliet, the tumor is more often recognized in children than in adults, because tympanites is of less frequent occurrence in children, and because of the great frequency of intussusceptions involving the large intestine in them. According to Leichtenstern, the tumor was found in sixty-three per cent. of the cases occurring during the first year of life, against fifty per cent. in adults.

In Leichtenstern's cases the tumor was found upon the right side of the abdomen 34 times, upon the left side and in the rectum 144 times, and in the region of the transverse colon only 19 times. In the children it was almost without exception found upon the left side. The reason for this frequent location of the tumor upon the left side is to be sought in the tendency of a tumor to move onward, so that an ileo-cæcal intussusception, for example, could only be found upon the right side during the first few hours or days. Moreover, when an ileo-cæcal tumor first forms it is small, and often too soft to be recognized, and while passing through the transverse colon in the second part of its course it would be concealed behind the ribs; consequently it would be most easily felt when it had reached the descending colon in the left side, and by that time its consistency would also have increased. It is true that Leichtenstern expressly states that in his cases the tumor was generally discovered very soon after the first onset of the symptoms, but this is not inconsistent with the explanation just given, for the growth of the tumor is often very rapid. Instances of very slow growth are also referred to by Leichtenstern. In eight cases a tumor of the transverse colon was observed to pass on into the sigmoid flexure, and twice the cæcum was followed as it passed through the transverse colon to the same position.

The tumors formed by intussusception of the small intestine were found in Leichtenstern's cases nine times in the region of the cæcum, seven times in the epigastric and hypochondriac regions, three times each in the left iliac and hypogastric regions. These figures show that no conclusions can be drawn from the seat of the tumor to aid in the diagnosis of the location of the intussusception.

In the 222 cases of Leichtenstern's collection in which a tumor was noted, it could be felt by rectal examination in 31, and it prolapsed from the anus in 41—giving a total of 72 cases. Of course none of these intussusceptions were in the small intestine, but 30 were ileo-cæcal, and 2 were ileo-colic. The tumor makes its appearance in the rectum in children much more quickly than in adults, having been observed in children as early as the second day; but exceptionally it has also been found in adults at an early period. The tumor has generally been discovered in the rectum about the seventh day, except in the chronic cases, in which its average appearance in that situation takes place on the fifteenth day. But in some chronic cases it may not reach the rectum until the sixth or seventh month. Some cases have been recorded in which the tumor prolapsed through the anus at the very beginning of the symptoms of intussusception, but in these the lesion involved only the lowest part of the colon.

The tumor, when felt through the abdominal walls, is sausage-shaped, and is generally curved. Its consistency varies with the amount of constriction and œdema, and also with the degree of contraction of the muscle in the involved bowel. Owing to the latter fact the consistency may vary at different times, even becoming so soft that the tumor is no longer recognizable to the touch. The tumor has, indeed, been observed to grow hard, or undergo a sort of erection under the examining hand. The hardening of the tumor is accompanied with pain, from the spasmodic contraction of the muscular coats, and therefore the search for it should not be concluded until an examination has been made during the paroxysm, for the soft tumor between the paroxysms may be overlooked. The tumor itself is not usually tender to pressure, unless the disease has lasted for some time. The position of the mass is generally more or less fixed, but it is sometimes movable under the hand, and it may sometimes be made to change its place by enemata. As it drags upon the mesentery in its formation, it is more fixed as regards motion downward than in other directions, as is the case with neoplasms of the mesentery itself. The tumor has been observed to move spontaneously under the influence of peristalsis, and, as we have seen, it can sometimes be followed during the progress of the case in its advance toward the anus.

The length of the tumor is seldom great, and very rarely over six inches, even with the largest invaginations, for they are shortened by the wrinkling of their coats, and they are often concealed under the ribs in part of their length. Sometimes two tumors can be felt, and one of these will generally prove to be gas or intestinal contents held back by the obstruction in the lumen of the bowel. In other cases the two will prove to be only the two ends of one tumor, the intervening part lying behind the ribs. But a few cases of multiple intussusceptions have been reported in which two or three distinct tumors were felt during life.

Pain.—One of the principal symptoms of intussusception, and a very constant one, is pain. It is generally the first symptom, and is very characteristic. The solitary case referred to by Leichtenstern in which no pain was present is incorrectly quoted, for it was a case of obstruction due to a band, and not to intussusception, and pain was present at the beginning. As a rule, in cases of intussusception the pain comes without warning, even in the midst of sleep. But sometimes it may be preceded by diarrhœa, slight attacks of colic, or uneasy feelings in the abdomen. Or it may follow more or less immediately upon some overexertion or abdominal injury. The character of the pain is paroxysmal, similar to that of ordinary colic, and is generally described as twisting, pinching, tearing, or burning. In some cases it may be relieved by pressure upon the abdomen, and especially over the seat of the tumor. The intensity of the pain is very great when at its worst, and it is often described as agonizing, but according to Treves it is generally less severe than the pain of other forms of acute intestinal obstruction. In children the pain is often so intense as to bring on convulsions.

The paroxysm may reach its greatest intensity at once, but usually it is not quite so violent at the beginning, gradually increases in severity, and then as gradually diminishes. In some cases, however, the pain terminates as suddenly as it began. The first paroxysm may be the worst of all; but, as a rule, the severity of the pain increases with each succeeding attack, and the intervals between the paroxysms grow shorter and shorter as the case progresses, up to a certain point, when a distinct abatement of the sufferings of the patient takes place. This remission is supposed to coincide with the final fixation of the loop of gut by adhesions, or by constriction; but, whatever its cause, it is a characteristic feature of intussusception. There are usually several attacks of pain in the twenty-four hours, and sometimes they are more frequent in the night than in the daytime.

The intervals are of varying length, but sometimes a marked periodicity may be observed in the occurrence of the paroxysms, which come at regular intervals and last for a certain length of time. The pain is said by some to be most intense, and the intervals shortest, when the intussusception is situated in the small intestine; but others claim that the ileo-colic form is the worst in this respect. In chronic cases the pain is generally less severe and the intervals are longer, but the pain is paroxysmal and similar in character to that in the acute cases. During the intervals the patient may be entirely free from pain, and this is especially common in children; but generally there is some pain between the paroxysms, and in some cases even from the very onset of the disease the pain is continuous, with periodic exacerbations. A feeling of soreness or tenderness in the abdomen may be present in the intervals, and later in the case may cause as much discomfort as the paroxysm of pain itself, even before there is any extensive peritonitis.

The pain is sometimes accurately referred to the seat of the intussusception-tumor, radiating to other parts, but in the beginning of the case it is often more or less diffuse. Associated with the colicking pain retraction of the testicles has been observed in some cases. The tenderness in the intervals is more apt to be localized, but frequently it is also diffuse, and seems to be situated in the abdominal muscles, especially when the disease has lasted for some time. Pressure increases the pain if it is actively present, contrary to the general theory that the pain is less when the bowel is empty, and they may bring on an attack during the intervals. When the intussusception has sloughed the pains cease, and they are generally at their worst just before sloughing takes place. It is possible even for the colicky pains to disappear, being replaced or masked by the general pain of the new complication.

State of the Bowels.—Next to the presence of a tumor, and the paroxysmal pain, the most characteristic symptoms of intussusception are those furnished by the state of the bowels. In the acute cases, as a rule, diarrhœa is present at first and constipation later, but in some cases these two conditions alternate at short intervals, and this alternation is very common in the chronic cases of intussusception. In Rafinesque's collection of chronic cases the stools were normal throughout, or easily moved by laxatives, in 7 cases; constipation prevailed in 12; diarrhœa in 16; and the two latter conditions alternated in 11 cases. In 6 cases of chronic intussusception of the small intestine, he found that diarrhœa was not present once. In children the proportion of cases of diarrhœa is said to be greater than in adults. According to Treves, constipation, that is, an absence of fæcal matter from the stools, is a marked symptom in only thirty per cent. of the cases of all ages. But Henoch [illegible] states that absolute constipation is the rule in children, no fæcal matter being contained in the frequent evacuations of mucus and blood. This difference of opinion makes it worth while to quote Leichtenstern's figures upon this point in full.

In 108 cases in the first year of life, Leichtenstern found that 104 had stools of blood and mucus, 25 had blood alone, 3 had constipation with occasional passages of blood, and in one case only was there diarrhœa without blood in the stools. On the other hand, in 185 cases over one year old, 101 had stools of blood and mucus, 39 were constipated from the beginning and 21 of the first set became constipated later, with occasional bloody passages, while diarrhœa without blood in the stools was present in 15, and alternating diarrhœa and constipation in 10.

The characteristic passages of acute intussusception are small, and contain mucus and blood, and they may be very frequent, closely resembling an attack of dysentery. These passages are found even when no fæcal matter comes away. The quantity of blood in the stools is very variable, from a mere streaking of the fæces to large clots, and the amount may even be so great as to cause death. Sometimes the small, frequent stools consist of pure blood without mucus. Bleeding is generally more marked in the beginning of the disease, but it also accompanies the casting off of the slough, and alarming quantities of blood may be lost at this time. According to Treves, blood is present in the stools in four-fifths of the acute cases, and according to Rafinesque it is found in only half of those which run a chronic course. It is more common in children than in adults, and in intussusception of the large than of the small intestine, but the latter fact may be a sequence of the former, owing to the rarity of enteric intussusception in children and to the greater frequency of intussusception of the large intestine on the whole. Sloughing is generally preceded by complete constipation, and followed by the sudden appearance of bloody stools and very offensive loose passages.

In many cases, chiefly those intussusceptions which have passed low down in the colon, and very rarely when the lesion is situated in the small intestine, there is tenesmus of the anal sphincter, or relaxation and even paralysis of that muscle. Leichtenstern looks upon the relaxation as secondary to the tenesmus. He found tenesmus in 104 cases out of his 593 (eighteen per cent.), and of these the intussusception was seventy-five times ileo-cæcal, fifteen times colic, and only four times was it in the small intestine. Rafinesque found tenesmus present in thirteen per cent. of his collected chronic cases. Treves reports that this symptom is present in fifty-five per cent. of all cases, and considers Leichtenstern's percentage altogether too low. The tenesmus is an early symptom, and it may be moderate, or so severe as to give the patient no rest and to cause prolapse of the mucous membrane of the rectum. It is most commonly met with among children, and this fact may be due to the frequency of intussusception of the large intestine at that age.

Dilatation of the anus is considered a pathognomonic sign of intussusception by Salzer,[illegible] and he says that it is present even when the tumor is high up in the bowel. In extreme cases several fingers may be passed into the anus with ease.

Vomiting.—Vomiting is most frequent in children, occurring among them in nearly all cases, and at an early period in the disease, but it is also common in adults. From Leichtenstern we extract the following figures:

Relation of Vomiting to the Age of the Patient.

	Under 1 year.	Over 1 year.
Vomiting present in	[illegible] cases.	[illegible] cases.
Vomiting only present in	7	3
Not noted, or absent in	4	[illegible]

Fæcal vomiting occurred in 53 cases over one year old and four times in those under one year; and hæmatemesis occurred twice in the first class and four times in the second. Vomiting is less frequent, less persistent, and less violent in intussusception than in other forms of intestinal obstruction. According to Treves it appears early in about three-fourths of the acute cases, and when it occurs in the rest it appears on the average about the third day, but in about eight per cent. of all the cases it is entirely absent. In chronic cases vomiting is rather less frequent. Thus in Rafinesque's collection of cases, out of 47 cases in which the symptom is mentioned it was altogether absent in 8; and in 7 others it was present only in the last stages.

The vomiting comes and goes without apparent cause. The vomited matter usually consists of the contents of the stomach or bile, and, according to Treves, it becomes fæcal in only about one-quarter of the acute and chronic cases, rather more frequently than was found by Leichtenstern. Very early and severe vomiting is most common in children, or in adults when the obstruction is in the small intestine. The frequency and severity of the vomiting seem to be dependent upon the degree of obstruction to the lumen of the bowel which may be present, and consequently the vomiting is apt to be severe when constipation prevails. Fæcal vomiting generally begins about the fourth or fifth day, and is most common in adults, and with intussusception of the small intestine. Vomiting of blood is noted in some rare instances, but these have generally been in chronic cases among children.

Among the curiosities of the subject, it may be well to note that in certain cases the appetite remains good, and isolated instances have even shown an increase of appetite—a voracious appetite, as the reporters of the cases describe it.

Course.—We have already explained the distinctions which are made between the various forms of intussusception according to their duration. We have seen that the peracute form runs its course with the symptoms of internal strangulation only, the forces of the patient being overwhelmed by the nervous shock of that condition, before any characteristic symptoms can be presented. The acute form of the disease begins more or less suddenly, and increases very rapidly to its extreme severity, and unless death then ensues simply from the exhaustion of the patient by pain, loss of rest and of food, some complications develop, and the subsequent course of the disease depends upon them. In a few rare cases the symptoms have disappeared as suddenly as they began, and the case has terminated in recovery—probably by spontaneous reduction of the intussusception. It makes but little difference whether the onset be very sudden or the symptoms begin mildly but quickly reach their height, for death is the inevitable result, unless they soon relax. When the strength of the patient is great, exhaustion may be delayed beyond the usual limit of time, and these cases may then be included in the subacute class, although they resemble in every other respect the acute form.

In the subacute cases there is more variety of evolution. In the beginning we may have very acute symptoms, or the symptoms may develop very gradually; while subsequently they may remain severe until the termination of the attack, they may diminish in severity very early and then remain moderate in character, or they may remain moderate throughout. If the violence of the symptoms is not too great, or too prolonged, the patient may retain strength enough to enter into the second term of the disease, and nature endeavors to save him by separating the intussusceptum by sloughing. As has already been described in the section on pathology, the sloughing usually results in the separation of the intussusceptum in one piece, although it may melt away by a slowly advancing gangrene beginning at the apex. When sloughing occurs the severity of the pain and nervous prostration diminish, but complete obstruction may be set up and no fæcal matter be passed, although the small passages of blood and mucus continue. Vomiting may be severe while this obstruction lasts. Then the slough gives way, sometimes so suddenly, and with such relief to the obstruction, that it is observed by the patient. Large amounts of blood may be lost at this time, and the stools are very fetid.

The removal of the intussusceptum restores the continuity of the bowel, and if no complication develops the patient soon recovers. It is evident that this method of cure requires time, usually from ten to fourteen days, and, if the strength of the patient is not sufficient to sustain him for that length of time, exhaustion will set in and cause death, just as it does when the patient has not sufficient resistance even to reach the stage of separation. As can be easily conceived, the dangers of this process of sloughing are very serious—from peritonitis, hæmorrhage, and sepsis; and cases are even on record in which the mass of slough was so great as to cause death by completely obstructing the calibre of the bowel at some point below.

Finally, the disease may run a chronic course, and here, too, we find a variety of modes of onset—sometimes acute, usually subacute, and occasionally, but rarely, a very gradual and insidious attack. It is evident that when the onset is very acute the symptoms must soon moderate, or the life of the patient would be promptly terminated. But they not infrequently retain a subacute character, and death results before many weeks have elapsed, seeming to be postponed simply by the great endurance of the patient, the cases closely resembling the subacute form both in symptoms and complications, and being separated from them by the rather arbitrary limit of time. In the ordinary chronic variety, however, after the symptoms have lasted in subacute form for a time they may almost disappear, leaving the patient quite comfortable, until an exacerbation sets in and the former history is repeated. The exacerbations become more and more frequent and the intervals grow less and less free from symptoms, and death finally comes from complete exhaustion, or by some complication, unless one of the exacerbations is sufficiently violent to terminate the life of the enfeebled patient in the same way as in a case of acute intussusception. Very rarely, if at all, does recovery ensue after the disease has passed into the chronic stage. In the chronic cases the symptoms during the intervals (pain, constipation, diarrhœa, and vomiting) are due to the mechanical obstruction to the lumen of the bowel, and resemble those of stricture of the intestine, bringing about a constant loss of strength by their interference with nutrition.

Complications.—The most frequent complication of intussusception is peritonitis, and it is usually caused by perforation of the bowel at the affected part, especially at the neck of the intussusception, although some cases are on record in which perforation occurred some little distance above, when the tumor had caused complete obstruction, with great distention of that part of the bowel. The peritonitis generally begins without warning, like ordinary perforative peritonitis, with a sudden and violent pain, often distinctly localized at first, but spreading quickly over the whole abdomen. The onset frequently takes place in one of the paroxysmal attacks of pain due to the intussusception itself. Severe shock accompanies the pain, followed by a rapid rise of temperature, vomiting, tympanites, and general abdominal tenderness. The usual picture of perforative peritonitis is thus presented, and the same fatal termination concludes the scene. Occasionally the peritonitis remains localized, all the symptoms being then of a milder type, but in time general peritonitis or septicæmia brings about a fatal result, except in those rare cases in which the intraperitoneal abscess bursts externally or into some of the viscera, and recovery is rendered possible by the establishment of a fæcal fistula. When general peritonitis develops the typical paroxysmal pains of intussusception disappear, probably because they are due to peristalsis, and the intestinal movements are paralyzed, or because they are masked by the pain of the peritoneal inflammation. But another form of peritonitis which it is important to recognize sometimes follows intussusception, although its onset is so insidious as to make the diagnosis difficult. This is the so-called peritoneal septicæmia, in which the inflammatory reaction of the peritoneal membrane is very slight, but the septic materials thrown out by the gangrenous gut are speedily absorbed, and give rise to a general septicæmia. In these cases there may be no tympanites, no pain, and no well-marked rise of temperature; in fact, the temperature more frequently falls slightly below normal. The patient complains less, for the sensibilities are diminished by the septic poison, but the vital forces have begun to fail, and in a few hours collapse sets in, and death comes with that surprising rapidity so often seen in cases of abdominal disease.

Septicæmia has been the cause of death in a few cases without the occurrence of any peritonitis, according to the post-mortem examination, but these cases may have been instances of the form just described. Abscess of the liver and general pyæmia are also possible results of intussusception, by means of a portal phlebitis. Besides the intraperitoneal abscesses mentioned above, abscesses might form from perforation of the colon into the cellular tissue, where no peritoneal membrane intervenes, resulting in a fæcal fistula, but there appears to be no such case on record. In fact, Treves states that he could find but one case of fæcal fistula of any kind following intussusception—which was that of a man who passed fæces in his urine for three or four months before his death.

We have already mentioned death by hæmorrhage among the dangers of sloughing. The tumor of the invaginated bowel may compress the bladder or ureters and cause anuria, hæmaturia, or even hydro-nephrosis. Or it may occlude the intestine by pressure, as has been observed in the sigmoid flexure and in the duodenum. Or it may cause œdema or even gangrene of the legs by pressure upon the great vessels. It is also possible that in some of the cases in which compression has been noted the effect was produced by the cicatricial contraction of masses of inflammatory tissue left after the intussusceptum had sloughed. In a few cases chronic diarrhœa has been observed, caused by obstinate ulceration at the point of sloughing, and it is said that stricture may be a sequel of this condition. The other complications of intussusception are simply those which are liable to occur in any acute disease, or in any chronic disease resulting in cachexia and malnutrition. The occurrence of pneumonia from the entrance of vomited material into the bronchi, and of intestinal obstruction due to bending of the bowel by adhesions after the slough has separated, need only be mentioned.

DIAGNOSIS.—In the diagnosis of intussusception it is necessary to consider the acute and chronic varieties apart.

Acute intussusception resembles more or less closely the other forms of acute obstruction of the bowels, but symptoms are generally present which render the diagnosis of intussusception the easiest among all the varieties of intestinal obstruction, except in the very acute form, which runs its course in a day or two, presenting scarcely any other symptoms than those of internal strangulation.

The different kinds of acute intestinal obstruction may be grouped for convenience of diagnosis under the following heads: (1) Internal incarceration, or stricture by bands, or through apertures; (2) volvulus; (3) gall-stones, or foreign bodies; and (4) intussusception.

Internal incarceration is marked by more violent symptoms of strangulation, and absolute constipation is the rule instead of the small and frequent stools of blood and mucus in intussusception; vomiting occurs early, and is more severe and constant than in intussusception; and pain is more continuous, although it has exacerbations which resemble the paroxysms of intussusception. Volvulus, although less acute in its first symptoms than is internal incarceration, is more acute than intussusception; the pain is more continuous, absolute constipation is the rule, and there is an absence of the characteristic stools of intussusception. There is usually no tumor in volvulus, but when there is one it is large, and has not the peculiar sausage shape of the intussusception tumor.

Occlusion of the bowel by gall-stones or foreign bodies is as a rule less acute in its course than intussusception; the constipation is absolute; the vomiting appears early, and is severe; and the pain is less intense, and more continuous than in intussusception. In the case of obstruction by a gall-stone there will be the history of previous attacks of biliary colic without obstruction, of hepatic disorder, and of peritonitis in the neighborhood of the gall-bladder, for stones large enough to cause intestinal obstruction are compelled to gain access to the bowel by ulceration, or by the formation and perforation of an abscess. In the case of foreign bodies there will also be the history to guide one. There may be a tumor in these cases, if the gall-stone or foreign body can be felt through the abdominal wall, but it will not have the shape and other characteristics of the tumor of intussusception. All of these varieties of obstruction are very rare in children, and all but internal incarceration are less common than intussusception, even in the adult.

Recapitulating the symptoms of intussusception by way of contrast, we find it occurring most frequently in children, beginning without warning, with intense abdominal pain coming in paroxysms which increase in severity for a certain time, and then grow milder. There is some shock, which may be severe, but is generally less so than in internal incarceration and volvulus. Vomiting is not very marked. There are frequent passages of small quantities of blood and mucus, and fecal matter may be absent in the stools during the entire course of the disease. The anal sphincter is often in tenesmus or dilated. A slight rise of temperature is common, especially in children. A sausage-shaped tumor is generally to be felt in the abdomen, advancing toward the anus with the progress of the cases. Finally, there is discharge of a slough.

Perityphlitis and perforative peritonitis have not infrequently presented the symptoms of acute intestinal obstruction, and laparotomy has even been performed under the erroneous diagnosis. In some cases the symptoms have been similar to those of intussusception, and it seems probable that some of the supposed spontaneous resolutions of intussusception, which occurred, were really instances of perityphlitis or typhlitis ending in resolution. The distinction of these diseases from intussusception should, however, be far easier than from some of the other forms of obstruction. Perityphlitis would generally present a less acute beginning, the pain would not be paroxysmal, constipation would be the rule instead of the mucous and bloody passages of intussusception; tenesmus would be rare, and there would be a totally different sort of a tumor—large, rounded, tender on pressure, and immovably fixed in the right iliac fossa, where the tumor of intussusception is seldom found. Perforative peritonitis would generally be more acute in its onset than intussusception, the shock would be more severe, the subsequent rise of temperature would be greater, and the pain more continuous; tympanites and abdominal tenderness would appear earlier, and there would be no tumor, and no dysenteric passages.

The symptoms of acute intussusception have a certain resemblance to those of dysentery and even cholera, although it would be unlikely to be taken for the latter except in the presence of an epidemic of the disease. Dysentery would be marked by greater tenesmus, unless the tumor of intussusception were actually in the rectum (and then it would be detected by examination); the pain would be referred to the rectum, and would be distinctly associated with the stools and tenesmus; fever would be more constant than in intussusception, and there would be an absence of shock. Cholera would be distinguished by the absence of abdominal pain, the presence of cramps in the limbs, the watery character of the diarrhœa, and the large size of the dejections. In both cases there would be no tumor to be felt in the abdomen or rectum. In both cases, too, the onset of the disease would be less acute, and would be initiated by a diarrhœa without pain, or at least with only the ordinary pains of colic.

Although the diagnosis of acute intussusception is comparatively easy, the recognition of the chronic form appears to be particularly difficult, if we are to judge from the fact that in Rafinesque's 66 cases the diagnosis was made only ten times, and even in the latter cases erroneous opinions as to the nature of the disease were held for some time by those in charge. The diseases with which chronic intussusception is most likely to be confused are the chronic forms of obstruction of the bowels (fecal impaction, stricture, and cancer), chronic dysentery, tubercular enteritis and peritonitis, lead colic, biliary colic, chronic diarrhœa, dyspepsia, and prolapse or polypus of the rectum.

Fecal impaction generally produces less severe constitutional depression than intussusception; it is found in elderly persons, and especially in women; it is of gradual development; and although alternating diarrhœa and constipation are sometimes seen, the diarrhœa is wanting in the blood and mucus which are found in intussusception. There is no pain and no vomiting. No small sausage-shaped tumor is discovered on examination, but the distended colon is often to be felt—full of hardened feces. Stricture of the small intestine produces symptoms which are very similar to those of chronic intussusception, especially if the lesion be situated high up in the bowel. But here, too, the beginning of the disease is gradual, the stools seldom contain blood or even mucus, there is seldom pain unless acute obstruction develops, and no tumor can be felt.

Cancer of the intestine, especially the annular form causing stricture in the large intestine, if low down, will closely resemble a chronic intussusception, with alternating diarrhœa and constipation, the presence of blood and pus, or muco-pus, in the stools, and attacks of abdominal pain. But no tumor can be felt in the early stages of the disease, and in the later stages the tumor is chiefly made up of adherent and thickened loops of intestine, and presents an irregular shape and an uneven surface of considerable extent. The pain is less paroxysmal, and might be better described as constant with exacerbations. If obstruction is caused, although it may be of the most acute kind, it is, as a rule, more like fecal impaction, while intussusception in its exacerbations generally reproduces more or less faithfully the symptoms of the acute variety. The mucous element is less prominent in the stools, and the blood is apt to come in larger quantities.

The distinction between an intussusception tumor in the rectum (whether it is formed in that section of the bowel or descends into it from above) and a polypus growing in that locality, as well as the diagnosis between an intussusception which has prolapsed and a simple prolapse of the rectum through the anus, must be made by careful examination of the parts. The slit-like opening in the apex of the intussusception, completing the resemblance of the latter to the portio vaginalis of the uterus with its os, and the attachment of the intussusception to the bowel in its entire circumference, will distinguish it from a polypus. The fact that the finger can be passed between the margin of the anus and the intussusception, while in simple prolapse of the rectum the outer surface of the prolapsed part is continuous with the mucous membrane or the skin at that point, is sufficient to assure a diagnosis in the latter case. But it must be borne in mind that, on the one hand, a polypoid tumor in the rectum may be the cause of an intussusception, and, on the other, an intussusception high up in the rectum might cause a prolapse of the rectal mucous membrane through the anus. Therefore, if there are symptoms of intussusception, and physical examination reveals a polypus or simple prolapse of the rectum, care must be taken to exclude the possibility of an intussusception in addition.

It is scarcely necessary to go over in detail the other diseases mentioned above as liable to be mistaken for chronic intussusception, for the simple recollection of the fact that there is danger of such errors should put the physician sufficiently upon his guard to recognize the true nature of the case. It is also unnecessary to mention that the elimination of a slough will be absolutely pathognomonic of the disease, for it can be easily distinguished from the shreds and casts passed in the rare membranous enteritis.

Diagnosis of the Site.—The determination of the locality of the intussusception is by no means so easy as was at one time supposed, but in certain typical cases it is possible to settle this point from the symptoms alone. We have seen that in children under one year the ileo-cæcal and colic intussusceptions form nearly four-fifths of the cases, and in persons over five years only one-half. The older the individual, therefore, the greater will be the chance of an intussusception in the small intestine, which is very rare indeed in young children.

Rectal tenesmus and relaxation of the sphincter ani are symptoms almost entirely confined to ileo-cæcal and colic intussusceptions, but they may also be found in the ileo-colic form when the tumor has advanced into the lower part of the colon. The stools afford us some clew, for complete obstruction is common in intussusception of the small intestine, and diarrhœa in that of the large. Blood is more frequent in the passages in those forms which involve the colon, and especially in the ileo-cæcal variety. As a rule, the onset of the disease is most sudden, and the shock is greatest, in the enteric and the ileo-colic forms. The pain, too, is more severe, and the paroxysms come at shorter intervals when the lesion involves the small intestine, or is of the ileo-colic variety.

Vomiting is more severe, appears earlier, and is more continuous in the enteric and ileo-colic intussusceptions. It is said by Treves never to be fæcal in the enteric cases, but in Cruveilhier's case of intussusception of the duodenum the vomiting is described as fæcal, and it is often impossible to draw a sharp line between vomiting which is fæcal and that which consists simply of altered bile. There can be no question, however, as to the general truth of the statement that true fæcal vomiting is not seen in obstruction of the bowels which is situated very high up. Another fact in regard to the vomiting is important in respect to the determination of the site of the intussusception, and that is the relief afforded to the symptoms by copious vomiting when the obstruction lies near enough to the stomach to allow the distended bowel to be efficiently emptied by the evacuation of the collected material in that direction.

The tumor will be small in intussusceptions of the enteric and ileo-colic varieties, and large in those involving the colon; and in the latter forms it will generally be found in the course of that part of the intestine, whereas it may occupy almost any position, and will be more freely movable, when the lesion is situated in the small intestine. As the tumor has been recognized in only twenty-four per cent. of the cases of intussusception of the small intestine, against sixty-one per cent. of the ileo-cæcal and fifty-two per cent. of the colic intussusceptions, the mere fact that a tumor has been discovered is in favor of the latter forms. The presence of the apex of the intussusception in the rectum is, of course, impossible in the enteric, and rare in the ileo-colic forms. No reliable conclusions can be drawn as to the situation of the intussusception from the time of appearance of the tympanites, or from its character, for reasons given elsewhere.

From these facts, in cases which begin suddenly and acutely, with great shock, severe pain, short intervals between the paroxysms, nearly complete obstruction of the bowel, early appearance and persistency of the vomiting, and especially if the vomiting affords distinct relief to the symptoms, we may assume that the obstruction is high up in the intestinal canal, and this assumption is rendered certain by the recognition of a small movable tumor in the abdomen.

On the other hand, when an ileo-cæcal or colic intussusception occurs, the beginning is apt to be less acute, the pain less severe, the intervals between the paroxysms longer and freer from pain, the obstruction of the bowels less complete, and vomiting not so common or persistent —at least in the early stages. Tenesmus of the rectum is present in these cases, and the tumor is large, often immovable, lies in the course of the colon, and may be felt in the rectum.

PROGNOSIS.—The general prognosis of intussusception is very bad. Leichtenstern gives the mortality as seventy per cent. Rafinesque found only nine recoveries in his series of 59 chronic cases; and in three of these the diagnosis was doubtful, spontaneous recovery having taken place, while in three others recovery was obtained by laparotomy. If the doubtful cases are excluded, his mortality might fairly be placed at ninety per cent.

The two factors which are most important in determining the prognosis in any case are the age of the patient and the situation of the intussusception. The following table, from Leichtenstern, shows that the mortality is greatest among the very young, and least between ten and fifty years of age. It also indicates that the difference is caused by the varying frequency of sloughing, for in the last column is given the percentage of mortality in those cases in which sloughing did not take place, and it will be seen that it remains nearly constant for all ages.

Mortality according to Age.

Age.	General mortality.	Mortality when sloughing did not occur.
	Per cent.	Per cent.
1 to 6 months	88	86
6 to 12 months	82	
1st to 10th year	72	80
11th to 20th year	63	86
21st to 40th year	63	82
41st to 50th year	63	80
50th to 60th year	71	
Over 60 years	77	..

In 408 cases in which sloughing did not occur, the mortality was eighty-five per cent.; in 149 cases in which it took place, forty-one per cent died.

If we omit the cases under eleven years, of which nearly all were ileo-cæcal intussusceptions, we obtain the following figures from Leichtenstern, showing the mortality for each variety of intussusception and the proportion of cases in which sloughing occurs in each, and again we find a distinct relation between the two.

Mortality according to the Location of the Intussusception.

Variety.	Mortality.	Sloughing occurs.
	Per cent.	Per cent.
Ileo-cæcal	72	20
Colic	70	28
Enteric	58	61

Sloughing is almost unknown in the ileo-colic intussusceptions. When sloughing occurs, the mortality is about the same for all varieties. Without sloughing the mortality would probably be greatest in the enteric intussusceptions, but the diagnosis in these cases is so uncertain, unless it is proven by the passage of a slough, or by a post-mortem examination, that there are no figures to be depended upon as regards this point.

Sloughing with elimination of the slough occurs in about forty-three per cent. of all cases. Excluding those under six years of age, it takes place in fifty-four per cent. of the female patients against only thirty-one per cent. of the males, according to Leichtenstern. The same authority gives the total mortality of sixty-eight per cent. in males, and seventy per cent. in females, which would indicate that although separation of the slough occurred more often in women than in men, a larger number of women died from the subsequent complications of the process.

The separation of the slough depends upon the age of the patient, and the mortality after it has occurred is also affected by the same factor, as Leichtenstern shows by the following figures:

Relation of Age to Separation of the Slough.

Age.	[illegible]	Mortality after sloughing.
	Per cent.	Per cent.

40th to 50th year	41	[illegible]
Over 50 years	[illegible]	[illegible]

The least mortality after sloughing takes place is found between ten and fifty years of age, and, taken in connection with the table above given, the figures show that the high mortality in infants depends upon the rarity of sloughing, while in old age and in children it depends upon the complications which develop during sloughing, or upon lack of the necessary strength for recovery when it is complete. It would appear that in children under one year recovery was impossible unless treatment succeeded in reducing the intussusception; and that even up to the age of five years recovery seldom occurred, unless under the same condition.

Separation of the slough generally takes place between the tenth and twenty-first days; but in children the average time is somewhat earlier—from the fifth to the tenth day. As a rule, separation is effected more quickly in the intussusceptions of the small intestine than in those of the large. In chronic cases sloughing very rarely takes place, contrary to what would naturally be supposed, and contrary to the statements of authors before Rafinesque. The latter authority found but six cases of elimination of the slough in fifty-six cases of chronic intussusception, and recovery followed in only two of these.

It cannot be too strongly emphasized that sloughing is by no means equivalent to recovery, for we have seen that 41 per cent. of the cases in which the slough is eliminated perish from the complications dependent upon that process, or are so exhausted by their severe illness that they are unable to complete the recovery which is thus begun. The prognosis will, therefore, depend in great part upon the complications, for if peritonitis develops, a fatal termination is almost assured. Passing by the less common modes of death, such as septicæmia and hemorrhage, the two main causes of death are peritonitis and shock or exhaustion. In children, most of the deaths are the result of shock or exhaustion, for perforation of the intestine, or peritonitis without perforation, was found in only six cases by Leichtenstern, while in one hundred and seventy-five cases over one year of age peritonitis was the cause of death in twenty-four per cent.

The proportion of deaths from peritonitis varies with the seat of the intussusception, being thirty-seven per cent. in the ileo-cæcal form, twenty-two per cent. in the enteric, fourteen per cent. in the colic, and only three-fourths of one per cent. in the ileo-colic. The extreme rarity of perforation in the ileo-colic intussusceptions, and its frequency in the ileo-cæcal, are due to the different course of the disease in these varieties, for the ileo-colic cases die of shock before peritonitis can set in. This is proven by the fact that perforation takes place on the average in fifty-seven days in the ileo-cæcal intussusceptions, and in twenty-four days in the enteric—both periods being longer than the average duration of life in these forms, showing that perforation occurs only in cases with a prolonged course. The rarity of perforation in the colic, however, must depend upon a different cause, for a chronic course is the rule in these cases. Leichtenstern attributes it to the greater thickness of the wall of the large intestine as compared with that of the small; but it seems more reasonable to seek the cause in the larger calibre of the bowel, and the consequent diminished liability to strangulation.

The time of death in the fatal cases is influenced by the age of the patient, as appears by the following table from Leichtenstern, which shows that the shortest and most rapid course is found in children, especially during the first year of life. This result agrees with other facts which have been pointed out, especially that death in children is caused by shock, and that the most acute cases are the most fatal.

The Time of Death and its Relation to the Age.

The mode of onset does not assist us in estimating the prognosis in any case, for we have already seen that the most chronic cases may begin very acutely, and, at the same time, cases which will run their course very rapidly may have a very mild beginning. But in so far as acute symptoms at the outset indicate the greater probability of an ileo-colic or enteric intussusception, just so far an acute commencement of the disease is a bad sign.

The exact effect of treatment upon the prognosis of intussusception is as yet undecided, but it will be considered when discussing the various forms of treatment, at least, as far as it is possible to do so at the present time. It may, however, be briefly said here that the results of laparotomy are not so good as it was hoped some years ago that they would be, for the mortality appears to be seventy-six per cent., which is worse than the general mortality of seventy per cent. which is given by Leichtenstern. Undoubtedly these results can be improved in the future. The results of treatment by injections appear to be better, but there is as yet no accessible material for determining its real value in figures.

TREATMENT.—*Expectant and Medicinal.*—Brinton is the chief advocate of leaving the case to nature in the hope that sloughing will take place and recovery become possible, for spontaneous reduction of the intussusception is such a rare event that it is scarcely worth while to take it into consideration. If spontaneous reduction occurs at all, it will take place very early, unless the whole course of the case is very mild. But many case a posttive diagnosis will scarcely be possible, unless a tumor has actually been discovered in the abdomen. The treatment to bring about spontaneous resolution would be the same as that adopted when it is intended to wait for sloughing.

The first necessity is the avoidance of purgatives, for they tend to increase the spasm and even to enlarge the intussusception. We have seen that Leichtenstern found two cases in which the displacement had been brought on by purgatives. It is true that some cases of recovery from intussusception have been claimed for the use of purgatives, and we have seen that some of Nothnagel's experiments tend to support this belief. But even in the most striking case of the kind, reported by Wilks,[23] which occurred in a girl with intestinal obstruction and a tumor in the abdomen, the diagnosis is not beyond suspicion. The use of metallic mercury must be classed with the purgatives, for its action is due either to increased peristalsis or to mechanical pressure upon the tumor—both acting in the wrong direction, and tending to drive the mass farther on in the bowel.

The only permissible medication is the administration of opium and belladonna, to quiet spasm of the intestinal muscle. Belladonna has been recommended by many for the regulation of the peristaltic movements, but it is not a powerful drug in this direction, and its action is so uncertain, and the idiosyncrasies of patients toward it in doses of any size are so common, that it is not often employed except as an adjuvant to opium. Opium is the only drug which is of any value in the treatment of intussusception. Nothnagel's experiments upon rabbits have shown that morphine in moderate but full doses stimulates the splanchnic nerve, but in very large doses paralyzes it. This nerve is inhibitory to peristaltic movements; therefore its stimulation diminishes these movements, and its paralysis increases them. Consequently, opium affords the readiest means for controlling the intestinal movements and for relaxing spasm, and as the pain depends upon the contraction of the intestinal muscle we have in it a practical guide to the amount of the drug which is needed. The hypodermatic administration of morphine is the best method of using the drug, for the stomach often will not retain medicines, and the frequent passages and tenesmus interfere with their introduction by the rectum. There is one danger to be guarded against, at least in the early stages of the disease, namely, the possible spontaneous reduction of the intussusception, removing the stimulus of pain while a large amount of the drug is yet in the system, and resulting in poisoning. In adults this danger is not a very threatening one, but in children it is of the greatest importance, for opium is a more dangerous drug to them than to adults. Another danger in the employment of opium is that its favorable effect upon the pain and the more obvious symptoms will deceive the patient, and lull the physician into a false security, even when the latter has no faith in the drug except as a palliative. This apparent improvement may delay any active attempts to reduce the intussusception until it is too late, and thus result in the death of the patient.

The proper administration of the food is a very important factor in the treatment of subacute and chronic intussusception, and although the short duration of the acute form makes it less important in the management of such cases it should not be neglected even in them, for it is never possible to predict what the ultimate course of the disease may be. The food should be of such kinds as will be easily digested and absorbed by the stomach, leaving as little residue as possible to be disposed of by the intestine. Therefore milk, broth, soft-boiled eggs, and partially digested foods must be relied upon, and even these must be given in small quantities at short intervals, rather than in large amounts less frequently. Owing to the numerous passages and the tenesmus, and the danger of exciting undue peristalsis, it will not be advisable to use the rectum for feeding purposes, except, as has been suggested, by employing nutrient substances in the large injections when they are employed to reduce the intussusception. It will often tax the skill of the physician to the utmost to maintain the strength of the patient when the vomiting is troublesome, but fortunately the latter is by no means a constant symptom, and the morphine will often help to allay the irritability of the stomach. Probably the use of the stomach-tube and lavage will be of great assistance in improving the retaining power of the stomach in these cases, as well as in other forms of acute obstruction of the bowels. Stimulants must be employed as the indications arise, care being taken to give them in such form and so dilute as not to excite vomiting; and if the latter is uncontrollable, recourse may be had to subcutaneous administration.

When the separation of the slough is taking place, and for a long time after it has been eliminated, the greatest care should be exercised in the diet, in order to avoid rupture of the freshly formed adhesions. Anything which might excite strong peristalsis, such as purgatives, fruit, and green vegetables, must be strictly avoided; also any substances which might cause obstruction, such as indigestible portions of food, tendon, bone, and improperly cooked beans. More than one case is on record in which rupture was caused by errors in diet some months after the slough had separated, when recovery seemed complete.

Electricity.—From the experiments of Nothnagel it appears as if there were some ground for hope that an intussusception might be reduced by the use of electricity, if the current could only be carried in sufficient strength directly through the affected loop of bowel just below the intussusception; but the practical difficulties in the way seem insuperable. While repeating Nothnagel's experiments, the writer frequently observed that when an intussusception had been formed, a fresh application of the electricity at the same place as before caused the intussusception to reduce itself. In no case could the intussusception be made to increase by a second application of the electricity. But to produce these effects it is necessary to employ a current of considerable strength, probably stronger than the patient could easily bear upon the skin, especially when we take into account the loss which occurs as the current passes through the abdominal wall. Some recoveries have been claimed for electricity, but they are not of such a character as to compel belief in the method. Still it would be worth while to try the application of strong faradic currents upon any intussusception which lay near the abdominal wall. Although negative evidence is always of doubtful value, there is probably no danger of increasing the growth of an intussusception by the use of electricity. If the tumor can be reached by the rectum, one electrode should be applied to it within the bowel, while the other is applied to the abdominal wall above the tumor. If the abdominal wall were sufficiently flaccid to allow of grasping the tumor between the electrodes, the current might be passed directly through the intussusception, the electrodes being placed in position before the current was turned on. It is not probable that currents passed in the course of the pneumogastric or splanchnic nerves (by having one electrode upon the spine in the dorsal region, and one upon the abdomen) would have any effect, for currents strong enough to act with the necessary force upon these deep-lying nerves could not be safely employed. An ingenious but not very practical use of mercury in connection with electricity has been suggested, the idea being that when the mercury was administered by the mouth, it would collect above the tumor, and serve to direct the course of the electric current through the intussusception; but it is not certain that the mercury would reach that point.

Massage.—Manipulation of the abdomen has been frequently recommended for the treatment of various forms of intestinal obstruction, and especially for intussusception. We know by experiment that the intestinal muscle can be made to contract locally by mechanical irritation, such as a pinch or bruise, but this contraction remains localized, and does not develop into a peristaltic wave. Massage, however, does excite a general peristalsis in some cases of intestinal torpidity, acting probably by the application of the mechanical stimulus to successive portions of the bowel in turn, and in restoring the normal irritability of the intestinal muscle if this has been diminished. It is conceivable that massage might do harm in intussusception, rather than good, for if the tumor were still growing, anything which would excite more active peristalsis would possibly be as likely to increase the size of the tumor as to cause its reduction. An apparent contradiction to this supposition has just been noted in electricity, but this may be explained by the hypothesis that the electric current does not simultaneously affect all the layers of the intussusception, and waves of contraction, which run through one layer only, cause the reduction of the bowel. If the tumor is swollen from œdema or congestion, it is possible to reduce the size of the whole mass by energetic compression with the hand, which renders its solution [illegible] likely. It can be imagined also that simply pushing the tumor to one side might tend to draw out the invaginated bowel, by pulling upon the mesentery which has been dragged in with it; or even that the bowel above or below the intussusception might be held stationary against the spine or some other fixed point, and then the tumor could be pulled upon or pushed aside in such a way as to exert traction upon the intussusceptum, or even to squeeze it out from below. But these manœuvres must be carried out through the entire thickness of the abdominal wall, and are therefore too vague and uncertain to make it worth while to persist in them, if speedy relief is not obtained. Probably, after all, the principal benefit of massage lies in exciting increased peristalsis.

But although massage probably cannot accomplish much when employed alone, it is very useful in connection with inflation or injection of the bowel. Here the conditions of the problem are somewhat altered, for there is a force below the intussusception which is tending toward reduction and the massage assists this force by exerting additional pressure upon the enclosed air or fluid, and by giving short lateral, rocking movements to the intussusception, which favor its reduction—just as such movements favor the drawing of a nail from wood, or the slipping of any tightly wedged bodies. The presence of this pressure from below also prevents any peristaltic movements of the bowel which may be excited by the massage from increasing the growth of the intussusception. But massage must be employed with great caution if lapse of time, or very severe symptoms, gives us reason to believe that the coats of the bowel have been softened. Nothing would be easier than to produce a tear even in perfectly sound intestinal walls by too violent manipulations, and especially if considerable pressure were already being exerted from below by injection or inflation of the bowel.

Injection and Inflation.—Injection of the bowel is one of the oldest methods of treatment in intestinal obstruction, and in no case does it promise so well as in intussusception. Given a section of the bowel which has been invaginated into that just below it, what easier or more reliable way for returning it could be found than the injection of water or air from below? What mechanical device could be more perfect than the penetration of the fluid into the space between the middle and external layers of the intussusception, thus distending the sheath and compressing the intussusceptum, while at the same time it presses the latter upward, the pressure being evenly diffused over the entire surface of both? It has been objected that injection would tend to increase an ascending intussusception, although Rokitansky claimed that injections would reduce the ascending as well as the descending; and one of Nothnagel's experiments on ascending would seem to show that he was right. Practically, however, ascending intussusceptions are so rare in the clinical form that we can afford to disregard them.

The first question which suggests itself is as to the amount of pressure which the bowel will bear. We know that there are instances in which spontaneous rupture of the gut has been observed in intestinal constriction, even when the wall had not been weakened by ulceration, but as a rule it will bear a very considerable pressure when healthy. But very few exact observations are at hand for determining the amount of this pressure, the only facts which I have been able to discover bearing upon this point being the following: Forest[illegible] made some experiments upon cadavers (three of four infants, an eight months fœtus, and one adult), and reached the conclusion that the colon of a child would bear a pressure of eight pounds to the square inch without rupture, and that of an adult would bear twelve to fifteen pounds. His experiments appear to have been made after the abdominal cavity had been freely opened. Rosch[illegible] had a case of [illegible] ileo-cæcal intussusception in a child, in which he employed the pressure of a column of water [illegible] feet high, without success; and after death a pressure of [illegible] also failed to reduce the intussusception, the bowel bursting at this pressure, half way between the anus and the ileo-cæcal valve. This experiment agrees with those of Forest. We are told by one observer that he connected the tube of a Davidson bulb-syringe with a siphon of carbonated water, inserted the nozzle of the syringe in the rectum, and when he opened the valve of the siphon, the pressure was so great that he was unable to compress the bulb of the syringe with his hand; and yet he did not rupture the gut, and cured his patient. We may, I think, accept the limit laid down by Forest, that a pressure of six pounds to the square inch can be safely employed in children as long as the bowel is probably in a healthy condition.

This force is sufficient in most cases to reduce the intussusception, for although there are very few cases reported in which data are given from which the force employed can be computed, we have two cases reported by Bayliss[illegible] in which the pressure of a column of water not over five feet high (giving a hydrostatic pressure of only about two pounds to the square inch) reduced the intussusception—which recurred in each case, it is true, but ended in eventual recovery. Putnam[illegible] also reports a case cured by the use of the same amount of pressure.

But it is self-evident that a pressure which would be safe while the bowel retained its original strength, will not answer when it is weakened by the changes resulting from impaired circulation, and therefore the problem does not admit of a purely experimental solution. We have seen that in some cases these changes take place very early, and in others they do not occur until a very late period, but some indication of their intensity can be gained by considering the course of the symptoms. It is generally allowed that in the acute cases the changes may be very considerable within forty-eight hours, while in the subacute cases they are not decided for from five to seven days and in the more chronic cases they may be slight even after the lapse of several weeks. Leichtenstern found the time at which reduction was made, given in 41 of his cases which recovered, and 29 of these cases were reduced during the first week, 6 in the second, and 4 in the third, while one case is reported by Wilks[illegible] of successful reduction after seven weeks—a doubtful case of spontaneous reduction. These limitations may be accepted as broad working rules, and in doubtful cases the treatment must be applied tentatively, without anæsthesia, in order to use the feelings of the patient as a guide. But it must not be forgotten that the feelings of the patient are not very reliable, for in passing through the structure of the rectum, the latter has frequently been perforated, and the peritoneal cavity opened, without causing unusual pain at the time. Fecal passages and much blood passed in the stools should contraindicate all attempts at reduction, for they show that the strangulation is severe, and that sloughing has probably begun.

Some claim that air is far better than water as an injecting material, and others prefer carbonic acid gas. While it is true that air is more compressible and therefore would give a more elastic pressure, it is much more difficult to use it with measured force, and water is therefore to be preferred, for by the employment of the siphon or fountain-syringe apparatus, consisting of a long rubber tube and funnel, the force admits of exact measurement and control. If the nozzle of the syringe is of sufficiently large calibre, the only effect of a sudden contraction of the muscles of the intestine or of the abdominal wall would be to return a portion of the injected fluid, and the hydrostatic pressure is sufficiently elastic for safety. The local sedative action of carbonic acid gas upon the intestinal muscle is probably not sufficiently powerful to be worthy of consideration. The claim that air or gas would be less irritating to the peritoneum than water, in case a rupture took place, may also be disregarded, for the active irritant in case either should enter the peritoneal cavity would not be the air or water itself, but the fecal matter which would pass in with it from the bowel. It has been recommended by some to use tobacco enemata, but in morphine we have a drug which acts more powerfully upon the intestinal movements, and at the same time is much safer. The addition of purgatives to the injected fluid is of course forbidden in intussusception, for we do not desire to excite peristalsis. For the same reason the use of ice-water enemata is inadmissible, to say nothing of the shock to the enfeebled system which would be caused by the cold water. The suggestion to add nutritive materials to the injected fluid has already been mentioned.

The ileo-cæcal valve places a practical barrier to the employment of injections for reduction of intussusception of the small intestine. The much-discussed question, whether an injection can be made to pass the valve from below, seems to have reached an affirmative decision, at least for certain substances and in some subjects. It has been especially claimed for carbonic acid gas (v. Ziemssen), and for hydrogen gas,[39] that they will pass the ileo-cæcal valve under low pressure; but the difficulty does not cease here, for the innumerable turns of the small intestine act as valves and "traps," which constantly add new obstructions to the upward flow of the injected material, and diminish its pressure, so that it is not easy to conceive that it would retain sufficient force to reduce an invaginated loop of bowel. As we hope to be able to demonstrate that the dangers of laparotomy are not great enough to warrant much loss of time with doubtful means of treatment, or to justify the risk of using very great force in injection, we shall find it practical to limit the use of injections to the treatment of intussusceptions of the large intestine.

The selection of the best method of giving the injections requires careful study. As has already been shown it is necessary to measure accurately the force employed, and to keep it within certain limits. For this reason many of the ordinary means of giving the injections—the ordinary enema syringe, the siphon bottle of carbonated or aerated water, the bellows (for air), and especially the introduction of chemicals into the rectum, in order to generate gas within the intestine—must all be rejected as uncertain and dangerous. With these methods it is impossible to judge of the amount of force employed. The force exerted by a hand of ordinary strength compressing the bulb of a Davidson syringe is much too great to be safe, and as it is impossible to graduate this powerful pressure, this instrument should never be employed.

The siphon bottles of water charged with gas are particularly dangerous, for they are charged at a pressure of one hundred to one hundred and twenty pounds to the square inch, and although this force could be kept within bounds by allowing only a drachm or so of the liquid to enter the gut at a time, the surgeon would have no idea of the force actually employed. The most dangerous of all is undoubtedly von Ziemssen's suggestion to introduce bicarbonate of soda and tartaric acid into the rectum separately, and to generate gas by their combination. Even if the total quantity of gas produced is limited by the measurement of the salts introduced (according to Ziemssen twenty grammes of bicarbonate of soda and fifteen of tartaric acid will fully distend the colon in the adult), and by the introduction of these amounts in three separate portions, as recommended by him, the crudeness and dangers of the method are evident.

The only method worthy of consideration is the use of the simple tube and funnel, for it enables us to accurately determine, and easily control the pressure employed, and fortunately its simplicity allows of its improvisation and use in almost any locality. As has been shown above, a pressure of from eight to nine pounds is the bursting capacity of the colon in the infant, and from twelve to fifteen in the adult, so that we may safely employ a pressure of six pounds in the former case, and somewhat more in the latter, if the intussusception is sufficiently recent, and the symptoms sufficiently mild to warrant the supposition that the walls of the bowel are still in a healthy condition. As a column of water two and one-third feet in height gives a pressure of one pound to the square inch, an elevation of fourteen feet, measured from the level of the water in the funnel to the level of the intussusception will exert a pressure of six pounds, which is the force desired. Consequently the only apparatus needed will be a rectal tube of large calibre, a rubber tube fourteen feet long, and a funnel or irrigator for the upper end. It is well to have some extra tubing, for generally the ceiling of the room will not be high enough to admit of fourteen feet of elevation, and if the tube is long the funnel can be carried out of the door, and up a stairway until the desired height is reached.

In children always, and generally in adults, it will be advisable to employ anæsthesia, for although Nothnagel states that ether does not diminish the contraction of the intestinal muscle, it is well to remove the tension of the abdominal wall, for it certainly hinders reduction by pressing upon the intestinal contents above the intussusception. It is even possible that a sudden contraction of the abdominal muscles would so increase the pressure in the intestine distended with the injected fluid as to cause rupture, especially if there were no gas in the bowel to take up this increased pressure by its elasticity. Where it is feared that the wall of the gut is already weakened, it may be safer to inject without anæsthesia, as has been mentioned above.

The pressure of the injected fluid should be increased slowly, and in this way it will often be found that the intussusception has been reduced before the limit of permissible force has been reached. The injection should also be retained for twenty or thirty minutes when the limit has been reached, for occasionally the pressure does not take effect at once. In one case, in which the injection reduced an intussusception six inches long to three inches, and was then allowed to escape, examination of the remaining tumor, some time after, showed that it had spontaneously diminished one-half, and the small tumor still present was made to disappear by a little manipulation with the hand. This case shows that sometimes, when the reduction has been begun by the injection, it may go on spontaneously.

There is generally great difficulty in closing the anus so as to prevent the escape of the fluid, especially if there is any dilatation of the sphincter. Treves recommends Lund's apparatus, which consists of a hollow rubber ring inflated with air, through the centre of which the rectal tube passes. This ring is held against the buttocks by a stout handle, with a disk upon it, which compresses the ring against the skin. A useful apparatus is easily made by wrapping a roller bandage, about an inch wide, around a stout enema tube, so as to make a sort of conical plug, the apex of which is inserted into the anus with the tube. Putnam[40] describes an ingenious method of using the force of the injecting fluid to occlude the anus. He employed a soft rubber bulb, to which was attached on one side the enema tube, and on the other, the rubber pipe from the reservoir of fluid. The rectal tube was inserted and the soft bulb held against the anus, so that as the water flowed from the reservoir it first distended the rubber bulb and then passed into the rectum, the pressure in both places being the same. If the bulb was pressed against the anus with more force than the pressure of the water in the pipe, the water was forced back in the latter and the bulb collapsed and allowed the water to escape from the rectum.

Massage is a very useful adjuvant in the treatment by injection, and should always be employed in connection with it. Caution is necessary, however, for it must be borne in mind that the bowel is already distended, and a slight additional pressure might rupture it. The position of the patient has often been insisted upon as very important in administering injections, and indeed some cases have been reported as a result of simple inversion of the patient without the assistance of any other means. It is difficult to understand how changing the position of the patient could affect the reduction of an intussusception, unless it were in a case in which the tumor was very large, and perhaps the bowel loaded with faeces behind the obstruction, so that when the patient was suspended by the feet the weight of the tumor would carry it into the upper part of the belly and thus make traction upon the mesentery where it was shortened by being drawn into the tumor. But it is important to have the patient so placed that the tension of the abdominal muscles will be reduced to a minimum, and this can be done by flexing the pelvis and the thighs while on the back, upon the side, or in the gynecological "Sims" position.

There is one class of cases in which it is not advisable to attempt reduction of the intussusception by injections: this includes all cases in which no tumor can be felt, and the diagnosis has been made solely by the symptoms. In these it will be impossible to tell whether the efforts at reduction have been successful or not, and the surgeon might be led into employing a dangerous amount of force; hence an exploratory laparotomy is less dangerous for such cases. The proof of successful reduction is the disappearance of the tumor under the hand, which should be kept upon it during the injection to ascertain this fact. Some observers report a sort of gurgling sound which is heard at the moment of reduction, and nearly all have noted that a general distention of the abdomen suddenly appears as the injected water or air removes the obstruction and passes on into the bowel above. The patient, if conscious, has often remarked that the pain decreases as the injection progresses, and ceases entirely at the moment of reduction; and children will stop crying and fall asleep during the injection.

The percentage of recoveries brought about by injections is not known, but it is remarkable that many observers have reported groups of two or three cases treated successfully by this means. It is much to be desired that some sort of collective investigation by reliable men who have carefully observed cases should be made, in order to gain some definite idea of the real merits of the method.

We might class with injections the reduction of intussusception by sounds introduced into the rectum. This method is full of danger and should never be resorted to, at least with any force.

There remain to be considered the operative methods of treatment: Removal of an intussusception prolapsed at the anus by incision and suture, enterostomy, and laparotomy.

Amputation of a Prolapsed Intussusception.—An intussusception projecting from the anus has been removed by excision in several cases, generally owing to an error in diagnosis, the surgeon supposing it to be a polypus or, at the most, a prolapse of the rectum; but this has also been done intentionally, and the results have sometimes been very good. If the diagnosis has been made and the tumor is entirely outside of the body, it is certainly wise to remove it. This is best accomplished by circularly incising the bowel a little above the tumor by short cuts, following each extension of the incision immediately by sutures, uniting the coats of the bowel above the invaginated part to the rectum just inside the sphincter of the anus. In this way the peritoneal cavity is not broadly opened, and there is no danger of prolapse of other loops of intestine.

Enterostomy.—Enterostomy has very seldom been performed in intussusception. When done in the ordinary way, simply making an artificial anus above the intussusception, it is obvious that it could only give relief to the pressure of the pent-up contents of the bowel above, and thus allow life to be prolonged until the slough could be eliminated. Not infrequently the surgeon does not see the patient until he is in extremis, and any other treatment is out of the question, so that this operation undoubtedly has its place, and should not be rejected because the results have hitherto been unsatisfactory. There can be no question that when the patient is in collapse a laparotomy is but little more than an autopsy held before death, and that it gives the patient no chance of recovery. Enterostomy, on the other hand, would at least do no harm, and in some of these cases in which the intestinal obstruction was the principal element it would certainly do good. In cases in which strangulation was the marked feature, and there was no perceptible collection of fecal matter, enterostomy could of course do nothing to relieve. Some would exclude enterostomy from consideration in the case of children, because of the fact, already shown, that a slough is to be expected in only two per cent. of the cases under a year old. But even at this age, when no tumor can be felt which can at once be cut down upon, securing a very short operation, and when the patient is too feeble to endure a full exploratory laparotomy, it would be better to try what simple relief to the obstructed intestinal contents would accomplish, rather than leave the child to its fate. Although the proportion of cases at this age in which the slough separates is so small, and although the reason for this fact is the early and severe strangulation, it may be that in some cases the little patients have not sufficient strength to carry them through the period of obstruction which precedes the discharge of the slough, and enterostomy would undoubtedly give such cases a chance of recovery.

Braun in his study of intussusception,* gives thirteen cases of enterostomy performed for intussusception, and to these I have been able to add three others ([illegible]), making sixteen cases in all. Of these, eleven cases died, and five recovered. In two of the successful cases the diagnosis might be questioned, but the other two admit of no doubt, for in one there was a slough passed, and in the other the presence of the intussusception was verified by exploration of the abdomen at the time of the operation. In four of the cases which recovered, the intussusception appears to have undergone spontaneous resolution when the pressure upon it by the faeces collected above was removed, and as one of these was the case in which the intussusception was verified at operation, there can be but little doubt that an intussusception can recover in this way. It is not fair to include in the statistics of enterostomy those cases in which laparotomy was performed, and an artificial anus made in addition, a class of cases in which there is as yet no recovery on record. In all the cases of this group the operation was so long postponed that the strength of the patient was entirely exhausted, and yet he was subjected to the shock of a prolonged operation, with efforts to reduce the intussusception, before the artificial anus was made. We need not fear that the artificial anus will be permanent in these cases, for, according to the study made by the writer,* of the cases which recovered after enterostomy had been performed for acute intestinal obstruction, sixty per cent. regained the natural course of the faeces and the anus then closed spontaneously, or was readily closed by a plastic operation. It is to be hoped that the cases for which enterostomy is suited will constantly diminish, by the more systematic use of injections, and by the earlier resort to laparotomy, but probably there will always be some cases in which it will be indicated.

Laparotomy.—We come finally to the vexed question of laparotomy in the treatment of intussusception. What surgeon who has seen how easily intussusception can be unravelled in his hands at the autopsy table, when the adhesions are not strong, and then has been brought face to face with the same condition in the living, has not longed to get the invaginated bowel within reach of his hands, instead of trusting to the relaxing effect of chloroform, or the blind use of injections? But even in these days, when the fear of peritonitis no longer deters him, a more subtle enemy remains unconquered, and owing to the effects of shock, the mortality of these operations still remains very high.

In 36 cases of laparotomy performed for intussusception, of which 30 were in children, Braun found 25 recoveries, and 40 deaths—a mortality of 78.4 per cent. In 27 of these cases, however, in which the intussusception could be reduced at the time of operation, 11 recovered and only 16 died, two-thirds of these cases being children, and four of the recoveries occurring in them. His collection of cases includes a few chronic intussusceptions, in which the mortality is less than in the acute; but it also includes all the operations on record, even those performed before the principles of antisepsis were generally acknowledged.

Among a large number of cases of laparotomy for acute intestinal obstruction, collected and analyzed by the writer,[43] there were 71 cases of acute intussusception operated upon since the year 1878, acute being understood to mean of not over three weeks' duration. The mortality of these 71 cases was seventy-six per cent., which is only a trifle lower than Braun's figures. Examining these cases a little more in detail than was done in the paper just referred to, the following table has been constructed, similar to Braun's:

Results of Laparotomy for Acute Intussusception.

	Children.		Adults.		Age unknown.		Total.		Mortality.
	Recovered.	Died.	Recovered.	Died.	Recovered.	Died.	Recovered.	Died.	
									Per cent.
I. Intussusception reduced	7	22	5	6	2	..	14	28	67
II. Intussusception not reduced:									
A. Nothing done	..	3	..	2	.	..	..	5	100
B. Resection and suture	..	3	2	7	1	..	3	10	77
C. Artificial anus made:									
1. After resection or reduction	.	4	..	..	..	..	..	4	100
2. Without resection or reduction	..	1	..	6	..	..	.	7	
Total	7	33	7	21	3	..	17	54	76

From this table it appears that out of 42 cases in which the intussusception could be reduced 28 died, giving a mortality of sixty-seven per cent.—among the children seventy-six per cent.; among the adults fifty-four per cent. In 13 cases in which the intussusception could not be reduced, and in which it was resected, and the bowel united by suture, only 3 recovered, all adults. Of the other 16 cases in which the operation was abandoned, or an artificial anus was made, all died. These figures would indicate that there is almost no hope of recovery when laparotomy has been performed, unless the intussusception can be reduced, but we have already shown that this fact need not entirely contraindicate the performance of enterostomy if it is not preceded by a full laparotomy. The age of the patient has a very important bearing upon the prognosis as affected by operation, for while only seventy-five per cent. of all the adults died, eighty-three per cent. of the children were lost. Among the cases in which reduction was possible were 22 children under one year old, and of these only 5 recovered.

But if we examine the causes of death in these cases, a satisfactory explanation of their heavy mortality is discovered in the poor condition of the patients when the operation was performed. Out of the 54 fatal cases 28 were in very poor condition at the time of operation (in fact, 2 are described as moribund); 9 cases died of peritonitis, gangrene of the gut, or other complications due to delay in resorting to laparotomy; and in 3 cases the cause of obstruction could not be remedied. Against these we have to set only 5 cases of death from shock, 6 cases of sepsis not due to gangrene of the gut, and 3 cases in which the cause of death remained undetermined—a total of 14 which can be said to have died from the operation.

It would appear as if the percentage of mortality ought to be very much less than it is if cases were taken in hand early, and it is impossible to exaggerate the dangers of delay. A very early operation would be feasible, if, as soon as a proper systematic trial had shown that injections were useless, laparotomy were performed at once. If a tumor could be felt in the abdomen beforehand, indicating exactly where the incision could be best made, and preventing loss of time in searching for it, if adhesions had not been formed, and if the operator were skilful enough to complete the operation in the shortest possible time, the mortality need not be very high even in children. The great danger of prolonged operations is shown in the high mortality of resection and suture when attempted in these cases.

As bearing upon the possibility of cure by laparotomy we may mention in this connection the rare case reported by Kleberg.[44] In a man, forty years of age, operated upon for strangulated hernia, a double intussusception of the colon was found in the sac, which was reduced after some difficulty when the incision had been prolonged upward, and the patient made a perfect recovery.

The technique of laparotomy for intussusception may be described in a few words. The rules of cleanliness and antisepsis must be fully observed. The incision should be made in the median line, unless the tumor is small and immovably fixed at one side of the abdomen, when it may be made over the tumor. The invaginated bowel, which may be brought outside of the abdomen if necessary, is reduced by making traction upon the entering layer of the intussusceptum from above, and at the same time squeezing it out from below with the other hand. If the intussusception is situated in the large intestine, the reduction can be greatly assisted by the simultaneous use of the injection given in the way just described. Any rents which are made in the intestinal wall by the manipulations must be closed at once with Lembert sutures. If reduction is impossible, the implicated bowel must be cut away between two ligatures and both ends secured in the abdominal wound, either by sutures, as in forming the ordinary artificial anus, or, if the condition of the patient is very bad, simply by a clamp—to be kept in place for from twenty-four to forty-eight hours. If the bowel is greatly distended above the intussusception, the contents should be allowed to escape before the ends are secured in the wound, turning the patient upon his side, and covering the wound with cloths or sponges. Everything must be arranged beforehand, so that no time shall be lost, and the whole operation must be carried out as rapidly as possible. For this reason it will not be advisable to attempt the tedious operation of suturing the divided ends of the bowel when resection has been necessary, except in chronic cases, in which the patients are in fairly good condition, and the cases resemble resection of the bowel for a neoplasm. The anaesthesia should be as light as possible, and therefore chloroform will frequently be the best anaesthetic to employ, as it can be suspended during the manipulations within the abdomen, which are painless, and administered again while the abdominal wound is being closed.

Summary of Treatment.—When the diagnosis of intussusception has been made in an acute case of less than forty-eight hours' duration, and without severe shock, morphine should be given at once, but in small doses, especially in children, for if the intussusception should yield readily to treatment, opium-poisoning might follow. Injections should be begun immediately, according to the method recommended above, using an anæsthetic, putting the patient in Sims' lateral position, and employing continue massage of the tumor. If the intussusception is not reduced after a careful trial, lasting half an hour at least, gradually increasing the pressure to the limit of a column of water fourteen feet high for a child, and somewhat more for an adult, all attempts should be discontinued, and consent obtained for a laparotomy in case a second trial should fail. Everything being prepared for operation, and the patient meanwhile having been carefully stimulated, the anæsthetic should be administered again after twelve or twenty-four hours, and another thorough trial of the injection made. Not until this attempt has failed should the operation be performed; but when its failure is evident, the laparotomy should at once be undertaken without interrupting the anæsthesia.

If the case is of longer duration, or if there are severe signs indicating that the strangulation is extreme, laparotomy should be performed after a single thorough trial of the injection, in order to avoid the second administration of the anæsthetic. If the duration of the case is more than three days, unless the symptoms are very mild, the injection should not be employed at all, but laparotomy should be performed at once, on account of the liability to rupture of the gut, for it is then probably weakened by the strangulation. The injection must not be attempted when the passages are fetid and contain a great deal of blood, for these are tolerably certain signs of strangulation, no matter how short a time the symptoms have lasted. If in such a case the patient is already in collapse, it will be a delicate question to decide between laparotomy and enterostomy. The latter should be given the preference if there is any fecal accumulation behind the constricted point, or if there is great tympanites; otherwise the former; and in any case the anæsthetic must be given with the greatest care. In some cases it may even be possible to operate without a general anæsthetic, by the local use of cocaine. When peritonitis has developed, laparotomy has become a necessity, to allow of cleansing the abdominal cavity; for if enterostomy is done, openings for drainage of the peritoneal cavity could not be made without danger of infecting them from the artificial anus. We have already seen that when the diagnosis depends upon the symptoms alone, and no tumor can be felt in the abdomen, injections must not be attempted; but if the patient's condition will permit it, an exploratory laparotomy should be made at once, otherwise an enterostomy will have to be performed.

[illegible]

JOINTS, CHRONIC DISEASES OF. PATHOLOGY.—Chronic joint diseases may be grouped pathologically under the heads of

I. Diseases affecting the synovial membrane.
II. Diseases affecting the cartilage.
III. Diseases affecting the bone.
IV. Diseases affecting primarily the periarticular structures.

I. DISEASES AFFECTING THE SYNOVIAL MEMBRANE.—Chronic inflammation of the synovial membrane is either a continuation of the inflammatory process described under acute synovitis (Synovitis, Acute, in Volume VI.), or it may be primarily insidious and chronic. After persisting it is characterized by thickening of the synovial membrane, an increased secretion, and retrograde metamorphosis of the connective tissue. This metamorphosis may develop granulation tissue and attack the cartilage and bone in a degenerative and destructive process, or it may terminate in an alteration and chemical change of all the tissues, which will be described under the head of chronic rheumatic arthritis; or the process may be chiefly limited to the synovial membrane.

FIG. [illegible].—Serous Synovitis of the Knee. Side view. [illegible]

(a) *Chronic Serous Synovitis* (Dropsy of the Joint, Hydrarthrosis, Hydarthrosis, Hydrops articulorum chronicus).—The pathological appearances of chronic synovitis vary much, but an increased amount of fluid is always present. Certain cases show no pathological changes beyond this increase of fluid for a long time, and these are the cases which have given rise to the names hydrops, hydrarthrosis, etc. These cases were at first thought to be dropsical and non-inflammatory, like hydrocele, but such a view is sparingly held now. Nélaton and Dupuytren may be mentioned among those who believe it. On the other hand we have Bonnet, Broca, Billroth, Volkmann, Cornil and Ranvier, and Marsh placing it among inflammatory affections. The contained fluid resembles that of hydrocele in color and consistency, but it contains mucus, and also more albumen than does the fluid of ordinary dropsy. Femoral aneurism and other obstructions to the leg circulation do not cause joint distention, even in extreme œdema, and even in the cases of primary hydrops articulorum (which are not so common as those where it is secondary to acute affections) the view is now that it is an inflammation of low grade with slight tissue change. The commonest phase of chronic serous synovitis is when it succeeds the primary acute form, and here the pathological change is at first slight and only shows a moderate increase of vascularity, and a little tendency to thickening of the membrane, which soon begins to look boggy from the continued soaking. The fluid may be brown from blood originally effused. It is not uncommon to find in these joints a small fibrinous or fibrous coagulum, when the condition is left over from an acute synovitis, and to this Barwell attaches immense importance in the production of the synovitis by irritation. These two classes, where there is little or no pathological change, may then be dismissed, and we come to the cases where pathological appearances are marked.

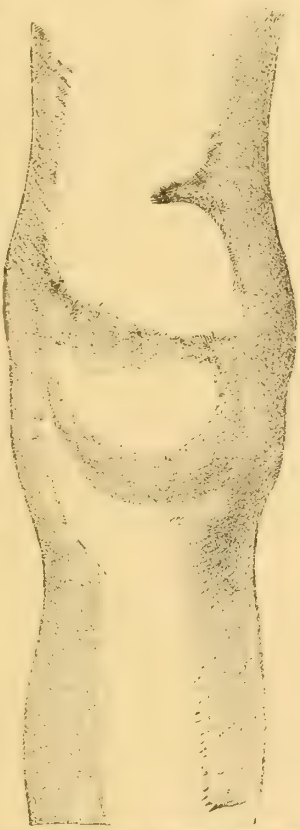

Fig. 4913. Chronic Serous Synovitis of the Knee. Front view. (Schreiber.)

The change coming next after increased vascularity and thickening of the synovial membrane is an hypertrophy of the synovial fringes. This varies from a slight hyperplasia to a condition where fibrous tissue-change has set in, and solidified them into a multitude of small fibrous polypi, so that the synovial membrane is fairly shaggy with them. In other cases they are translucent and seem to be, as they often are, fat-globules enclosed in a delicate fibrous capsule. Meantime the subsynovial tissue has hypertrophied and thickened, to even an inch in some cases, and if the fluid has been long in the joint the synovial membrane and the parts below it look light yellow, pulpy, and boggy. If the effusion has been extreme the capsule has either become enormously thickened or has given way and become much distended. If so, the lateral and internal ligaments, weakened by the continual tension and soaked by the contained fluid, have also stretched, and lateral motion may be found in the knee-joint, even to the extent of 60°.* When thickening of the capsule has predominated, cartilaginous and even bony plates may be found in the tissue. The synovial membrane in certain cases begins to encroach upon the cartilage. Normally, it runs into the cartilaginous border for two or three millimetres, but now the hypertrophied membrane sends out processes which creep in still further, as pannus does on the cornea. These cases Hueter calls synovitis hyperplastica pannosa. It is simply an extension of the process that we have considered above. It may go on to the formation of granulation tissue, but it is not likely that it will. Purulent cases generally follow another type, as we shall see. There is also an increase in the spaces between the cells in the subsynovial tissue, and a thickening and soaking of the peri-articular structures. Then come the secondary changes of the cartilage, fatty degeneration of the cartilage cells, fibrillation of that structure, and disintegration. The moment that the bone is bare, the work of condensing the tissue begins, and eburnation and enlargement of the ends of the bones result.

The outcome of this kind of serous synovitis may be in absorption, in suppuration, or in a persistent condition such as we have described, with an always increasing disability of the joint, with an extreme amount of peri-articular thickening and flexibility laterally. The hydrops articulorum tuberculosus of König is a primary tuberculosis of the synovial membrane, and König accounts for its existence by the supposition that the irritation caused by the tubercules' growth is not enough to produce its ordinary manifestation in fungous granulations; oftenest it occurs in a diffuse tuberculosis of the synovial membrane, sometimes in that form of chronic synovial inflammation characterized by the enormous connective-tissue formation described above, the class of cases which Hueter calls synovitis hyperplastica tuberosa;[8] and thirdly, in some cases of fungous synovitis in children, to be described later, the effusion has more of a serous than of a purulent character. The tubercles may be found present in a synovial membrane almost unchanged by inflammation where there were no symptoms of note before death. Ordinarily, however, the membrane is thickened and succulent, and studded with tubercles even into the subsynovial tissue. The surface tends toward granulations; if these are fully developed the effusion is generally purulent rather than watery. The exudation is often fibrinous, so that coagulation products of many shapes are present in the form of loose bodies like melon-seeds, rice, etc.; and, although formerly it was held that such bodies did not occur in tuberculous affections, König and Riedel[9] now consider that the finding of these loose bodies in the hydrops of a joint or a tendon increases the likelihood that the affection is tuberculous. This tuberculosis of the synovial membrane ordinarily coexists with a tuberculosis of the neighboring bone, although there is no communication between the two, and, from their appearance, neither is secondary to the other.[10]

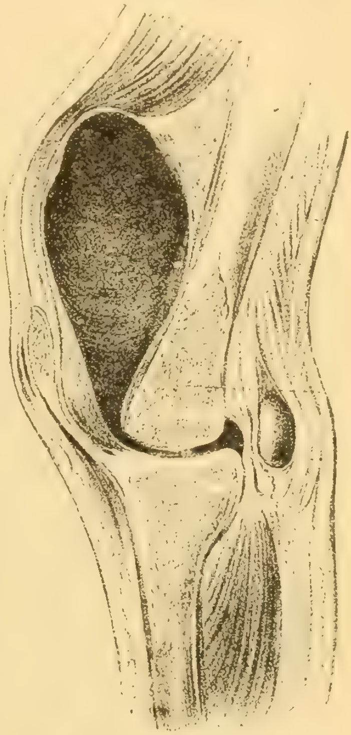

Fig. 4914.—Section of the Knee-joint in a Case of Chronic Serous Synovitis. (Schreiber.)

Arthrite Plastique Ankylosante.—There is a form of acute and subacute synovitis which has been described under the acute forms as dry synovitis. This condition is sometimes found as well in the chronic class. It represents an inflammation with a small exudation very rich in fibrine. It is apt to be associated with an infectious cause, as in gonorrhœa. The destruction of the cartilage is slight, and the ends of the bones are soldered together directly by the organized exudation. It is more common in the knee, but it may affect the hip, elbow, or shoulder (*Gaz. des Hôp.*, January 23, 1881).

---

* There may, however, have been, instead, a development of cysts in connection with the joint, practically herniæ. These occur oftenest in the popliteal space in connection with the knee-joint (Baker).[7]

Chronic serous synovitis which begins slowly and not from an acute affection, and which is characterized by the slight pathological changes mentioned above, is an affection whose cause is wholly obscure. It occurs oftenest in young men; it is not associated ordinarily with the rheumatic or any other diathesis, and any attempt to assign a cause is mere speculation. It is said to be an obscure form of osteo-arthritis, but such cases are oftenest marked by the occurrence of marked hypertrophy of the synovial fringes and a tendency to connective-tissue formation. One phase of the affection is represented by the intermittent form described by Seeligmüller, in which thirteen cases are detailed. In only two cases could any constitutional cause be assigned, and these suffered from intermittent fever. The affection has no established pathology beyond this. The most common form of chronic serous synovitis, of course, is where it remains from the primary affection caused by a blow, a wound, a strain, or exposure to cold, an over-exertion, or in those obscure cases where no cause is to be assigned, which are sometimes called rheumatic on very insufficient evidence. Here the appearance is that modified appearance of the acute form described above. Next comes the gonorrhoeal variety, the result of a urethritis, the rheumatic synovitis, with its tendency to relapse and to ankylosis, and a rheumatic form without any primary stage occurring as a sequel or complication of clearly marked rheumatism. These forms are both marked by hypertrophy of the fringes and a tendency, in long-continued cases, to bone enlargement and tissue formation; and allusion is made to pure chronic rheumatism, not to rheumatic arthritis, which will be described by itself. Syphilis as a cause of this form of synovitis appears in two phases: one in the secondary stage, where it simulates the rheumatic form very closely and is ordinarily acute but sometimes chronic and persistent. At times it is markedly intermittent. If it persists it leaves the joint enlarged, indurated, and subject to subsequent attacks. And the second form is encountered in the tertiary stage, where it appears as an infiltration of the synovial membrane and subsynovial tissue of a gummatous type (Lancereaux), with a varying amount of effusion, and a tendency, if continued, to enlargement of the bones, but not especially to stiffening of the joint. Richet called it "syphilitic white swelling." The effusion may be purulent, but it is also at times serous. Chronic serous synovitis occurring in hereditary syphilis is often secondary to bone or cartilaginous affections, especially a bilateral painless form which attacks children from eight to fifteen years of age. It does not tend to go on to destructive changes, though primary forms are described. Gout is occasionally to be counted as the cause of primary synovial change where the deposit of urate of soda occurs first in the synovial membrane rather than in the cartilage or capsule. The synovial membrane is seen to be studded by the small chalky masses. Chronic rheumatoid arthritis is said also to affect at times the synovial membrane primarily, but these affections will be discussed under the head of primary bone affections. Lastly, gonorrhoea is to be mentioned as a more or less common cause of joint effusion of a chronic character, and in the joint fluid gonococci are to be found, ordinarily as a sequence of an acute or subacute synovitis of long-drawn-out course. The attack ordinarily occurs in the second or third week of the discharge, and obstinately continues the course of rheumatism and sometimes that of pyæmia; women are exceptionally attacked by it. The discussion of the etiology of the tuberculous affection will be postponed until the commoner forms of joint tuberculosis are considered.

(b) *Chronic Purulent Synovitis.*—Syn.: Tumor albus, White swelling, Pulpy degeneration of synovial membrane, Fungous joint disease, Fungous synovitis, Fungöse Gelenkentzündung, Synovitis hyperplastica fungosa, Tumeur blanche, Strumous arthritis or synovitis, Tuberculous synovitis, De granulirende Gelenkentzündung, Pyarthrosis, Gliedschwamm, Empyema articulorum, Osteitis granulosa, etc.

The name tumor albus was originally given by Wiseman to practically all cases of chronic joint disease characterized by swelling, and Brodie was the first to restrict its application to that class called by him "pulpy degeneration of the synovial membrane." Since that time it has stood as the name for that pathological condition, until of late years the terms strumous and tuberculous have come to be applied to it.

In appearance joints affected by chronic purulent synovitis differ but little from one type, although in degree they vary very greatly. The appearances in the earliest stage are those described under acute, serous, or purulent synovitis, or the synovitis hyperplastica pannosa of Hueter (see above). These are an increase of vascularity in the synovial membrane, some thickening and swelling of it, with perhaps an extension of it on to the cartilage, and an increase of synovial fluid, together with a perivascular infiltration. From this stage the membrane becomes velvety, the cartilages look roughened, and the synovia has been replaced by a fluid varying from turbid serum to laudable pus. It is possible to say in advance what a continuation of this condition would lead to, and the changes found in chronic purulent synovitis represent this continuance.

The striking thing noticed on opening a joint affected moderately is the amount of gelatinous material which seems to have replaced the synovial membrane and perhaps the cartilages. The process is simple: the hypertrophied and infiltrated synovial membrane takes on still greater activity, cell formation and vascular supply become very much increased, and the result is a typical but rather low grade of granulation tissue, which is yellowish or pinkish, and admirably described by the terms pulpy and gelatinous. Macroscopically it does not differ in any way from granulation tissue as found elsewhere, except that it often contains in its structure small white specks, which are visible to the naked eye, and which are the structures described by Köster (*Virch. Archiv*, Bd. 48) as tubercles. They were almost constantly found by him embedded in this tissue around the edge of the joint, and later in the disease generally through the fungous tissue. The proof of the identity of these structures is well enough established. Köster considered them true miliary tubercles (*Arch. de Phys.*, 1870, p. 220). Brissaud (*Rev. Mens. de Méd. et de Chir.*, June 10, 1879) thought that although pulpy fungus undoubtedly occurs without the presence of tubercles, there is abundant and ample proof that tubercle is the chief element. In this view, that the structures found are true tubercles, agree König (*Deutsch. Arch. f. Chir.*, 1879, xi., 317 and 338), and Friedländer and Ranke as quoted by him. Bacilli are found in a certain proportion of cases, as we shall see later. Barwell, as the chief dissenter, considers the structures primarily the results of fatty and suppurative degeneration ("Diseases of Joints," 1881, chap. v., p. 140). Sometimes mere accumulations of mucus constitute these structures. They are prone to undergo cheesy degeneration, either singly or agglomerated, as they are often found. When the granulations are fully developed they secrete, of course, a purulent fluid, and they may melt into pus very rapidly or very slowly, and in certain parts of the joint the process may be much more advanced than in other parts.

But this stage of disease in the synovial membrane will not have been reached without accompanying changes in the cartilage and bone. The cartilage becomes yellow and loses its opalescence, and if one tries to lift from it the synovial hypertrophies which have grown over on to it, they often cling to it, and if they are pulled away leave a red and eroded surface of cartilage under them. The cartilage may, however, become granular first in other places, especially where the opposing surfaces are in contact, and notably does this take place when the limb is in malposition and part of the cartilage not altogether used or it becomes tightly pressed together by the tonic muscular contraction. The pathological change which takes place in the cartilage in general, and which leads to these granulating spots, is this: a fatty degeneration of the cartilage cells, and a fibrillation of the hyaline substance, with cell infiltration and a tendency to a gradual return to embryonic connective tissue; and this change is, as we have seen, more advanced in some spots than in others, and in these spots is formed an erosion of the cartilage probably reaching to the bone. Often the degenerated cartilage is cast off into the joint in one piece or in flakes. As soon as the granulations reach the bone they attack the tissue of the epiphysis in all directions. Hyperæmia of it has already been present for some time, accompanying the inflammation, and its structure is readily destroyed by the action of the granulations. When the destructive processes are not too active, the osteophytes are depositing fresh bone and the periosteum is thickened. There is now no limit to be set to the destructive processes; the ends of the bones, softened and embedded in a mass of jelly, are crowded against each other by the muscular contraction, and a sinus probably is draining off the products of the destruction. The ligaments, infiltrated and degenerated, have given way or stretched, and dislocations, complete or partial, have probably already occurred, generally as a result of the predominance of the flexor muscles over the extensors. The formation of intra-articular abscesses and their escape to the surface through the degenerated capsule needs no explanation; a fistulous track, lined with the same gelatinous material, marks their path. Sometimes the abscess has been extra-articular, and results from the breaking down of the peri-articular cellular infiltration, which contributes so much to the enlargement of the joint. The division of the disease into stages has no pathological basis. The appearance of joints affected secondarily from a primary bone lesion does not differ from that described above.

At any period of the affection reparative processes may set in. The granulation-tissue then becomes less succulent, and the areolar tissue in it becomes more prominent and the cells less numerous. In time, fibrous tissue forms in its place, and from this may result complete or partial anchylosis, and if these fibrous bands become ossified so-called true anchylosis is the result. If the cartilages have not been extensively destroyed, or if the affection has been chiefly synovial, any degree of restoration, even complete mobility, may result.

It is not uncommon to find associated with fungous joint disease tuberculosis of the lungs, or of the meninges, or general miliary tuberculosis.

Chronic purulent synovitis is sometimes the result of an acute serous or purulent synovitis, but the tendency in healthy individuals is not to run on to this form; when this occurs it is oftenest in adults of feeble constitution and in children of the feebly resisting type described as strumous, tuberculous, and scrofulous, as we shall see later. It is ordinarily a very difficult matter to say, clinically, whether the disease is primarily synovial or osseous; formerly the tendency was to regard such diseases as synovial, but of late years the view has changed, largely in consequence of the work of Volkmann and König, until now it is considered that in the great majority of cases chronic joint disease, especially in children, begins as an osteitis. Müller[21] analyzed 232 preparations, mostly from resections, with the following result:

	Bone-origin.	Synovial origin.	Indefinite.	Total.
Knee	69	33	16	118
Hip	47	3	11	61
Elbow	42	10	1	53
Total	158	46	28	232

Age.	Bone.	Synovial.
Three to fourteen years	50	21
Fourteen to thirty years	64	18
Thirty years and upward	39	12

Of 71 other cases analyzed by König,[22] 47 were osseous, and the distribution was as follows:

	Bony.	Synovial.
Hip	8	7
Knee	17	6
Foot	11	7
Shoulder	3	1
Elbow	8	3

Volkmann,[23] as the representative of extreme German views, believes that fungous joint diseases begin usually, and in children always, as a localized osteitis limited to a spot in the epiphysis near the joint. Unhappily figures bearing on the subject are scarce.

With the discovery of tubercles in fungous joint disease came into vogue the terms tuberculous, etc., which have given rise to so much discussion. The histological identity of the structures described by Köster is well enough established by the weight of evidence. Tubercle bacilli are found in a certain proportion of the cases, and a clearly tuberculous history is present in the families of the greater proportion.

Schüller, of Greifswalde, in support of the tuberculous theory of joint inflammations, rendered guinea-pigs and dogs tuberculous by the injection into their lungs of (tuberculous) sputa from cases of phthisis, and by causing others to inhale the same material. He then wrenched and strained the knee-joint and in the greater proportion of cases a fungous synovitis, sometimes attended by suppuration, followed. The same wrenching and straining in the knees of healthy animals did not induce disease of the joint.[24] Barwell is the chief objector to the experiments, but his objections lack force altogether.[25] Hueter demonstrated[26] that tuberculous matter (phthisical sputa, etc.) injected into the joint of an animal will cause a fungous hyperplastic synovitis of the type that we have been considering, and from this focus general tuberculosis may follow; and that a piece of the granulations from a human synovitis fungosa, introduced into the anterior chamber of a rabbit's eye, caused choroid tubercle, and, later, general tuberculosis. And König (*loc. cit.*), by introducing the fungous proliferations of joint-synovitis into the general circulation of animals, caused general tuberculosis. So much for the experimentation bearing directly on the subject. The bearing of this on the etiology, as well as on the questions of heredity, trauma, and so forth, can be best discussed after the consideration of joint disease of bone origin, for the two run into each other so much that any separate consideration of their etiology is almost impossible.

II. JOINT DISEASES AFFECTING THE CARTILAGE (Syn., Chondritis, Ulceration of cartilage, Degenerations of cartilage, Fibrillation, etc.).—Cartilage is a tissue of low grade, non-vascular and sluggish in all its reactions, and it is to this that we must turn for the explanation of the extreme rarity of primary inflammatory disease of the cartilages of the joints. Surrounded on one side by synovial membrane and on the other by bone, this tissue lies in the neighborhood of far more irritable tissues than itself, which react to any trauma or constitutional irritant long before the cartilage does, and, rightly or wrongly, are to be considered as preceding and originating the changes in the cartilages.

Hyaline cartilage is a bluish-white, opalescent structure of great density which covers the ends of the bones in all diarthrodial joints. It is, as we have seen, non-vascular, and derives its nutriment from the bone and synovial membrane, which furnishes another explanation why secondary affections are so common. It consists of hyaline substance and corpuscles, which lie embedded in the former and contain one or more nuclei; they fill the spaces in the matrix. These corpuscles lie near the joint surface in layers parallel to it, but deeper, near the bone, in columns perpendicular to the cartilaginous surface, which accounts for the readiness which the cartilage shows to be chipped vertically. Externally the cartilage is attached to the bone by the perichondrium, and the internal surface lies free and moist in the joint.

Fibro-cartilage, when present, appears as something intermediate between fibrous tissue and cartilage. It appears vertebral bones—intervertebral, sternoclavicular, and [illegible] the symphyses; and, lastly, as the connecting substance in joints which are not more completely formed, as in the [illegible] joints. Histologically it consists of fibrous tissue interspersed with cartilage cells and it possesses far greater toughness and elasticity than hyaline cartilage.

(a) *Hypertrophy.*—Simple hypertrophy of cartilage, without the soft condition so often found in chronic synovitis from continued irritation, is rare in the articular cartilages except in the marginal ecchondroses which are found in the degenerative changes accompanying certain general conditions, such as rheumatoid arthritis. Such circumscribed hypertrophies occur around the margins of the surface. Sometimes they occur also in the degeneration of cartilage characterized by the deposit of urate of soda, and sometimes in connection with synovitis fungosa, or synovitis tuberculosa of Hueter. In children whose ossification has been delayed the articular cartilages may have the appearance of great thickness.

(b) *Atrophy.*—Except as the result of degenerative changes atrophy of the articular cartilages does not occur, unless it be to a very slight extent in the joints of old people, and sometimes slightly in joints subjected to great pressure.

(c) *Degenerative Changes.*—The type of degeneration in cartilage is peculiarly constant. Its phases are many but the process is essentially one. In a word, it consists of a cell-multiplication and fatty or granular degeneration of the corpuscles, and a fibrillation of the hyaline substance. Whether we have in question primary or secondary degeneration, the results of injury, or the degeneration of gout, we shall see the type clearly demonstrated. The processes are phases of one degeneration rather than separate pathological processes.

1. Inflammatory (primary).—In the overwhelming number of cases these changes are purely secondary. The existence of primary disease is denied by such men as Hueter, Barwell, etc., but there have been recorded from time to time certain cases which seem to establish the fact that primary erosion of the cartilage does occur.

The writer in "Holmes' Surgery" says: "Inflammatory alterations of the cartilages, unaccompanied by disease of any other joint tissue, may possibly take place, though cases of it are not easily met with;" and that seems a fair statement of the situation. Years ago the discussion was not as to primary disease, but as to whether inflammation was present in cartilage at all, and whether the changes found were not the result of the other tissues acting on it. The researches of Redfern, Goodsir, Virchow, and Weber[32] establish the active character of the changes well enough, and their writings give the story of the controversy. As to the existence of primary disease, Brodie reported some cases that he considered primary cartilage disease; but, looked at in the light of modern pathology, there seems but little doubt that they were cases of primary disease of bone. The same is true of a case called "acute idiopathic ulceration of cartilage," reported by Mack, where the bone "was extensively carious." Paget claims to have found erosion and ulceration of cartilage without disease of other tissues. Bauer reported a case in 1871 where there seemed little doubt that it was a case of primary cartilaginous disease of the intervertebral disks, and at autopsy the eight upper dorsal disks were found to have been destroyed, while the cervical disks had become soft and pulpy. The patient was fifteen years of age, and the disease had lasted six years; there was probably a traumatic origin. Other cases of suppurative inflammation of the intervertebral disks are recorded by Ogle, Bruns, and Chassaignac, where ulcerative changes were found in one or more of the intervertebral disks, which varied from a small perforation to complete disappearance of the disk.

The pathological process in itself is the same, of course, so far as primary disease of cartilage is concerned, as the one to be described under secondary inflammatory degeneration. Koenig reports three cases of circumscribed fungous disease of the internal meniscus in the knee-joint.

2. Inflammatory changes (secondary).—As a result of the inflammation of synovial membrane or bone, secondary inflammation of cartilage is common enough. The number of nuclei in the cells, and the number of cells in the corpuscles, multiply very fast. There is a certain amount of fatty degeneration of the cells present, and striation of the hyaline substance goes on to fibrillation, and this to local or general disintegration. The cells break from the corpuscles and infiltrate the whole cartilage; it becomes yellowish and soft. But if the process is very acute the hyaline substance is disintegrated without having time to undergo much fibrillary degeneration; the proliferation of [illegible] is the prominent part of the process. If it is slower, fibrillation is more marked. At any rate, disintegration generally comes on, and where the cartilage is gone (generally where the pressure is greatest) an ulcer with a granulating base and clean-cut edges is seen, of greater or less extent. The base of the ulcer consists of typical granulation tissue. And in this way the entire cartilage may quickly disappear, or these ulcers may go on to cicatrization and heal by the formation of a connective-tissue scar.

At other times, where an osteitis is the primary disease, the deprivation of the cartilage's nutriment causes it to die, and the whole or parts of the necrosed layer of articular cartilage may be thrown off into the joint-cavity, leaving ulcers or the whole denuded granulating end of a bone. The yellow opaque pieces of cartilage lie a long time in the joint or are disintegrated into pus.

3. Fatty degeneration.—Another phase of this same pathological process, where the fatty or granular degeneration predominates and fibrillation is slow and more stable, constitutes what is generally classed as fatty degeneration. Unlike the other, it does not cause ulcers, but the degenerated fibres are tough and resistant and attached at one end, while the other lies free in the joint-cavity, and the whole surface may be thick and pulpy, or hard and fibrous. Intermingled with the fibres are fat globules and a few leucocytes, and the cartilage corpuscles are either disintegrated or filled with fat globules. The fibres may wear away and leave the bare ends of the bone, not ulcerated and covered with pulpy granulations, but white and eburnated. Fatty degeneration of cartilage is considered to be analogous to the arcus senilis of the cornea in its etiology and pathology.

4. Fibrillary degeneration.—Still a third phase of this same process constitutes what is called fibrillary degeneration. Fatty degeneration and cell multiplication in the cartilage corpuscles assume a subordinate place, and fibrillation of the hyaline substance becomes the all-important part of the degeneration. The fibres are well marked, and where pressure occurs they are worn away evenly or unevenly, and where they are worn away [illegible] white, thickened, ivory-like bone, and calcareous degeneration occurs in the patches of degenerated cartilage. It is "the ossification of cartilage." Around the edges the cartilage is covered by the synovial membrane, probably hypertrophied, and here cell-formation and fibrillation begin as well as elsewhere; but the cells cannot escape, having no free cartilaginous surface, and they are retained and become active in the formation of cartilage, and the marginal ecchondroses of which we have spoken are formed. In time calcareous deposits occur in these as well. Sometimes they break off, and form one kind of the "loose bodies" in the joint.

The deposition of urate of soda in the hyaline substance may perhaps be called the gouty degeneration. It is not a different process from the others—cell-multiplication and fibrillation go on as before; simply this urate deposit is superadded in the cartilage, where it is seen sometimes (in very acute cases) as a single superficial layer, then later in white patches which are larger below the surface, where on more careful examination it is seen to have left the corpuscles free and to have settled in the hyaline substance around the corpuscles. Later it invades them also, and disintegration goes on. A simultaneous deposit of urate of soda occurs in ligaments, bones, and the periarticular structures.

The etiology of primary inflammation of cartilage is, of course, extremely obscure. In some of the cases reported it was traumatic in origin, in others no cause was assignable. Some patients were old, others young; in fact, there seems nothing to indicate in which direction the cause lies.

The etiology of secondary inflammation is to be sought in the cause of the primary affection—trauma, tuberculosis, a penetrating wound of the joint, or whatever may be at the root of the synovitis or osteitis. Reyher described a change in the cartilage due to disuse of the joint characterized by a slow inflammatory process, which he produced by immobilizing for weeks the limbs of some dogs.

Fatty degeneration of cartilage is an ill-defined process accompanying the later stages of chronic synovitis, occurring in old age and as a subordinate process in rheumatoid arthritis. But here fibrillary degeneration is the characteristic form, along with the increased bone-formation, but fibrillary degeneration pure and simple is the expression of the general morbid condition known as rheumatoid arthritis.

Gouty degeneration expresses its etiology in its name. As to the deposition of soda urate there are two theories in vogue—one, that the uric acid in the blood is deposited as soda urate in the cartilages, the other, that the soda urate is formed in the cartilages itself and remains there because there are no blood-vessels to carry it away. The latter theory gets support, says Mr. Marsh, from the fact that gouty deposits outside of the joints are found in non-vascular structures like the fasciæ and tendons. It occurs more in the central than in the peripheral parts of the cartilage.

(*d*) *Loose Bodies in the Joints* (Syn.: Loose cartilages, Mures articulorum, Corpora libera articulorum, Joint mice, Floating or movable bodies in joints, etc.).—Loose bodies in the joints are classified according to their structure. There are three classes: 1, Fibromatous; 2, lipomatous; and, 3, chondromatous. (Hueter.) In size they vary from that of a small pea to that of a horse-chestnut or larger, and they are of all shapes. The smaller ones are oftenest shaped like melon-seeds or irregularly round, while the larger ones are more regularly round, concavo-convex, or spherical. Sometimes they are faceted and crowded together like the carpal bones, and sometimes they are mulberry-shaped or pyriform. In one joint they may appear singly or in great numbers, and they may vary a great deal in size in the same joint. Mr. T. Smith removed recently over four hundred from one knee-joint.[11] The knee-joint is by far the most apt to be affected, and Barwell estimates that nine-tenths of all cases occur in that joint.[28] Next in frequency comes the elbow,[40] and all of the larger joints are liable to contain these bodies, even the temporo-maxillary articulation, it is said, having been once affected. In external appearance they are whitish or yellowish, and vary from a soft consistency to a bony hardness. On section they show either a plain fibrous structure, or a fibrous sheath enclosing a mass of fat, or even the structure of hyaline or fibro-cartilage (ordinarily without corpuscles), or that of bone tissue, oftenest without Haversian canals. Not infrequently they present a combination of two of these forms.

Their chief interest lies in the method of their formation. A matter of much importance in their etiology is the fact that their presence is very often associated with rheumatoid arthritis. They are produced in several ways: 1. In the form of chronic serous synovitis, described as synovitis hyperplastica tuberosa, the hypertrophied tufts of synovial membrane often become pedunculated by so slight a stalk that it breaks and the enlarged tuft is set free in the joint-cavity; or, again, the cartilage cells occasionally found in these tufts take on activity and form a mass of fibro-cartilage, which is detached in the same way; or, rarely, an enchondroma develops from the cartilage itself and becomes detached. 2. Osteophytes grow into the joint from the periosteum, or calcareous or bony plates form in the joint capsule or cartilage (and exceptionally in the synovial tufts) in the condition of rheumatoid arthritis, and these bony masses are broken off or the nodules in the capsule are detached and form an important class of free bodies. 3. Sometimes the free body seems to be only the remains of a blood-clot or the deposition from a synovitis particularly rich in fibrine. 4. And lastly, there is certainly a class of traumatic cases which have been much discussed. Formerly it was held that these free bodies (of the chondromatous class) were the result of the direct forcible tearing off of pieces of cartilage by wrenches or strains or blows, and Hueter supports that view,[41] as does also Virchow.[42] The more modern view is represented by König, who does not deny the possibility of this tearing off of bits of cartilage, but he insists upon its rarity and shows the great force necessary to detach them in this way. Rather, he says, consider that these pieces are so bruised and injured by the trauma that their necrosis follows, and then a spontaneous osteochondritis dessicans which leads to their detachment and sets them free in the joint.

Further cases in which the traumatic origin of these chondromatous free bodies is beyond question are given by Mr. Marsh,[43] notably one where, three weeks after a wrench to the knee, a free body was removed by Mr. Simon, which Mr. Shattock pronounced to be a piece of the articular surface.[44]

There seems reason to believe that, despite the lack of blood-vessels, these bodies continue to be nourished, after being set free in the joint; not only does ossification take place after they are freed, but the case of Recklinghausen[45] would seem to show that growth is also possible.

III. Joint Affections Beginning in Bone.—The pathological appearances of primarily osseous joint-disease will be considered, so far as possible, under two heads—(*a*) degenerative, and (*b*) formative osteitis.

(*a*) *Degenerative Osteitis.*—The type can be described in a very few words—hyperæmia of the vessels, infiltration from the distended capillaries, and the formation of large spaces (lacunæ of Howship), with absorption of the trabeculæ; fatty degeneration of the bone-cells, and their final replacement by embryonic tissue. The mechanism is, then, at hand for any amount of destruction. The greater part of degenerative osteitis of the ends of the long bones follows one type, which is now called tubercular. It is not here assumed that this term is correct; the pathological appearances will be described, and the evidence for and against the tubercular character of the affection will be presented.

This type of disease presents itself ordinarily in the spongy tissue of the epiphyses of the long bones, oftenest near the line of junction with the shaft, sometimes very close to the articular cartilage, however, and sometimes in the periosteum. It presents itself under two forms (1), commonly as a single focus, or multiple foci of diseased tissue (encysted tubercle of Nélaton), and (2) rarely as a simultaneous tuberculous infiltration of the whole epiphysis (infiltrated tubercle of Nélaton). It is impossible to identify these appearances with all the various names by which they are known; some of the prominent are given. And first, the term caries must be considered, which is to-day only a loose term for all sorts of bone disintegration, used especially by surgeons. Oftenest it means this form of bone disease under consideration. It is a term which will be avoided in this article. Ziegler gives the following synonyms for tuberculous osteitis: "Caries mollis sive fungosa, scrofulöse caries, tuberculöse caries, Knochen-nekrose, Knochen-abscess, fungose arthritis, fungus articuli, Gliedsschwamm, scrofulöse Gelenkentzündung, Gelenk-caries, arthrocase, tumor albus, caries sicca," etc.[20] Of French terms may be mentioned osteopériostite tuberculeuse chronique, tuberculose articulaire, etc., not to mention such fine distinctions as tubercule tardif à évolution rapide and ostéite tuberculeuse aiguë.[46] In English one identifies, as synonyms, scrofulous joint-disease, tuberculosis of bone and joints, spina ventosa, and the greater proportion of cases of chronic articular osteitis (Gibney,[47] *e.g.*, considering no other form of this than the tubercular).

1. In the formation of single and multiple foci of disease the first change noticeable to the naked eye is the

appearance in an already hyperæmic spot of spongy tissue, of a small, grayish, yellow translucent spot, as small as can be seen, perhaps, which grows more gray and increases in size; and around it a zone of hyperæmic tissue develops, and the neighboring bone becomes a little boggy-looking from an excess of fluid transuded. There is no affection of the synovial membrane; it is purely a localized osteitis, or, more correctly, osteomyelitis. The diseased spot grows larger and begins to break in spots, yellowish, and to show a tendency to cheesy degeneration in the centre, and later in the history of the affection cavities will be found, varying in size from a pea to a hazel-nut, filled with a putty-like substance, like the cheesy material found elsewhere in the body, except that here it contains spicules of bone from the trabeculæ, and in the larger foci pieces of dead bone of considerable size. Later in the history of the affection the tuberculous nodule ordinarily breaks down into pus, and it is said that absorption at this stage has occurred, leaving nothing but a cavity filled with limpid serum.* Oftener than not the original focus is surrounded by smaller nodules which aid in its extension; but the chief work is done, as we shall see, by the erosive action of the granulations (rarefying osteitis). Sometimes a sequestrum of considerable size may be found in these cavities: the granulations have cut off the source of nourishment from a certain area of bone, and it has died and is loosened from the sounder parts and lies loose in the cheesy or liquid pus; or a piece of bone too large to be contained in the cavity may die and be loosened as a wedge-shaped piece at the end of the tibia. Ordinarily these larger pieces are of a wedge-shape, with the base at the end of the bone, the ordinary shape of an infarction. Even the whole epiphysis of the femur may be detached. The cavity, it should be noted, is sometimes sharply marked and lined by more or less of a pyogenic membrane; at first it is soft and gelatinous, later it becomes more resistant and tougher. If the retrogressive metamorphoses take place, the surrounding tissue takes on a sclerosis, a sort of scar formation.

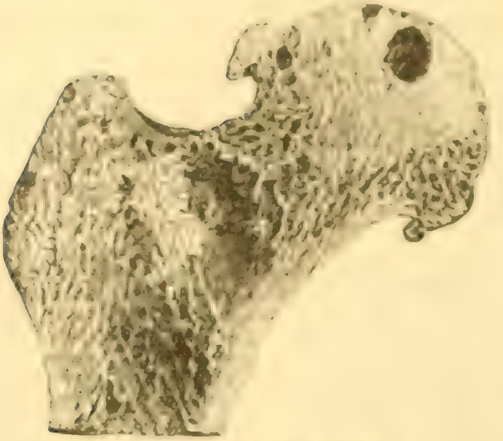

Fig. 4415.—Abscess of the Epiphysis.

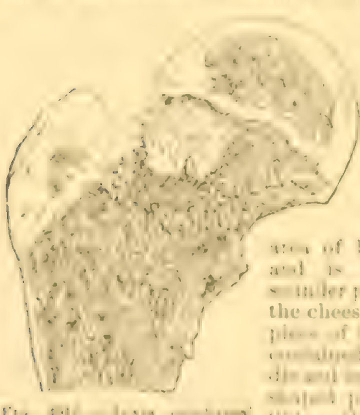

Fig. 4416.—Large Sequestrum [illegible]

From this stage of the process any one of three courses is possible: the diseased focus may be absorbed and sequestrated; it may extend to the periphery of the bone, and break through the periosteum and empty itself there; or, lastly, and probably most commonly, it may extend to the joint and infect that.

2. The second form—simultaneous tuberculous infiltration of a whole epiphysis—is much rarer than the focal form above considered. It is characterized by the deposit in the meshes of the spongy tissue of a gray substance like lymph tissue, which is in gross appearance like the focal lesion just mentioned, without limit or boundary. In spots are to be seen yellowish pus collections which ultimately extend, and the whole affected area assumes the aspect of a true purulent osteomyelitis. It is this stage that is ordinarily found on section. The true tuberculous infiltration presents a different appearance from the subsequent purulent infiltration, which is characterized by a dull yellow surface and an absence of blood-vessels.

Microscopic examination of the contents of the degenerated spots of either affection shows a typical granulating tuberculosis. As a rule, when cheesy degeneration has not proceeded too far, one finds within the low-grade vascular granulation tissue numerous and characteristic tubercles, with epithelioid and giant cells.** With the increase of cheesy degeneration the typical tuberculous becomes more and more obscure. Even in the cases where large sequestra form in the ends of the bones without any evident tuberculous foci, one can ordinarily find, without trouble, tubercles in the granulation layer between the sequestrum and sound bone.

The tubercles are found in a dense plasma composed of a great quantity of amorphous matter, fatty and calcareous granules and leucocytes. Outside of this one sees enlarged bone spaces, atrophy of the trabeculæ, fatty degenerated bone-tissue, surrounding embryonal tissue as compared the seat of disease. In short, the changes are those which we have seen accompanying long-continued hyperæmia in bone, and which constitute the rarefying osteitis of French writers.

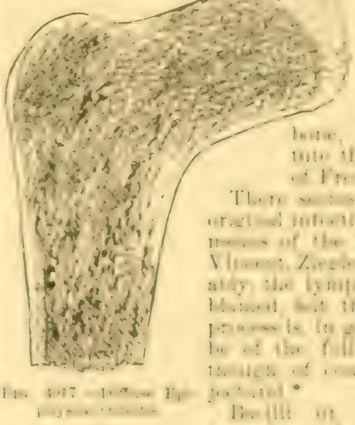

Fig. 4417.—Diffuse Epiphyseal Osteitis.

There seems little doubt that the original infection comes oftenest by means of the blood-vessels (König, Virchow, Ziegler). Sometimes, probably, the lymph-channels are to be blamed, but the beginning of the process is in general understood to be of the following character, although of course it is partly conjectural.*

Bacilli or micrococci become lodged up in the capillary of a Haversian canal, cut off the blood-supply, and start up in the neighborhood an endarteritis of the type known as tubercular, an infiltration of leucocytes, the formation of a lumen of Howship, and the formation and continual increase of embryonal or granulation tissue. The trabeculæ grow thin and the bone-cells undergo fatty degeneration and disintegrate, while their place is taken by the embryonal tissue-cells, which continually extend and soak away the bone substance. Hence the formation and extension of the diseased focus. Sometimes, however, the seat of disease is surrounded by a condensing rather than a rarefying osteitis. Kiener and Poulet make three stages of the process, which perhaps will explain the sequence a little more fully: (1) fibrous or embryonal transformation of the marrow; (2) appearance of the tubercles with condensing and rarefying osteitis; (3) caseation of the marrow and eventual necrosis of the trabeculæ. As to the absorption of a tuberculous focus the spot of diseased tissue becomes cheesy and the granulation-wall surrounding it changes from its erosive to a formative action, having a tendency to send processes into the cheesy mass, which processes become fibrous and ultimately bony tissue, but the tendency is to incomplete scarring. A bit of tuberculosis granulation remains behind perhaps for years, and explains in a measure the tendency to late relapses in this class of disease. The entire absorption of large sequestra is very doubtful (König).

---

* Kiener and Poulet (Arch. de Phys., 1883) have demonstrated that the seat of the tuberculosis [illegible] the beginning of the disease [illegible]

Primarily or secondarily, the periosteum is quite sure to be affected. If, primarily, a tuberculous focus is seen under the periosteum and the bone destruction around it is superficial, it is called a peripheral caries; but if the periosteal focus is secondary, it communicates with the original point of disease in the marrow. The periosteal foci, like the others, become cheesy or melt down to form abscesses. But even before the tubercular focus is deposited in the periosteum, increased periosteal activity begins; sometimes with absorption of the deposited inner layers, as in spina ventosa, where the whole circumference increases, yet the marrow cavity increases still more all the time; while in other cases osteosclerosis (a formative osteitis) takes up the whole bone.

With Koch's discovery of the bacillus of tubercle in 1882, there came in a new criterion in the determination of whether or no certain microscopical appearances really represented tuberculosis. The question of the importance of inoculation results belongs rather to the domain of etiology, whereas the presence or absence of bacilli is determined by a simple microscopical examination. They are found lying oftenest in the giant-cells, sometimes in the other cells; they are few in number, and hard to find. Koch[50] found them in two cases out of four in fungous joint disease. Since then various observers have found them in a varying proportion of all cases examined. Schuchardt and Krause examined all cases of "fungous and scrofulous joint disease" coming to Volkmann's clinic for some weeks, some forty cases altogether, in all of which they found the bacilli of tuberculosis; but they were very few in number, and very hard to find. A modification of Ehrlich's method was used, the details of which can be found in the article Bacteria. In one cold abscess twenty sections were required to find two bacilli. Kanzler,[51] in 15 cases of bones and joints examined, found bacilli in only 8. Müller[52] examined some 39 cases, using pus for the most part, and in a few cases he was unable to find the bacilli, although he would examine most carefully perhaps twenty preparations of each. He believes, on the strength of this, that it is possible to have tuberculous joint disease without the presence of bacilli. Castro Soffia,[53] in a great number of clinical cases of bone tuberculosis examined for bacilli, was always able to find them. Reuben,[54] in 5 cases of spina ventosa, otherwise free from tuberculous disease, found the bacilli in all cases, looking for them in the granulations, and, moreover, inoculation was successful. In general, the results of later years are more positive than the earlier results, probably from perfection of methods. The evidence presented seems to justify the conclusion that in most cases of chronic joint disease of the character just described, tubercle bacilli are present, but that the examination for them is difficult; and, moreover, that they are present in smaller numbers at the late stage, when most examinations are made; probably in the stage of invasion an examination of the tissues would show many more.

The results of inoculation experiments, as establishing the identity of bone tuberculosis, and that of the lungs, for instance, will be considered under the etiology.

Secondary Infection of the Joint.—With regard to the ultimate infection of the joint from the epiphyseal focus, the process is easily understood. The seat of the disease is ordinarily not far from the cartilage when it is beginning, as we have seen; it excites no joint inflammation, but when it reaches a certain stage, even before it breaks into the joint, inflammatory reaction in the joint begins. This is perfectly well established; take one of Lannelongue's early autopsies:[55] *e.g.*, in a case of early hip disease, a focus the size of a pea was found in the epiphysis, 2 mm. from the cartilage; it was caseous and did not in any way communicate with the joint, yet although there was no effusion the capsule was thickened, the synovial membrane in parts thickened and fungous, and the round ligament already vascular and fungous. The cartilage in certain parts was thinner and losing its elasticity. One other of his autopsies and the early resections of Volkmann[56] show the same point, even more advanced joint changes being found than Lannelongue's autopsies showed, viz., increased synovial fluid, swelling of periarticular structures, and thick and red synovial membrane.

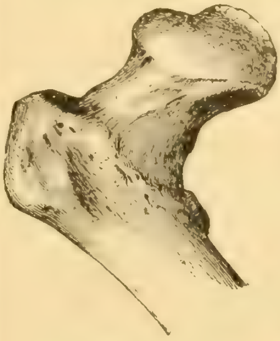

FIG. 4918.

It should be remembered that opportunities to study the early stages of joint affections are very rare, but it would seem then as if often the joint were involved and inflamed in the first place by contiguity rather than by direct infection, and, by its inflammation and softening, the cartilage over the diseased spot of bone was rendered the more ready for the direct invasion of the pus and caseous material from the primary focus. The destruction now spreads in the direction of least resistance, ordinarily in the direction of the joint surface, the cartilage being already thinned and degenerated, and the synovial membrane soft and fungous with the articular lamella perforated; the cartilage at last gives way, and the original focus cavity communicates with the joint cavity.

"The danger to the joint begins with the softening of the cheesy masses" (Volkmann). When once the pus has broken through the softened and degenerated cartilage and has reached the synovial membrane, a purulent synovitis is at once started up which speedily assumes a fungous and destructive character, and a "panarthritis" has begun. Thickening of the capsule, infiltration of the periarticular tissues, and thickening of the ends of the bones follow quickly, and abscess formation and all the other complications are ready to follow. It matters little now whether the process began in the synovial membrane or the bone; this stage being the same in its clinical appearances and its capability for evil. Any amount of destruction is of course easily possible—erosion of the articular surfaces, spontaneous subluxations and luxations of the joints, cold abscesses of any extent reaching the surface and continuing to discharge by many sinuses; and, worst of all, from the local disease comes the dissemination of general tuberculosis, or tubercular meningitis, or phthisis.

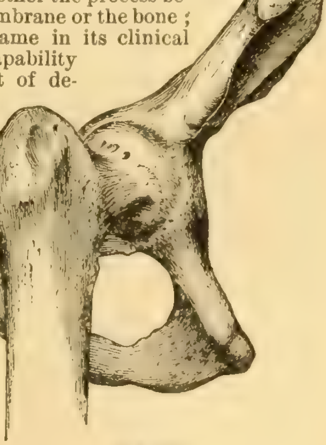

FIG. 4919.

Sometimes, however, the focus is so situated that the line of least resistance takes it to another part of the bone surface away from the joint; Volkmann showed clearly that this was no very uncommon occurrence. As it reaches the periosteum the latter thickens and inflames, and finally softening, allows the pus from the original focus to pass into the periarticular structures, there to form an abscess which must be evacuated externally or break. Sometimes this ends the disease, the granulation tissue becomes fibrous and then osseous, and the disease is over.

Gummatous Synovitis.—There is another and much less common form of degenerative arthritis which affects the subjects of tertiary and hereditary syphilis. This is characterized by the formation of gummata in the spongy tissue of the epiphyses, or more commonly in the periosteum; but a much more common location still is in the shaft of the bone. It is not common for the epiphyses to be affected before the synovial membrane, but it does occur, although synovitis is much more common from this cause. On section the bone shows, oftenest in the periphery, a yellowish-gray focus of disease, in appearance strikingly like the early stage of focal tuberculosis. But from this latter it may be distinguished, according to Schüller, by the absence of any surrounding hyperæmia or infiltration, which, he says, always goes with tuberculous disease. Often, of course, these gummata exist along with much synovitis of a characteristic type, and a much thickened and diseased periosteum. Gummata in the periosteum appear as elastic swellings, rich in fluid, poor in cell-elements; later they degenerate to stuff like pus and, by fatty degeneration and absorption, a cheese-like substance and scar tissue; and finally only a thickening remains.

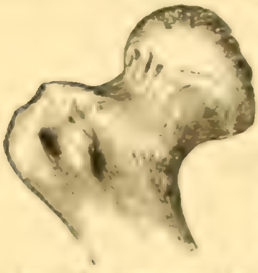

FIG. 4[illegible].—Destructive Epiphyseal Osteochondritis.

Secondarily to these periosteal and bone lesions come the capsule and synovial thickening, and the cartilage degenerations noted above.

Osteochondritis.—One special form of syphilitic disease deserves mention, viz., syphilitic osteochondritis with accompanying epiphyseal periostitis and perichondritis as Ziegler calls it. Before the joint is infected, one finds a circular swelling around the epiphysis; this is a periostitis with much spongy tissue under the periosteum, which later affects the joint perhaps with a destructive purulent synovitis,[67] or a subacute or chronic synovitis with much effusion and thickening.[68] Occasionally the inflammatory process is of such a character that the epiphysis is loosened from the shaft by the destructive process.

To make the diagnosis between syphilis and tuberculosis from the appearance of the bone alone might occasionally be difficult, but aided by clinical characteristics there would not often be much difficulty.

The microscopical structure of the focus of disease shows a typical gummatous structure.

Acute Infectious Osteomyelitis.—Acute infectious osteomyelitis sometimes affects the epiphyses of the long bones and in that way secondarily infects the joints. It begins in the bone-marrow or the periosteum. The marrow becomes hyperæmic, the periosteum infiltrated and thickened, and in both are seen beginning foci of pus, and sometimes hemorrhages in their tissue; soon pus formation obscures everything, and the bone fairly melts away; large collections of pus may form between bone and periosteum. Ordinarily this affects the shafts of bones, but sometimes the epiphysis, and secondarily the joint, become infected when the foci of disease are near the joint; like the tuberculous foci, they tend to infect it.

Cocci are constantly found,[69] oftenest staphylococcus pyogenes aureus and albus. Extensive necrosis results.

Simple or Traumatic Ostitis [illegible] affecting the joints is very different. In the traumatic form one finds blood effused and beginning inflammatory processes of the kind described above as typical. The periosteum is infiltrated and the bone-marrow filled with a fluid cellular exudation. Then it depends upon circumstances whether absorption will take place, or whether pus formation will begin and the trabeculæ will be absorbed and the bone broken down, or whether the whole affair will take on the tuberculous type and run the course of that affection. If no infection comes, wounds, tears of the joint capsule, fractures, etc., result in only a series of fractures or bloody effusion into bone, joint, and capsule; but where the bone is opened, so that infection may take place, destruction and necrosis are only too apt to result.

Formative Osteitis (*Arthritis Deformans*).—The chief kind of formative osteitis affecting the joints to any degree is the form known by the following names: Rheumatic gout, chronic rheumatic arthritis, arthritis sicca, arthritis deformans, osteoarthritis, senility of the joints, rheumatoid arthritis, nodular rheumatism, dry arthritis, proliferating arthritis, malum senile, chronic articular rheumatism. The name arthritis deformans will be adopted here, inasmuch as it describes the condition and involves no etiological theory.

The condition has been asserted to have its origin in the bone,[?] the synovial membrane (R. Adams and Smith, Volkmann, Cruveilhier), and the cartilage (Marsh, Ord, R. Smith, Cornil and Ranvier).

The weight of modern authority places its ordinary origin in the cartilage, or the cartilage and synovial membrane. There is a thickening of the synovial membrane, a hypertrophy of the fringes, and finally the development of the shaggy surface already spoken of. The changes in the cartilage are of the usual type of cartilage inflammation, only more severe. The hyaline substance becomes fibrillated, and where there is pressure it is worn away in small patches or large surfaces, exposing the bony lamella, which speedily becomes polished and ivory-like from the friction. The same process of cartilage degeneration taking place at the periphery results differently. There is freedom from pressure enough to wear away the degenerated substance, and the covering of synovial membrane retains the proliferated corpuscles, cells which remain and, taking on a formative activity, make the marginal hypertrophies or ecchondroses already mentioned.

Sometimes these perforate the synovial membrane and become intra-articular, and often break off to form loose bodies; at other times they grow laterally, and do not encroach upon the joint. Inasmuch as these ultimately ossify, an explanation of the extreme changes in the shape of the ends of the bones is afforded. The chief changes are to be found in the bones. The destruction of the overlying cartilage leads to the exposure to friction of the articular lamella and the consequent irritation of the articular ends of the bones. This irritation is followed by hyperæmia and a consequent slight degree of rarefying osteitis, which is the necessary first stage of a formative osteitis; but after the enlargement of the Haversian canals and the degeneration of the bone-cells, a formative activity springs up in the periosteum, and in the endosteum covering every one of the cancellar walls, and a compact "eburnated" layer is quickly made, which covers the exposed end, under which layer a formative activity is going on, while the polished surface is always being worn away; and to this constant wearing away is due the "worm-eaten" appearance so generally spoken of, which is due to the exposing of the end of the Haversian canals. But while pressure and friction are wearing away the centre of the articular ends of the bones, the margins where pressure and friction are slight are rapidly proliferating. Hypertrophy of the cartilages here affords a field for the deposit of lime salts, and the hypertrophic bony enlargement is closely bound up with the development and increase of the marginal ecchondroses already alluded to; their growth goes on superficially, while ossification takes place in the deeper layers by a process similar to physiological ossification. These lumps internally, then, are bony; superficially they are cartilaginous. Growing out with surprising rapidity, they form a buttress-like growth which speedily restricts the motion of the joint; although true anchylosis rarely or never takes place, the stiffness and loss of joint movement being due to this overhanging bony growth.

Extra-articular changes.—Degeneration of the ligaments takes place early in the affection—they first become inflamed, then thickened and degenerated into a substance like fibro-cartilage or elastic tissue, and in this stage the joint may show marked lateral mobility; and finally, at the attached border of the capsule as well as in the ligaments themselves, there begins a dense bone formation which contributes to the ensheathing bony mass. The osteophytes are more rounded and flat than one is accustomed to see in bone formation, after fractures, *e.g.*, and from the fact that ossification is not preceded by any especial vascularity, the new-formed bone is more dense and compact than normal; the tissues ossify just as they are. The muscles controlling the joint atrophy, from disuse largely, and the tendons are "absorbed" as well as the intra-capsular ligaments. "The absorption of tendons is best illustrated in the shoulder, where that part of the long tendon of the biceps which lies within the capsule is often found displaced from its groove and frayed out, or completely worn through, and its two ends, separated by a considerable interval, are adherent to the subjacent bone."

There is oftenest at the commencement more or less synovial effusion, but suppuration practically never occurs, and synovial effusion occupies at most a subordinate place. In the late stages there is apt to be periarticular œdema of the affected joint, and the skin, even before that, becomes thin and drawn, and shows most plainly the deformed outline of the joint.

Exostoses. Exostoses of the articular ends of the bones are rarely large enough to affect the joint, except by involving tendons in their growth. They are of two kinds: first, small spur-like processes or rounded projections, the result either of an inflammatory process, or of a simple hypertrophy; and, second, several large lobulated, spongy masses of bone called diffused osteoid tumors, which occasionally involve and destroy a joint, as in the cases of Paget [60] and Lancereaux,[29] where the knee-joint was so badly involved by the growth of one of these osteoid tumors from the tibia and femur that amputation became necessary. In structure they all show typical bone formation, and both classes belong rather to the order of pathological curiosities.

Morbid Periosteal Growth. There is, of course, a certain amount of formative osteitis of the articular ends of the bones accompanying tuberculous and syphilitic disease of the epiphyses, from the deposit of either tubercles or gummata in the periosteum, and oftener perhaps from the simple morbid activity of the periosteum. Thickening of the great trochanter in hip disease, *e.g.*, is a well-marked physical sign in most cases.

IV. DISEASE OF PERIARTICULAR STRUCTURES AFFECTING JOINTS.—(*a*) *Ligamentous Affections.*—It was formerly thought that diseased ligaments were often the cause of chronic joint disease. William Adams wrote: "Strumous joint disease commences most frequently in some of the ligaments of the joints." To-day we know that the commonest beginning of chronic joint disease is in the bones; yet the fact remains, that a wrench or sprain causing evidently injury to a ligament (of perhaps ever so slight a character) is sometimes the starting-point of a chronic joint affection.

Ligaments are as slow to repair as they are to inflame; occasionally they are found in a state of inflammation, in which case they are thick and pulpy, even when no laceration has taken place. In gout they may be the seat of the deposit of chalk-stones (tophi) before other localities are affected.

(*b*) *Periarticular Abscess.*—Suppuration in the peri-articular cellular tissue and subsequent affection of the joint, may start from an open skin-wound which has been infected, or from an injury to the limb where cellulitis has come on in consequence of the trauma. Again, in children of feeble type, periarticular abscess of a slow and chronic character is not unlikely to arise after slight bruises, and sometimes after no perceptible injury at all. Any of these abscesses, if they are not at once evacuated, are, of course, likely to infect a neighboring joint; occasionally, the abscess from one diseased joint burrows a long distance, and in its course either opens into another joint or passes so near to it that infection of the second joint takes place. This may follow psoas abscesses, where the pus travels near enough to the hip to infect it. This explains a certain number of the cases of hip disease secondary to Pott's disease.

(*c*) *Inflammation of Bursæ.*—The inflammation of bursæ from wounds, bruises, or constitutional causes, may lead to the secondary inflammation of the joints with which they happen to connect. For example, the large bursa between the neck of the glenoid process and the subscapular muscle is ordinarily in connection with the shoulder-joint, as is the case more rarely with the bursa under the deltoid. The bursa beneath the triceps tendon is oftenest a prolongation of the elbow synovial membrane. The bursa under the psoas and iliacus tendon frequently communicates with the hip-joint, and the bursa in the popliteal space often communicates with the knee-joint. These are the common paths of communication, but at most joint disease is rarely caused in this way.

As other causes of impairment, rather than disease, of joints, may be mentioned the following: cicatrices after burns, wasting of muscles and ligaments after infantile paralysis, and muscular contractions causing malpositions of the joints after hemiplegia, etc.

JOINT AFFECTIONS DEPENDENT UPON A CONSTITUTIONAL DISEASE.—Joint affections may be simply the local manifestations of a constitutional disease as in rheumatism and gout, and to a certain degree in malignant disease and syphilis.

Tuberculous affections are primarily local, but dependent on a diminished power of resistance on the part of the patient. A consideration of this view of the subject is important.

(*a*) *Tuberculosis.*—It was noted, in speaking of the chief class of degenerative osteitis, that microscopical evidences of tubercle structure were found, and that, moreover, tubercle bacilli in small numbers were almost always present in the same group. The importance of inoculation results is perhaps of more consequence in establishing the etiology of this affection than either of these others.

Hueter injected sputa from phthisical patients and detritus from tubercular glands into the joints of dogs, and found that it excited in them a synovitis hyperplastica granulosa, as he terms it, of the same type that one finds in tumor albus, etc., of the human subject. From this focus a general tuberculosis often developed, and caused the death of the animal.[26] Also, he introduced the granulations from a human tumor albus into the circulation of several dogs, and caused, with much regularity, general miliary tuberculosis. Schüller [61] threw further light on the relationship between joint affections and general tuberculosis by the following experiments: Guinea-pigs and dogs were rendered tuberculous by inhaling solutions of phthisical sputa and tuberculous detritus for half an hour a day for several days, and by the occasional injection into their lungs of the same solutions. The knee-joint of each was then wrenched or violently contused, and, with a few exceptions, a synovitis granulosa hyperplastica of a purely tuberculous type followed in the injured joint, while but few tubercles were found in the lungs. Similar injuries to healthy animals caused no such joint disease. Barwell [62] takes exception to these experiments, and considers that Schüller's experiments conclusively prove "that a tubercular state of the body does not produce joint disease. In other words, the earlier phases of joint disease are not tuberculous," chiefly on the ground that in only six of the twenty-four animals were structures like tubercles found in the granulations of the diseased joints, and these structures Barwell considers as purely inflammatory. He is, however, the only author of note who rejects Schüller's very careful work, and his article is not convincing or modern.

Müller [63] showed very clearly the channel of infection by which the bacilli enter. Tubercular material was injected into the femoral artery of sixteen rabbits with no results, next into the crural arteries (whence come the bone-nutrient arteries) of ten other rabbits, and in some of them were found tuberculous bone lesions. Finally, the nutrient arteries were found, and into them alone the tuberculous material was injected in twenty goats, and were dispersed there. The germ alone yielded positive results. Most of those whose arteries were injected showed typical local tuberculous disease of the ends of the bones. One young goat was well for four months, then he began to limp, and at the end of thirteen months his knee joint showed a typical fungous joint disease, beginning as a cheesy focus in the bone, with a wedge-shaped sequestrum and several tuberculous foci around.

Schuchardt, on the other hand, failed to produce tuberculosis in animals by the injection of fungous material into their circulation. Garré, using the pus from cold abscesses, usually of joint origin, found specific bacilli present in only a small number, and attempts at cultivation in these gave no results; but this pus injected into animals caused general tuberculosis. More recently still, Tresse put pathological sputa and pus from the cases of diseased joints into the epiphyses and diaphyses of the bones, with the result of starting up a disease like bone tuberculosis in the human being, and once a knee injection caused also a synovitis.

Burdon Sanderson and Klein have obtained practically the same result from inoculation experiments, and those of Villemin are historical.

So much for experimental inoculation in animals. The generalization of tuberculosis from a diseased joint in the human subject is a process unfortunately of such common occurrence that it can be passed over very briefly, and it shows even more clearly than experimental inoculation the relationship of tuberculosis and this class of joint diseases. A few figures may show the great liability of this. Billroth found that fifty-four per cent. of patients dying with this form of joint disease died of acute miliary tuberculosis; Jaffé that fifty-three per cent. of the deaths are from general tubercular infection. Gibney's extensive statistics show that in hip disease tuberculosis is, in spite of antiseptic precautions, the commonest cause of death. Nor does the removal of the diseased joint seem to diminish this liability very much. König did 117 resections for this class of joint disease, and of 25 deaths he found 18 due to general tuberculosis, and 9 more patients hopelessly tuberculous; and he has more recently called attention to the danger of "operative tubercular infection," where, by opening the lymphatic and blood channels in an operation which at the same time stirs up the focus of disease, tuberculous material is carried over the body, and general tuberculosis results.

Caumont found no preventive effect in resection, for in twenty-six cases of hip disease, treated expectantly, one-fifth died of generalized tuberculosis, while twelve others were resected and one-third died of the same cause. Yale says, in quoting it, "Others may have had better results, but the prophylactic effect cannot be very decided if such marked exceptions occur." Esmarch agreed with König as to the small preventive value of resection.

In the causation of this form of joint disease, characterized by this formation of tubercles and this tendency to generalize, much stress has always been laid upon the inheritance of what has been called a "scrofulous tendency," an inherited vice of constitution. The use of the word "scrofula" has intentionally been avoided here, and the reader is referred to Mr. Treves' "Manual of Surgery" for a discussion of the relation of scrofula and tuberculosis. "The modern view holds, although by no means is this generally accepted, that 'tuberculosis' is a definite infectious parasitic disease, and that scrofula—although presenting certain modifications arising from the difference of the tissues in which it is seated—is, from a pathological point of view, identical with tuberculosis." In accordance with this view, the word scrofula will, therefore, not be used in speaking of this class of joint diseases, as referring to the inheritance of tuberculosis, or a tendency to it, from the parents.

Experimental investigation has shown clearly enough the possibility of the transmission of tuberculosis from parent to offspring. Landouzy and Martin, taking a six-months' fœtus born of a phthisical mother, found it to all appearances perfectly free from tuberculosis; yet a piece of its lung put into a guinea-pig's stomach caused general tuberculosis in four months, and inoculation was then carried through five animals. The cardiac blood from another fœtus caused the same tuberculosis in other guinea-pigs. Again, one of these tuberculous guinea-pigs gave birth to a litter, and a young one of two days was killed and appeared perfectly healthy, yet pieces of its viscera inoculated into other guinea-pigs caused general tuberculosis. And finally, the semen of a guinea-pig thus rendered tuberculous was removed from the vesiculæ seminales with much care, and being inoculated into other guinea-pigs, it soon caused tuberculosis.

It is, of course, impossible to determine what proportion of children inherit these diseases or a tendency to them. Gosselin analyzed 300 cases of different tubercular joint diseases, and found tuberculous disease in one or both parents in sixty-eight per cent., and what he calls an "acquired diathesis" in thirty per cent. more; and of the whole number, after a close investigation, he could only find one case which did not present an acquired or hereditary diathesis; but he represents an extreme point of view in the matter. C. Fayette Taylor, in the analysis of 845 cases of Pott's disease, found thirty-four per cent. where there was tubercular or so-called scrofulous disease in the parents, and in sixty-six per cent. the disease came on in patients of a sound diathesis.

In 401 cases of hip disease from the Alexandra Hospital Reports, twenty-four per cent. had phthisis in the family history, and thirty-five per cent. were classed as traumatic. Albrecht, tabulating 825 cases of tuberculous disease of various joints as to etiology, classed thirty-three per cent. as "associated with scrofula."

The chief opponents of the point of view that these joint diseases are oftenest the results of inheritance are those who hold, on the ground of experiment, that the common cause is an injury to the joint. We have seen that trauma to the joint of a tuberculous animal will cause tuberculous joint disease, but that it does not do so in the healthy animal. It has been established that contusions and wrenches cause the effusion of blood in the spongy tissue of the bone. König has seen cases where tubercles developed directly from the clot, just as in a syphilitic individual a gumma will develop at the site of an injury to the bone. "There are cases where the swelling from the fall merges into the tuberculous swelling."

The fact remains that joint disease of a tuberculous type often follows injury in the case of children whose family histories are exceptionally good. Such cases must come under the observation of every surgeon. König estimates half the cases as traumatic; Albrecht, one-sixth; Croft, thirty-five per cent.; Gibney, forty-two per cent. (of which seventy-two per cent. were also hereditary); Taylor, fifty-three per cent. on 845 cases; and Sayre still represents the extreme view on this side in maintaining that practically all are traumatic. Gibney observed 845 cases of spinal paralysis in a class of children subject to constant falls and injuries, for several years, and found only 4 complicated with joint troubles. Roser observed 100 children at Marburg with fracture of the elbow, and in no case did tubercular disease follow. Stadler says, "Experience proves that traumatism excites only acute disease as a rule. In those constitutions strong enough to resist and repair the injury, these acute troubles soon subside. Under reverse circumstances they are apt to be followed by a chronic form of inflammation which may end in suppuration." There is no authority in the matter; the views of the most eminent men are but expressions of opinion. Adams, Agnew, Barker, Sayre, Petit, represent the advocates of traumatism. S. D. Gross believed that it could not exist without a vitiated constitution. Volkmann says, "Individuals with fungous joint disease spring practically without exception from families in which scrofula and tubercle are hereditary." That such is the rule, but that exceptions are common, is the view held by Schuchardt, König, Howard Marsh, Roser, and the majority of modern writers.

Exanthemata. A certain number of cases of joint disease of this type develop after the exanthemata. Gibney sets it at eighteen per cent., and Croft at 7½ per cent.; but the subject has been but little investigated.

Distribution. The frequency with which different joints are affected can only be learned by the consideration of large groups of cases. Schuller[80] gives the following table from 439 cases of Socin and his own: Knee, 35.8; hip, 15.9; elbow, 12.7; tarsus, 11.8; foot, 9.6; hand, 6.2; shoulder, 4.1 per cent., etc.

Billroth and Menzel[81] in 1,996 cases found the distribution as follows: Vertebral column, 35.2; knee, 11.9; head bones, 10.2; hip, 9.4; sternum, clavicle, ribs, 9.2; ankle and foot, 7.5 per cent.

Of 421 cases observed at Basle[82] 265 were classed as caries, and 156 as fungus disease, and their location was

Caries.	
Head	8.3 per cent.
Pelvis...........	33.6 " "
Upper extremities	22.3 " "
Lower extremities	33.6 " "
Multiple	2.2 " "

Fungus Disease.	
Upper extremities	25.6 per cent.
Lower extremities	74.3 " "
Hip	41 " "
Knee	50 " "
Foot	25 " "

Gibney, in 614 cases, mostly in children, found 209 cases of spinal disease; 271 cases of hip disease; 103 cases of knee disease; 31 cases of ankle disease.

Five hundred and thirty cases of chronic joint disease of this type in children have been observed in the surgical out-patient department of the Boston Children's Hospital, in the last three years, and they have been located as follows: Hip, 220; knee, 64; ankle, 36; vertebral column, 202; shoulder, 3; elbow, 1; wrist and fingers, 4.

At the New York Orthopedic Dispensary, dealing also almost wholly with children, from 1884 to 1886, inclusive, there were observed 2,644 cases of chronic joint disease of this type, in which there were 1,178 cases of hip disease; 1,024 of vertebral disease; 83 of ankle disease; 319 of knee-joint disease; 7 of wrist disease; 11 of elbow disease; 11 of shoulder-joint disease; 11 of multiple joint disease.

Age. Tuberculous joint disease is pre-eminently a disease of childhood. It is rarely, if ever, congenital,[55] and under one year it is not common. Of Gibney's 860 cases, so often alluded to, 84½ per cent. of all cases occurred before fourteen. Of 619 cases of hip disease tabulated by Mr. Wright,[83] there were:

Under 6 years	40 cases.
From 6 to 10 years............	110 "
" 10 to 15 "	129 "
" 15 to 20 "	66 "
" 20 to 25 "	39 "
" 25 to 30 "	17 "
" 30 to 35 "	9 "
" 35 to 40 "	4 "
" 40 to 50 "	3 "
" 54 to — "	1 case.
Total........................	418 cases.

And

Two years and under...........	28 cases.
From 2 to 5 years............	62 "
" 5 to 10 "	81 "
" 10 to 14 "	30 "
Total........................	201 cases.

Mr. Bryant has tabulated 360 cases as follows:

Under 4 years	126 cases.
From 5 to 10 years............	97 "
" 11 to 20 "	86 "
" 21 to 30 "	27 "
" 31 to 40 "	13 "
Above 40 years.................	11 "
Total........................	360 cases.

Taking Mr. Wright's and Mr. Bryant's cases, and adding 365 others reported by Dr. Sayre,[84] we have 1,344 cases of hip disease, of which 1,000 occurred under fifteen years of age. This is perfectly natural, for the tubercular diseases affect the growing epiphysis or the epiphyseal junction during the period of activity, and tuberculosis of all sorts is common in childhood.

The records of the New York Orthopedic Dispensary show the liability at different ages in the cases of joint diseases of the leg treated for the years 1884–1886:

	Under 3.	3 to 5.	5 to 10.	10 to 15.	15 to 20.	Over 20.
Hip	115	316	509	140	47	51
Knee.......	43	69	94	28	22	63
Ankle......	12	18	24	18	4	7
	170	403	627	186	73	121

The liability of the aged to tuberculous joint disease must, however, not be overlooked. The fact that people over sixty are more often "scrofulous" than people between thirty and fifty, is noted by Sir James Paget.[85] The patients may be seventy-five or ninety, and cases of hip disease present the same pathological appearances here as in young children. Paget speaks of the affection as one which he frequently meets. The course of the disease is naturally more rapid and destructive than in the young.

There is probably a slightly larger proportion of tubercular joint disease among boys than among girls. Of 619 cases of hip disease collected by Wright, there were 371 males. Holt,[73] in 2,307 cases of hip disease, found 1,178 males and 1,129 females, but the preponderance is very slight, and Mr. Bryant thinks one sex as liable as the other. Barwell thought that the presence of phimosis in a measure accounted for this preponderance of males in hip disease, at least, and in 100 cases of hip disease he found 83 in a condition of more or less complete phimosis. Wright examined 63 cases taken at random, 12 of which were hip disease, and he found, although the number is too small to generalize from, that in the hip-disease cases sixty-seven per cent. had phimosis, while in the others only fifty per cent. Dr. Sayre is also an advocate of phimosis as an exciting cause of hip disease, but its true place has yet to be settled.

Quiet disease, a term applied by Paget, simply refers to a class of tuberculous joint disease characterized by absence of all characteristic symptoms. Muscular fixation is present, however.

(*b*) *Joint Complications in Acute Infectious Diseases.*—The acute infectious diseases in which joint complications occur are as follows: Measles, scarlet fever, smallpox, typhus fever, typhoid fever, cerebro-spinal meningitis, pneumonia, dysentery, diphtheria, erysipelas, epidemic parotitis, pertussis, puerperal fever, pyæmia, septicæmia, malaria, gonorrhœa, and after the use of catheters and sounds.

The pathological appearances are those of acute and chronic serous or purulent synovitis of one or several joints. Sometimes the inflammation assumes a pseudomembranous character, as occasionally in scarlet fever and puerperal fever. The infectious material ordinarily reaches the joint through the circulation, but sometimes, as in puerperal fever, acute infectious osteomyelitis, and erysipelas, it comes from separate foci of disease, either by the lymph-channels or by direct extension.

These diseases are now almost universally attributed to the presence in the joints of micro-organisms of infectious character. Such theories as that of William Ord, *e.g.*, that gonorrhœal synovitis is the result of reflex nerve disturbance, have not enough in their favor to make them acceptable in the present tendency of pathology. Micro-organisms are found in the diseased joints and in serous synovitis, their character differing from those in purulent synovitis. It seems as if the question of whether the synovitis were to be a mild serous one, or a violent destructive purulent form, was determined by the kind of micro-organism reaching the joint, rather than by the especial infectious disease which may be present. In serous effusions one finds the organisms which characterize the especial disease present, and in greater or less number different forms of pyogenic cocci; whereas in purulent and phlegmonous processes one finds exclusively such regarded as simple but except pyogenics in enormous numbers. These facts have been established in the joint diseases of scarlet fever, acute infectious osteomyelitis, puerperal fever, etc. It is suggested that the synovitis of rheumatism is of the same character, but no evidence in support of the theory has been adduced. Gonococci alone have been found in gonorrhœal synovitis, but as a purulent urethritis not uncommonly supervenes, it must be assumed that pyogenic organisms reach the joint. The fact that synovitis occasionally follows urethral irritation, where gonorrhœa is not present, is well established, e.g., after dilatation for stricture.

Joint complications occur oftenest during the full course of the general disease, when they are apt to be polyarthritic, but in scarlet fever they generally come on at the time of desquamation, and in small-pox in the suppurative stage. In other affections they are commonest toward the end of the disease, as in diphtheria, after weeks or months of gonorrhœa, and late in dysentery as well. Of course they only occur in a very small proportion of all cases; coming late in the disease they are much more apt to affect only one joint.

But little is known of the general liability of the different joints; the knee is, however, clearly the one most often attacked. With regard to scarlet fever Thomas found the small joints of the extremities oftenest attacked, while Gerhardt, in his cases collected, found the larger joints of the upper extremity most liable.

Nolen collected, out of literature, 118 cases of gonorrheal joint affections (111 men and 7 women), which affected 308 joints in the following relation: knee, 86; foot, 52; shoulder, 29; hand, 26; fingers and toes, 17; metatarso-phalangeal, 16; hip, 15; elbow, 13, etc. One joint alone was affected 21 times; two joints were affected 12 times; three joints were affected 12 times; many or all joints were affected 15 times.

(c) *Rheumatism.*—Rheumatic joint affections attack oftenest the knee, then the foot, elbow, hand, shoulder, hip, etc. They are monarticular or polyarticular, and are either the outcome of an acute joint rheumatism, or an affection beginning spontaneously, or more rarely resulting from some injury.

The structure attacked is chiefly the synovial membrane, which secretes much fluid and takes on the appearances of chronic proliferating inflammation, with a tendency to connective tissue formation. In long-continued cases the cartilage shows the signs of chronic inflammation; thickening of the ends of the bones is not uncommon. The whole tendency is away from suppuration and toward connective tissue formation. One form, which Schüller calls arthritis rheumatica ankylopoetica, shows but little or no effusion, but a tendency to the formation of fibrous, and later bony, anchylosis. This ordinarily occurs in people of lowered vitality through want, or the use of improper food.

Often what appears to have been originally simple chronic rheumatism shows the signs of arthritis deformans. For the most part, purely rheumatic affections attack youths and persons of middle age (Schüller). The article on Rheumatism deals with the more general manifestations of the disease.

(d) *Arthritis deformans* (or rheumatoid arthritis) is characterized by the clearly marked series of changes described as the chief group in formative osteitis. It is both monarticular and polyarticular, oftenest the latter, and its victims are selected from those who are between the middle aged and old; retrograde changes in nutrition seem to be essential for its development. How much of the disease is of nervous origin and how much is rheumatic, is entirely unknown. Joints are attacked in the following order: knee, hip, shoulder, elbow, hand, foot, etc. (Schüller); others place the hand and finger joints first in frequency.

It is more common among men than women, and women whose catamenia have ceased early are especially prone to the disease. It is not unknown, however, among children, perfectly typical cases occurring in them.

It may seem to be set up by injury, by dampness or insufficient food, and often no cause at all can be assigned for it.

Attacking the hip, it is known as "malum coxæ senile," a perfectly well-defined affection clinically.

(e) *Gout.*—The joint affection, which is the manifestation of the constitutional malady known as gout, generally begins as an acute affair, and then settles into a chronic inflammatory process, increased by repeated exacerbations. The synovial membrane first presents the appearances of acute inflammation; the cartilage also shows a tendency to inflammatory degeneration and necrosis, and on its free surface and in its tissue appears a deposit of urate of soda, as well as in the capsule and periarticular structures, where localized deposits are known as "tophi." Bony anchylosis may occur, and there is but little tendency to suppuration, unless the calcareous deposits ulcerate through the skin by pressure and act upon the periarticular tissue. The common seat of the affection is the metatarso-phalangeal joint of the great toe. Scudamore found one hundred and forty out of one hundred and ninety-eight cases to start there; and from that joint it tends to invade the other joints of the foot, the joints of the hands, and the knee and elbow joints. The article on Gout deals with the etiology and general manifestations of the disease.

(f) *Syphilis.*—Joint inflammations in syphilis occur at three stages of the disease: (1) In the early secondary stage; (2) in the tertiary stage; (3) in hereditary syphilis. Each of these forms must be mentioned separately.

(1) Coincident with the skin eruptions, the sore throat, the iritis, etc., of the early general manifestation of the disease, there is occasionally, though not commonly, seen a simple serous synovitis. No post-mortem examinations of joints in this condition are recorded. The joints most commonly affected are, in the order named, the knee, hand, elbow, foot, and fingers.

(2) In tertiary syphilis there are two manifestations of what is practically the same pathological process. The development of gummata in the peri-synovial tissues, with chronic hyperplastic synovitis, and later, cartilage destruction. And secondly, the development of gummata in the bone and a secondary affection of the joint, as we have seen under degenerative osteitis.

(3) The joint manifestations of hereditary syphilis fall under four classes, which are sufficiently well marked to be considered separately.

A simple serous synovitis attended with much effusion, and a tendency to cartilage necrosis in spots; the capsule may be more or less thickened, but the epiphyseal cartilage remains normal.

An osteochondritis, with an accompanying epiphyseal periostitis and perichondritis, as already considered under degenerative osteitis, with its accompanying chronic synovitis and, worst of all, its tendency to separate the epiphysis from the shaft of the bone.

A chronic serous hyperplastic synovitis, with papillary growths and gummatous changes of the synovial membrane. And lastly, joint inflammation, the result of syphilitic osteitis, periostitis, and osteomyelitis of the long bones.

The classification followed is practically that of Max Schüller.

Syphilitic joint disease attacks oftenest the knee, then the elbow, the small joints of the fingers, and the toes, the metacarpo- and metatarso-phalangeal joints, then the joints of the hand, the hip-joint, the ankle, and the sterno-clavicular joints in the order named.

In 61 cases of syphilitic joint disease collected from various authors, the distribution was as follows: knee, [illegible]; joints of hands and feet, 20; the elbow, 12; and the remainder about equally distributed among the joints mentioned above.

(g) *Hæmophilia.*—Occasionally, in the peculiar diathesis known by this name, one meets with a unique kind of hæmorrhage from the synovial membrane of the joints, as well as from the serous membranes in other parts of the body. It comes on either spontaneously or in consequence of some injury, and affects oftenest the knee, elbow, and ankle. Fresh dark blood is poured out and the cartilage, ligaments, and synovial membrane are stained by it, and the cartilage shows a tendency to degenerate. Microscopical examination of the cartilage in the case reported by Mr. Legg, showed only the ordinary early changes of inflammation. All the changes seem purely the results of synovial hæmorrhage.

(*h*) *Rachitis.* — Rickets needs only to be mentioned as an occasional cause of joint disease. The swelling of the ends of the long bones is of course characteristic, and in addition to that the twisting and bending of the shafts warps and distorts the articulations, so that the whole bearing of the knee-joint, for instance, may be changed. The stretched ligaments yield, and incomplete dislocations may result.[92] A laxity of the peri-articular ligaments often occurs in the early stages of rickets.[93]

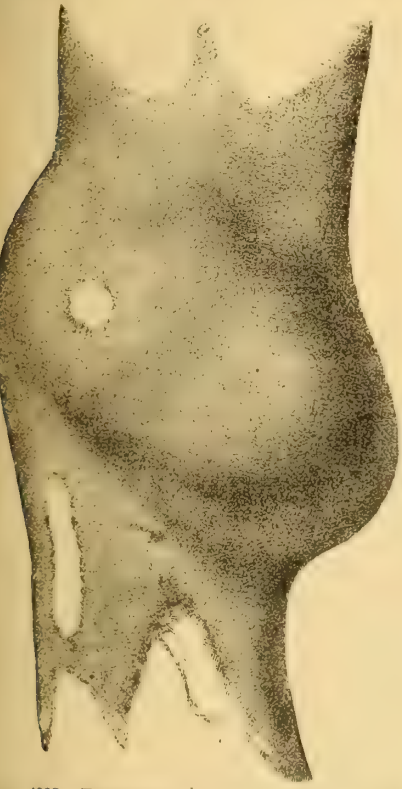

Fig. 4922.—Enlargement of the Knee-joint in a Case of Spinal Arthropathy. (Morrant Baker.)

Joint Affections Dependent upon Disease of the Nerves or Nerve Centres.—(*a*) *Spinal Arthropathies.* — Diseases of the joints dependent on diseases of the nerve or nerve centres are, as yet, but little understood. Cases, however, have been reported where local joint manifestations appeared to be secondary to the angular curvature of spino-hemiplegia, traumatism of the spine, and gunshot wound of the brachial plexus.

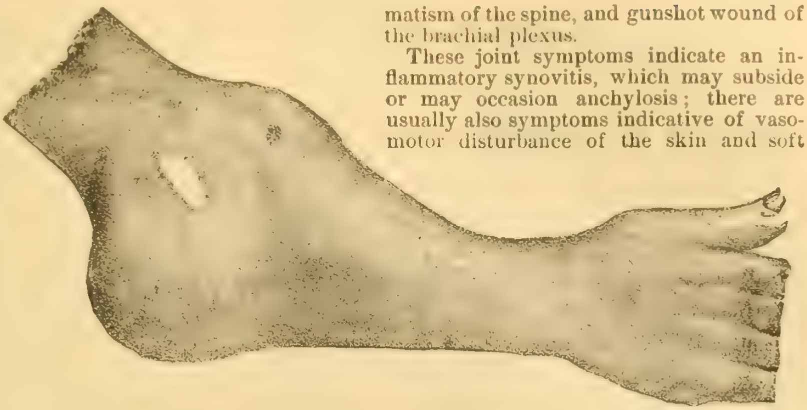

Fig. 4921.—Enlargement of the Elbow in a Case of Spinal Arthropathy. (Morrant Baker.)

These joint symptoms indicate an inflammatory synovitis, which may subside or may occasion anchylosis; there are usually also symptoms indicative of vasomotor disturbance of the skin and soft tissues, hyperæsthesia, etc.[94] In locomotor ataxia (tabes dorsalis) the joint symptoms are quite definite and characteristic.

Joint Affections in Tabes Dorsalis.—This affection, which was first demonstrated by Charcot, attacks the joints in the following frequency: out of 107 cases the knee was affected 78 times; the hip, 31 times; the shoulder, 21 times; the tarsus, 13 times; the elbow, 10 times; the ankle, 9 times; the wrist and jaw, each 2 times, and the spine, 1 time.

The joint symptoms usually appear suddenly, without known cause, and often without pain. The joint affection appears at an early stage of the disease of the spinal cord. The swelling of the joints may be quite large, and consist of an effusion in the joint, and an œdema of the whole limb. This often appears suddenly, and may subside, in part, with equal rapidity. There are, of course, severe and milder types. In the severe cases, the synovial membrane is pale and covered with granulations, the capsule is thickened and covered by a deposit of lime, and in the severest the capsule is entirely absorbed, and the ends of the bone are distorted, hypertrophied, or atrophied. The effusion is rarely purulent, and if so, it is due to violence. Luxation and spontaneous fracture may occur (Fig. 4923). The affection is, by Virchow and others, considered to be due to predisposition in the bones to faulty cellular change, resulting from the nervous disease of the spinal cord.[95] Pathologically, the morbid changes do not differ greatly from those of formative osteitis (arthritis deformans), except that the process may be much more extensive. The clinical course is ordinarily chronic, but it may become rapid and be attended by complete disability of the joint.

The treatment is, of course, only palliative. Rotter has excised the knee in four cases of this affection, with a fair result in two of the cases,[96] but such treatment must be only exceptionally indicated.

(*b*) *Functional Affections of the Joints.*—Under the different names of hyterical joints, hysteria of the joints, joint neuralgia, joint neurosis, neuromimesis of the joints, nervous affections of the joints, a disability has been classed which is characterized by pain, inability to use the limb, and at times marked stiffness of the joint. The affection is always chronic, and may be accompanied by distortion, which becomes permanent. The affection resembles, in many of the subjective symptoms, true organic disease of the joint, and differs from it in its course and objective symptoms. The trouble is usually idiopathic, dependent upon a condition of the nervous system; but it may follow trauma, and after fractures or sprains or

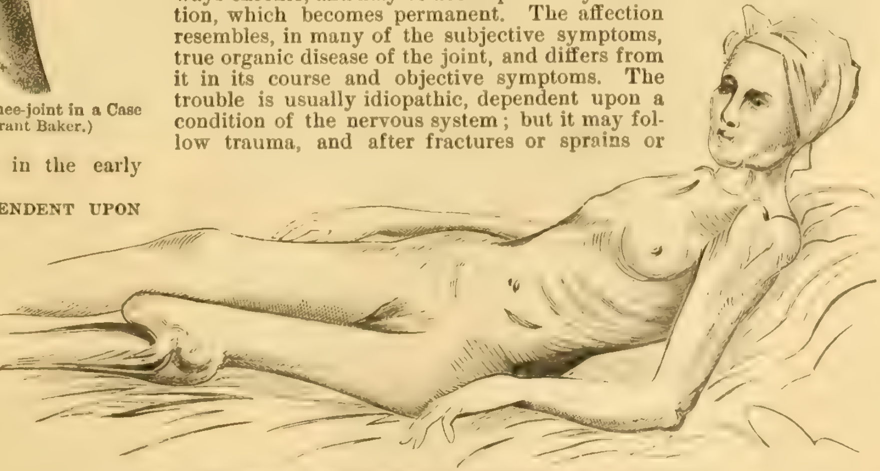

Fig. 4923.—Spontaneous Luxation in Spinal Arthropathy. (Schreiber.)

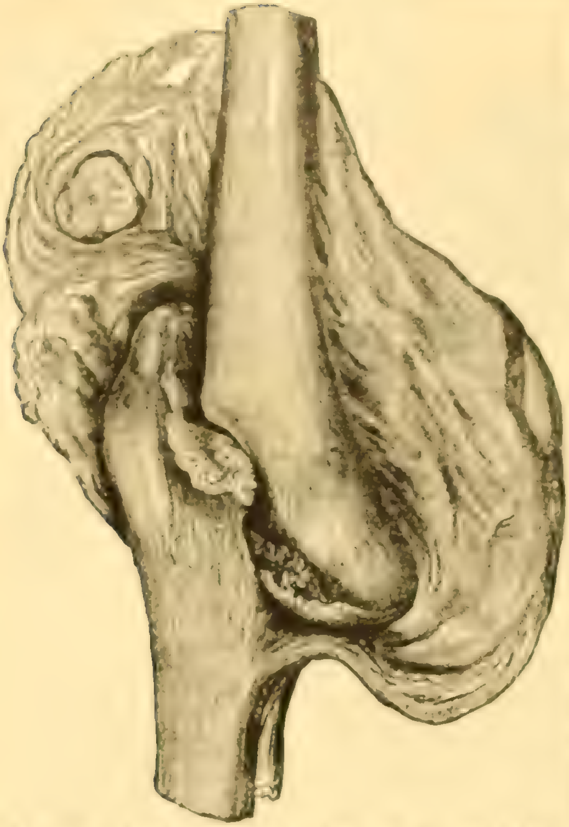

FIG. 2924.—Spinal Arthropathy of the Knee-joint. (Morrant Baker.)

severe injuries, an amount of pain or disability is complained of out of proportion to the actual organic disease, the result of a hyperæsthesia due to the injury, or to an amount of concentrated mental attention directed to the sensations of one part of the body. Any joint may be affected, but the hip, knee, and ankle are perhaps more commonly the joints complained of.

The affection, except in traumatic cases, appears gradually. The pain may be slight, but it is often severe and usually there are paroxysms of extreme pain at regular or irregular intervals, either dependent on motion or spontaneous while the limb is at rest. The pain may be a dull ache or a severe throbbing pain. The pain extends upward or downward and may be accompanied by paræsthesia or anæsthetic spots. The following points are frequently sensitive at the hip, viz., a point between the trochanter major and tuberosity of the ischium, and one at the anterior superior spine. In the knee the internal condyle, and on the inner side of the patella and above the head of the patella, there may be sensitive points. At the ankle, the points behind the malleoli. The affection is more common in women than in men. It may occur, rarely, in young children of a neurotic type.

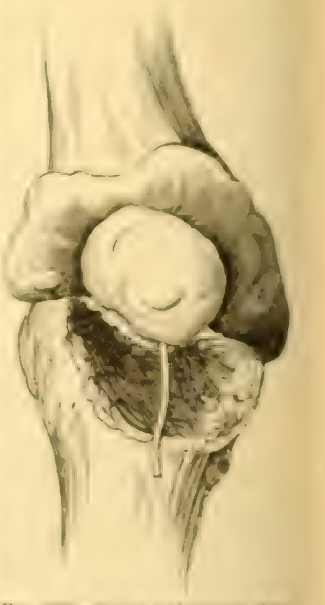

FIG. 2926.—Spinal Arthropathy of the Knee-joint. (Schreiber.)

Voluntary motion of the limb may be at times nearly normal, conscious motion of the limb may be extremely limited, and passive motion encounters resistance. Sensitiveness to pressure is great, and greater to superficial than to deep pressure.

Distortions of the limb are not common in the early stages, but may become habitual and finally fixed from adapted muscular changes. The patients complain sometimes of a sensation of grating at the joint.

A recognition of the affection is at times quite difficult. The diagnosis has to be based on a lack of correspondence between the severe subjective symptoms—pain, tenderness, sensitiveness—and the absence of evidence of organic changes—inflammatory destruction of bone, characteristic distortion. There is a lack of harmony between the symptoms presented and those found at any one stage of the usual joint affections. The limp is greater than would be found with the amount of unconscious active motion at the joint. The pain and tenderness are more severe than is usual at an early stage of the affection, unless it is unusually rapid and accompanied by marked swelling of the joint.

There may be slight periarticular swelling and occasional redness. These are, however, usually slight, and due to vasomotor disturbances rather than to true inflammation. There is but little or no muscular atrophy in functional affection of the joint, this condition being always present in true chronic diseases of the joint. There is no diminished muscular contraction to faradic irritation, as is the rule in organic disease of the joint. The pain, when present, is not as severe at night as in the acute stages of true joint affection.

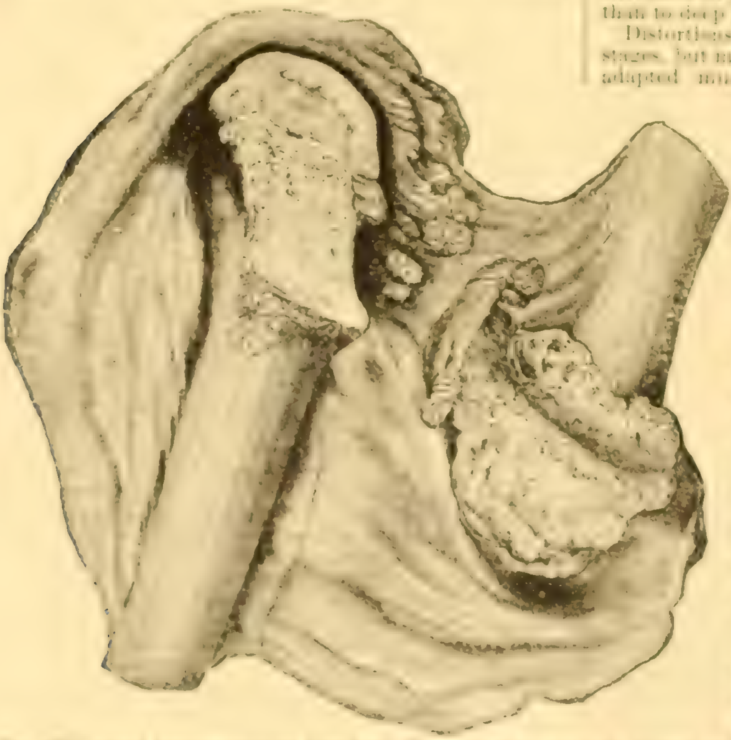

FIG. 2925.—Spinal Arthropathy of the Knee-joint. The same as the preceding, showing the [illegible] (Morrant Baker.)

There is rarely, in this affection, any conscious exaggeration or deceit on the part of patients. Whatever apparent exaggeration there may be is due to increased mental attention to symptoms, or to a local hyperæsthesia.

For the treatment the reader is referred to the subjects, Hysteria, Neuromimesis, as the treatment should not be local.

Growing Pains.—A joint affection incident to growth has been described by Bouilly, and has long been known but unclassified by practitioners, and is popularly considered to be incident to growth—"growing pains." There is slight pain, chiefly in the juxta-epiphyseal region, most commonly near the lower epiphysis of the femur. This pain is brought on by fatigue, strains, or exposure. In the lightest cases the symptoms pass away in a few hours. In severer forms they may last for several days, and the pain be accompanied by slight fever. In the severest form the affection may continue for months. There may be slight effusion in the joints, but recovery eventually takes place. It may occur during the ages between five and twenty-one.[97]

Acute Arthritis in Infants.—English writers have described, under the term of acute arthritis in infants, a form of acute epiphysitis or juxta-epiphysitis occurring in infants from two months to two years of age. It is of a particularly severe form. It is extremely fatal, death occurring in 13 out of 27 cases. Several joints may be attacked. The knee, hip, and shoulder are the ones most frequently involved. The joint at first is stiff, pain and swelling follow, and later an abscess is formed. Out of 27 cases, the hip was attacked 14 times, the knee 11, the shoulder 5, the ankle and elbow 4 times each, the wrist 1. Out of the 27 cases, in 20 the affection was monarticular.[11]

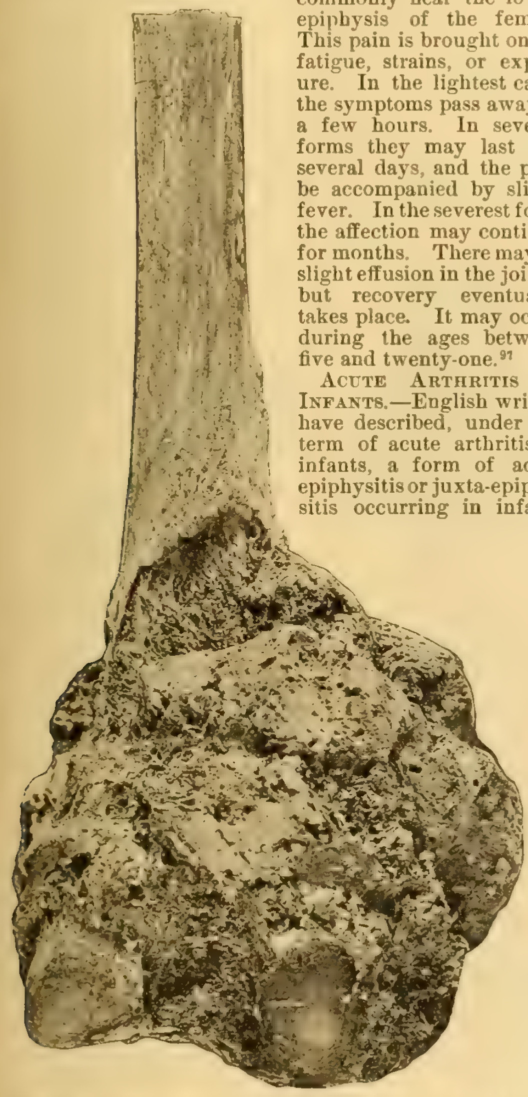

Fig. 4927.—Tumor of the Bone Involving the Joint. (From a Photograph.)

Tumors of the Joints.—Tumors involving the joints are malignant or benign. In the latter class are to be named exostoses, cartilaginous tumors, angioma, aneurism, and echinococcus. The last three are only pathological curiosities; exostoses have been considered under formative osteitis. Cartilaginous tumors grow from the peripheral or central part of the bone; they occur chiefly on the joints of the hands.

Malignant tumors are of vastly more importance. There is a tendency among certain writers (Billroth, Marsh, etc.) to identify all malignant joint tumors with sarcoma, ignoring the existence of carcinoma. The existence of primary cancer of bone is, however, attested by Virchow, Volkmann, Förster, Paget, and Barwell. Sarcoma is, however, vastly more common, and it occurs in many histological forms, round- and spindle-celled, myeloid, partly cartilaginous, and (rarely near the ends of the bones) partly ossified, as the osteosarcoma. The growth originates occasionally in the synovial membrane, ordinarily in the bones from the endosteum or periosteum. Sarcoma infiltrates soft parts of bone, and on section appears fleshy and mottled, being oftenest composed of myeloid or giant cells. The endosteal form, however, is ordinarily the spindle-celled form and grows less rapidly, absorbing the bone and having the appearance of having a capsule, which it really does not possess. Joint sarcomata affect chiefly young subjects from fifteen to twenty or twenty-five years of age. The joints commonly affected are the knee, the shoulder, and the wrist.

Anchylosis.—The loss of mobility in a joint may vary from a small diminution in its arc of motion to a complete obliteration of all movement. Some of the pathological processes that we have considered are perfectly capable of destroying the articular surfaces and replacing them by granulations. The granulations in turn are replaced by connective tissue "organized" directly from the granulation tissue. Consequently it is easy to see how fibrous bands of greater or less extent are formed, running from one bone surface to the other, and these in turn may ossify and a solid bony mass may be where there was at one time a joint. Oftener, fibrous and bony anchylosis are found associated with each other. In the form of synovitis characterized by a small fibrinous exudation (dry synovitis) the formation of fibrous bands between the joint surfaces is accomplished without the intervention of granulation tissue.

Other causes of the loss of motion in joints, besides fibrous and osseous anchylosis of the joint surfaces, are: 1, cicatricial contraction of the articular capsule and ligaments; 2, adhesions between the folds of the synovial sac, causing restriction of joint motion and secondarily degeneration of the cartilages, in consequence of inaction; 3, the buttress-like osteophytes in formative osteitis; and 4, in pathological luxations, the result of destructive bone inflammation causing loss of substance in the ends of the bones, and consequent malposition of the articular ends of the bones.

Bony anchylosis is of course oftenest the result of suppurative synovitis, primary or secondary, but not necessarily the result; for, of thirty-five cases of hip-joint disease analyzed with reference to the ultimate amount of motion in the joint in suppurative and non-suppurative cases, it was found that the presence or absence of abscesses had no effect upon the ultimate amount of motion left to the joint.[98] Marsh found bony anchylosis present in an ankle-joint one month after suppuration began.

On the other hand, as we have seen, true bony anchylosis may occur without suppuration at all.

Distribution of Joint Diseases.—Of 2,002 cases of all kinds of joint disease collected[103] from the clinics of Volkmann,[100] Langenbeck,[99] Hueter,[102] and Socin,[101] 1,387 were of the lower extremity, 615 of the upper.

The distribution of all the various forms among the special joints was as follows: knee, 711; hip, 333; foot, 234; elbow, 183; hand, 172; shoulder, 166; finger, 94; tarsus, 78; toes, 31.

Of 834 cases collected by Schüller,[103] as showing the frequency of the various kinds of joint disease, there were 240 cases (28.7 per cent.) of acute serous synovitis; 26 cases (3 per cent.) of acute purulent synovitis; 67 cases

8 per cent.) of simple chronic synovitis, 108 cases (16.3 per cent.) of arthritis deformans, 345 cases (51.5 per cent.) of scrofulous or tuberculous joint disease. Schüller estimates the general relation of acute to chronic joint disease as 1 to 8 in general, although hospital clinics would set it as 1 to 3. General acute joint rheumatism and metastatic inflammations are not seen here.

Two or more joints may be attacked at the same time, not infrequently in the affection known as chronic rheumatoid arthritis, but also in tuberculous disease.

CLINICAL HISTORY.—The clinical course of the different diseases of the joints, while varying somewhat according to the anatomical surroundings of the different joints, preserves its type sufficiently, so that a description of the disease in one joint will serve for that of another within certain limits. The best type of a serous effusion of a joint will be found in effusion of the knee-joint, while for typical tubercular osteitis of the joints the history of the larger joints, hip or knee, will serve; and the same is true of chronic rheumatoid arthritis. The subject will therefore be considered under the heads of the special joints.

DISEASES OF THE HIP-JOINT.—The clinical history of the diseases of the hip-joint varies not only according to the different affections, but also in the varieties of the same affections, according to the severity of the attack, the rapidity of invasion, and also, in all probability in chronic epiphyseal osteitis, according to seat of the primary lesion, that is, whether it is in the acetabulum, in the part of the epiphysis near the articulation proper, or in a part near the diaphysis.

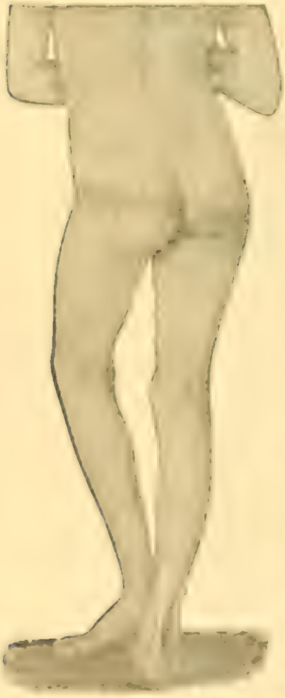

FIG. 4928.—Flexion and Abduction. (From a photograph.)

1. *Epiphysitis* (Morbus coxæ, Hip Disease, Morbus coxarius, Coxalgia, Coxitis tuberculosa).—The most common disease of the hip-joint is tubercular epiphysitis, occurring in the growing bone of children.

The beginning of the affection is usually gradual. The child will be noticed to limp at times. This lameness increases, and it will be found that the patient is inclined to strike the ball of the foot rather than the heel in walking; although the heel can be put down to the floor, yet instinctively the knee is slightly bent and the heel raised when the weight of the trunk falls on the hip. There is a certain amount of stiffness of gait apparent in the morning when the patient first gets out of bed, and after sitting for a while; this passes away after the patient has walked or played about. The symptoms may at first be unaccompanied by pain, but later there is an occasional complaint of pain in the knee. If the child be inspected it will be seen that, although able to run about and play freely, there is a noticeable limp, and in standing the knee of the affected side is usually flexed slightly, the pelvis being tipped, the thigh slightly abducted (Fig. 4928); the tilting of the pelvis and abduction of the thigh may be so slight that it is scarcely noticeable, except by the deviation from the median line of the fold between the two buttocks. In girls the vulva on the affected side will be seen to be lower than on the other side (Fig. 4929).

Lameness.—The symptoms gradually increasing, viz., limp in gait, stiffness, and slight pain, the patient may find difficulty in walking, and complain of rheumatism or "growing pains," which will pass away under friction or domestic remedies and rest, again appearing at irregular intervals.

The limb at this time will be found somewhat smaller in the circumference of the thigh than the other; there will be marked limitation of the usual free motion of the hip-joint, the pelvis moving on motion of the thigh, or moving on motion of the thigh beyond a limited arc.

Pain.—As the affection progresses, pain in the knee and sensitiveness in jarring the limb may become a prominent symptom—the pain being almost invariably located by the patient in the knee. The adductor muscles of the thigh will be found near the symphysis pubis to be prominent and contracted, and frequently there is a thickening of the tissues in Scarpa's triangle perceptible on palpation. An unconscious protection of the joint will be noticed in the movement of the patient; the foot of the well limb will be placed under the lower part of the leg when it is to be suddenly lifted by the patient, as from the floor to the bed, or from the bed to the floor, or in moving from one side of the bed to another. In walking, the patient instinctively avoids resting weight upon the limb, except for as short a time and with as little jar as is possible, the thigh being slightly flexed, the knee being bent, and the heel raised, so that the shock upon the acetabulum from pressure of the head of the femur when the weight of the body is thrown upon the limb may be broken at the knee and ankle joints, which serve as springs. This attitude of the limb—flexion of the thigh—becomes habitual and characteristic; to it is added in the earlier and acuter stages abduction and outward rotation of the limb.

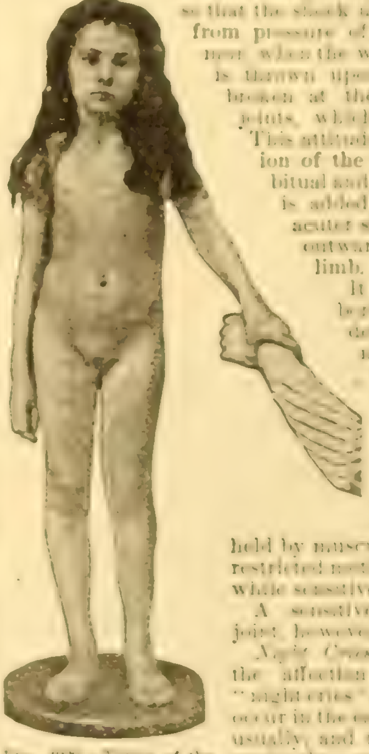

FIG. 4929.—Tilting of the Pelvis and Abduction of the Thigh in Hip Disease. (From a photograph.)

It should be always borne in mind that tenderness or sensitiveness at or about the joint may be absent, and the absence of these symptoms does not indicate the absence of well-pronounced disease. The joint may be firmly held by muscular spasm, allowing restricted motion on manipulation, while sensitiveness may be absent. A sensitive condition of the joint, however, may supervene.

Night Cries.—At this stage of the affection the symptom of "night cries" often appears. They occur in the early part of the night usually, and may become an exceedingly annoying symptom. After the patient is asleep and entirely unconscious, to all appearance, sleep will be interrupted by a loud cry as if of severe pain, followed by moaning or crying for a few seconds, the patient being unconscious or only half conscious of the cause of the pain. These do not occur when the patient is entirely awake, and are caused by the spasmodic twitching of the muscles abnormally irritable from irritation reflex to the inflammation of the joint. These cries may vary from a short moan to a piercing shriek, and may in the severest cases be repeated fifteen or twenty times during the night. They do not occur in the later stages of the disease, and may be entirely wanting in the mildest cases. They resemble somewhat the cry in the "night terrors" of nervous children, but differ from that in that there is greater evidence of extreme pain, and no connection with unpleasant dreams, apprehension, or fright. From the testimony of

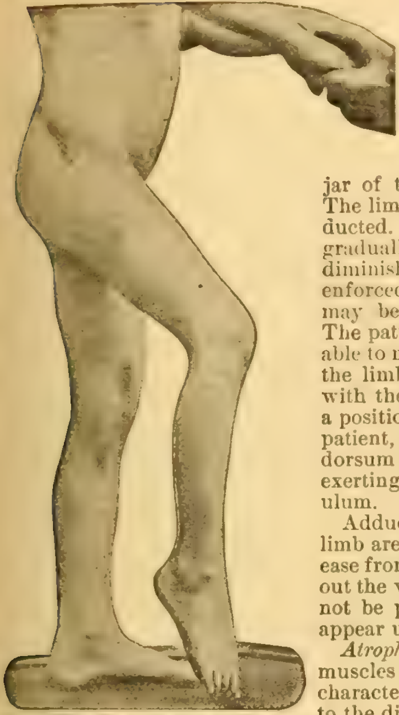

FIG. 4930.—Shortening and Flexion. (From a photograph.)

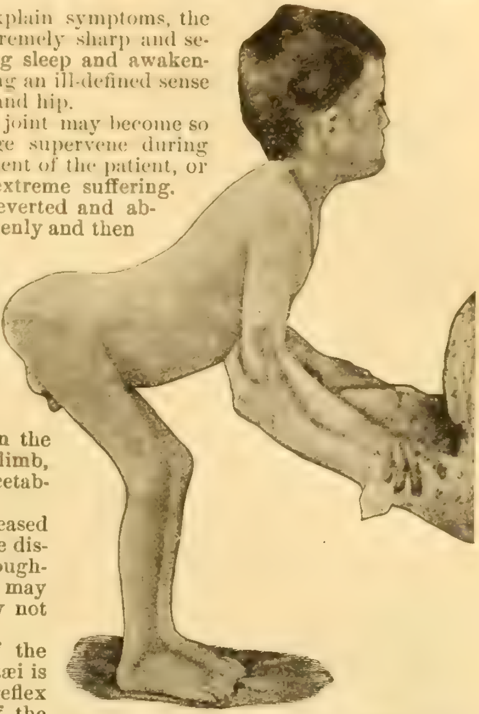

FIG. 4932.—Flexion in Double Hip Disease. (From a photograph.)

patients old enough to explain symptoms, the pain is reported to be extremely sharp and severe, suddenly interrupting sleep and awakening the patient, and leaving an ill-defined sense of an aching in the thigh and hip.

The sensitiveness of the joint may become so great, and an acute stage supervene during which the slightest movement of the patient, or jar of the bed or room, causes extreme suffering. The limb is flexed at the thigh, everted and abducted. This stage may come suddenly and then gradually pass away, the pain diminishing gradually under the enforced treatment of rest, but it may be prolonged for months. The patient will gradually become able to move the limb, or to steady the limb with the sound limb or with the hands. Characteristic is a position frequently taken by the patient, who places the well foot on the dorsum of the foot of the affected limb, exerting pressure away from the acetabulum.

Adduction or abduction of the diseased limb are neither characteristic of the disease from the first; they persist throughout the whole affection. Abduction may not be present, and adduction may not appear until late in the disease.

Atrophy. A marked atrophy of the muscles of the thigh and of the glutæi is characteristic. It is supposed to be reflex to the disease of the joint,[104] and if the muscles of the thigh are tested for contractility to the irritation of the faradic current, it will be found that the contractility is markedly diminished. The upper part of the thigh and the tissues in the vicinity of the hip may become swollen, particularly the lymphatic glands of the groin—an œdema of the periarticular tissues taking place, similar to that seen in the knee in the so-called "tumor albus;" this may disappear or become localized in the formation of an abscess.

Distortion of the Limb. Flexion of the thigh is a symptom which, noticeable even in the early stage of the disease, becomes more marked as the disease progresses. It was originally supposed to be due to an effusion in the capsule of the hip-joint, but it is seen together with adduction and abduction in cases where no effusion has taken place. It is chiefly due to the muscular contraction, which is constant in chronic disease of the joint, and partly to an unconscious effort on the part of the patient to assume a position most comfortable for the joint and most protected from jar.[56] In double hip disease flexion produces a terrible deformity (Fig. 4932). As the disease progresses adduction of the femur takes place, and the attitude of flexion and adduction is characteristic of the last stage of the disease (Fig. 4933).

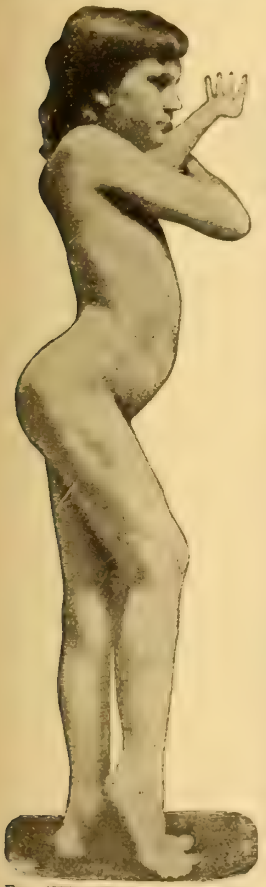

FIG. 4931.—Flexion in Hip Disease. (From a photograph.)

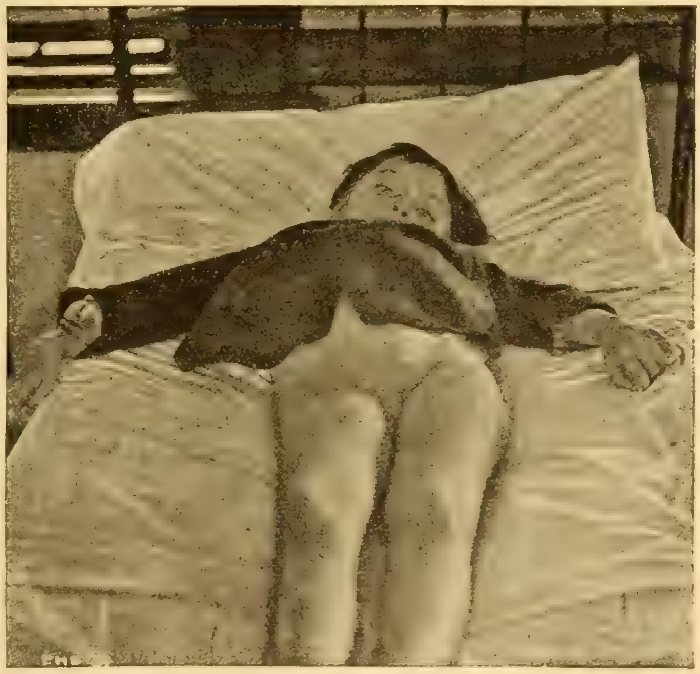

FIG. 4933.—Adduction. (From a photograph.)

Abscess.—In quite a large proportion of cases suppuration takes place. In the severe forms accompanied by much pain, by severe pain for a long period, suppuration is the rule. The site and course of the abscesses vary according to the seat and size of the original focus of the disease, in the femur or the acetabulum. Abscesses may be entirely periarticular, if the initial lesion of the epiphysis extend in a course outside of the joint; or they may come from suppuration within the joint; or having been periarticular, they may later involve the joint.

The formation of the abscess is frequently without constitutional disturbance, as is not infrequent in cold abscesses in general. Usually there is a slight fever. As the abscesses enlarge they are usually accompanied by the pallor incidental to suppuration—the suppurative leucocythæmia characterized by an increase in the number of white corpuscles. This condition may not interfere with a fair appetite and more or less satisfactory general health, but as a rule the appetite is capricious.

Abscesses may be absorbed spontaneously or may discharge themselves. They may evacuate themselves partly, and the residual fluid, following along the course of the sheaths of the muscles and the fasciæ, reappears later as a second abscess. In some cases the same abscess may even cause five or six fistulous openings.

Increased Intra-articular Pressure.—The effect of persistent muscular spasm of muscles about the hip joint, characteristic of hip disease, is to crowd the femur against the acetabulum. The amount of the force may be estimated as relatively great if we bear in mind the strength of the affected muscles. The result of this force is to produce the pseudo-luxation characteristic of hip disease, viz., the enlargement of the acetabulum and the absorption of the head of the femur, and the resulting shortening of the limb, and in certain cases the actual escape of the head of the femur from the socket.[4]

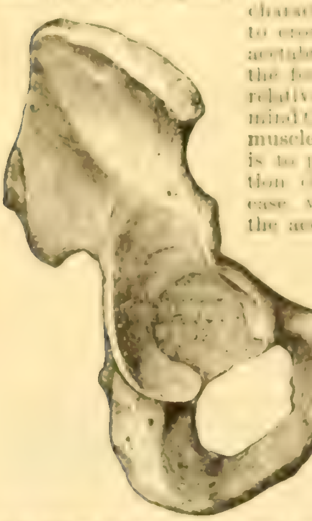

FIG. 2961.—Pathologically Enlarged Acetabulum.

Hip disease, like all diseases, is a self-limited one. A natural cure takes place in a majority of cases, but the cycle of invasion, efflorescence, convalescence, and cure always consumes a long period of time. The natural cure in the lightest cases leaves a slight limitation of motion in the hip. This is accompanied by a slight limp. More frequently there is practical stiffness of the joint, with fibrous or eventual bony ankylosis at the hip joint, flexion and adduction of the limb, with practical shortening. Subluxation of the femur with shortening of the limb is a common result of the natural cure, and an arrest of growth with actual shortening of the bone.

The openings of abscesses may close in time after the separation of sequestra; and in some instances a large sequestrum, constituting nearly the whole head of the femur, has been spontaneously evacuated, giving a useful limb.

Death in the course of hip disease takes place not infrequently from tubercular meningitis. Death may also be caused by exhaustion and the septic involvement or amyloid degeneration of various organs, liver, kidney, secondary to suppuration and abscess.

Acetabular Hip Disease.—It has been found that in a certain number of cases the disease begins, not in the epiphysis of the femur, but in the bony tissue of the acetabulum.

Pathologically, this class of cases becomes similar at an early stage to ordinary hip disease, as in the progress of the disease the head of the femur soon becomes involved. Clinically the cases differ somewhat, in that there is greater liability of perforation of the acetabulum, and the formation of pelvic abscess at an earlier stage than is common in the course of hip disease.

In focal disease of the hip joint, if the focus of osseous inflammation is situated in such a part of the epiphysis of the femur that, on extending, it evacuates itself into the periarticular tissue, rather than into the joint; or if the osseous inflammation is not rapid in its progress and is well limited by a surrounding ossifying circumferential osteitis, the symptoms of pain or sensitiveness will be absent for a long time, if present at all.

But in all these different types there is a common resemblance in the limb, in the peculiarity of attitude, flexion, abduction, and adduction, and the limitation of motion at the hip joint.

There is a certain amount of variation in the amount of deformity left in the natural cure of hip disease, depending upon the severity of the disease and the amount of bony destruction. The flexion and adduction may be so slight as only to cause slight shortening, or it may practically prevent the usefulness of the limb. A most distressing deformity follows the natural cure of double hip disease. This may leave severe flexion of both femora, or flexion and adduction so that the limbs are crossed.

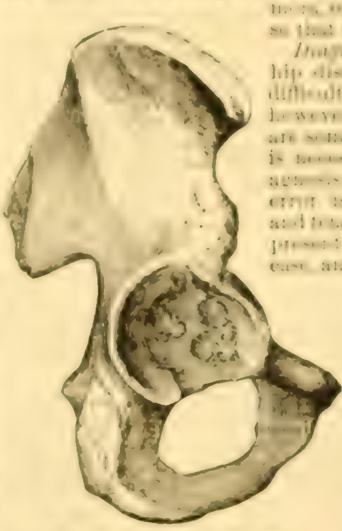

FIG. 2962.—Acetabular Caries.

Diagnosis.—Diagnosis of hip disease is ordinarily not difficult; in the earliest stages, however, errors in diagnosis are sometimes made, and care is necessary for a positive diagnosis. The most common error is the belief that pain and tenderness are necessarily present in all cases of hip disease, and that their absence excludes the possibility of hip disease. Pain and tenderness are not, however, early symptoms in a majority of cases.

Lameness.—A limp in gait is an early symptom, in fact the earliest symptom. It may be said that no hip disease can be present without giving rise to a limp in gait. At the earliest stages, however, the limping may be intermittent and not constant. The same may be said of a limitation of motion at the hip joint. A [illegible] that there can be no hip disease if the motions at the hip joint are perfect. In one case examined in the very earliest stages, which afterward proved to be hip disease, the motion at the hip joint on one examination appeared to be perfect; but on a second examination the next day, after a little exercise, it gave evidence of slight limitation of motion.

Muscular Stiffness.—It should be borne in mind that some care is required to discover slight limitation of motion in very young children, who are apt to resist thorough examination. The resistance to motion due to fright is, however, always resistance to any motion of the limb. If by slight force this is overcome, resistance to rotation of a flexed thigh, or to extreme flexion, will not be encountered. A comparison of the resistance of one leg with that of the other will reveal abnormal resistance. Limitation in motion at the hip joint in the early stages is recognizable at the extremity of the arc of normal movement. And there is limitation equally in motion in all directions, i.e., flexion, extension, abduction, or adduction. The normal amount of abduction is, however, slight. Resistance to motion in this direction, therefore, is an early test of importance. Extreme abduction, or abduction and rotation of the thigh flexed at right angles to the body, is also a delicate test.

In young and frightened children, the tests for limitation of motion at the hip-joint are best made with the child lying on the mother's lap, or leaning on the mother's shoulder; but ordinarily the best position is with the patient lying upon a hard flat surface.

A limitation to flexion is determined by flexion of the normal limb on the abdomen to its utmost limit, and afterward a repetition of the motion of the suspected limb. If the limb is then extended so that the popliteal space be placed upon the hard surface on which the patient lies, there will normally be no alteration of the position of the back; if, however, there is a contraction of the psoas and iliacus muscles, *i.e.*, a limitation in the normal extension of the limb, the back will be arched up as the popliteal space is pressed down.

This limitation to extension can also be determined by examining the patient lying upon the belly. If one hand be placed on the sacrum and the thighs be alternately raised from the surface on which the patient lies, a difference in the amount of motion at the hip without moving the sacrum can easily be determined. The limit to the amount of abduction or adduction is determined by placing one hand on the anterior superior spine of the ilium on the sound side, and with the other hand gently abducting or adducting the suspected limb.

Careful inspection in the early stages of hip disease will sometimes show fibrillary contraction of the muscles of the thigh on sudden or unexpected movement of the limb.

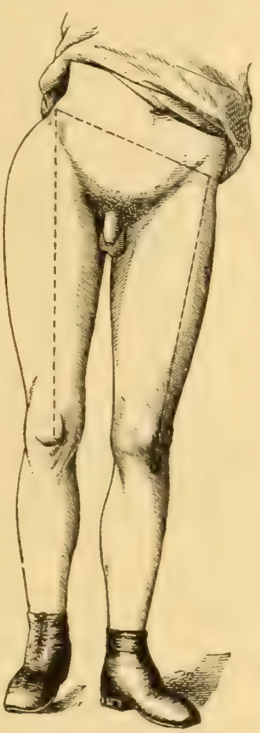

FIG. 4936.—Method for Estimating Abduction or Adduction.

In the later stages of hip disease practical anchylosis of the joint takes place, there being no motion at the hip-joint. This is due to muscular spasm and disappears under complete anæsthesia, unless a permanent degeneration of the muscle has taken place, or a fibrous anchylosis of the hip-joint has begun to be developed.

A limitation to rotation at the hip is not so readily detected in the earliest stages of hip disease. Often the foot can be turned in and out with apparently normal freedom; if, however, the thigh be flexed upon the abdomen, and an attempt be made to rotate the femur and at the same time abduct it, at a very early stage unusual resistance to this motion will be found on the affected side as compared to the normal side.

In examining the patient for muscular stiffness, the clothes should be removed and the patient should lie upon a hard surface (except in the case of an infant in arms, as above mentioned). Attempts to move the limb should be made gradually and gently and persistently—rough force only exciting resistance and making a delicate examination impossible. The most convenient order of motion in examination is first flexion, then abduction and abducting rotation with the thigh flexed, then extension. The suspected limb should be held at the ankle or knee.

Attitude. The peculiarity of the patient's attitude in standing or lying in bed—the flexion, abduction, or adduction of the limb—in marked cases of hip disease is pathognomonic. In the earlier stages this can usually be noticed on careful watching, and the peculiar care with which the patient moves and steadies the limb with the sound limb in getting in and out of bed, is of diagnostic importance.

The abduction of the limb is usually not recognized by the patient as abduction, but the complaint is made that the limb seems longer than the other. The pelvis is tilted, which gives a practical lengthening of the limb. In the same way the limb appears shorter to the patient if adducted. The tilting of the pelvis can be recognized by drawing a line from the anterior superior spine of one side to that of the other. This should be at right angles with a line from the umbilicus to the symphysis pubis.[31]

Atrophy. Atrophy of the muscles is an early symptom, and is determined by measuring the circumference of the thigh, or by inspection or palpation of the muscles.

The obliteration of the fold of the buttock mentioned in the older writers is due to this atrophy, but it is not always one of the earliest symptoms.

A diminution of the farado-electric muscular contractility in the muscles of the thigh is symptomatic of hip disease at an early stage.

The muscular atrophy of hip-joint disease differs from that of infantile paralysis in that it is not as great, and that the power of the muscle is not lost. The muscular atrophy is greater, as a rule, than that of simple disuse of the muscles.

In the earliest cases the atrophy may be so slight as to escape detection by the tape measure.

Pain. The pain in well-marked hip disease is almost invariably located at the knee; the cause of this is not certain, but it is probably analogous to the pain referred to at the end of a nerve in irritation in its course. Exceptionally, the pain is referred to the leg and follows along the course of the sciatic; pain located at the hip is exceptional and is usually indicative of suppuration or the pressure of an abscess under the fasciæ, or of nervous hyperæsthesia.

Tenderness on jarring the hip is rarely an early symptom. Sensitiveness on slight jar of the hip is sometimes indicated, previous to the presence of conscious pain, by an instinctive wincing on the part of the patient if the limb is jarred. The use of violently jarring the hip is unnecessary in the examination of a patient for hip disease.

The "night cries" characteristic of hip disease have already been mentioned; they are more common in an earlier stage of hip disease.

Swelling. In an early stage of hip disease there is, as a rule, no swelling, unless the affection is unusually rapid in its course.

The glands in the groin may, however, be found to be enlarged on palpation.

Swelling about the hip is not uncommon in the later stage of hip disease.

An apparent condensation or thickening of some of the superficial tissues, to be felt on palpation, usually can be found in hip disease at a comparatively early stage. It is common in the region of the tensor vaginæ femoris.

To recapitulate the symptoms on which a diagnosis of hip disease is based, they may be summed up as follows: 1, Limping; 2, limitation of motion or stiffness of the joint in all directions of normal motion; 3, peculiarity of attitude or distortion of the limb; 4, muscular atrophy; 5, pain or sensitiveness.

Differential Diagnosis.—A list of the diseases which have been mistaken for hip disease would be a long one. The table on page 350 indicates the means of making a differential diagnosis.

An error in diagnosis is only possible in the early stages, if an examination with ordinary care is made.

Sarcoma of the hip may at first be mistaken for hip disease, but there is greater hardness of the swelling than such as is to be met in early hip disease, and there is an absence of the usual symptoms of hip disease.

A differential diagnosis between chronic synovitis of the hip-joint and chronic epiphyseal osteitis is not possible at an early stage in the disease, and is not necessary, as the treatment is the same, though the prognosis of chronic synovitis may be somewhat better.

Periarticular disease, which has not yet attacked the

joint or the epiphyses of the joint, is recognized by the fact that the inflammation invading certain groups of muscles causes a limitation to motion greater in one direction than in another, while the limitation to motion in disease of the joint is equal in all directions of normal motion of the joint.

Under the head of periarticular disease may be included inflammation of bursæ or of lymphatic glands, or psoas abscess, or psoas muscular spasm from caries of the lumbar spine (psoitis). This latter disease is not infrequently mistaken for hip disease. A careful examination of the muscular spasm aids the diagnosis. The diagnosis between true and neuromimetic affections of the hip is at times difficult. In a functional (hysterical) trouble there is a predominance of subjective symptoms of pain, sensitiveness, etc., and an absence or relative insignificance of the objective symptoms of muscular atrophy, characteristic attitude, and distortion. The stiffness on passive motion of the hip is much greater than would be usual in an early stage of hip disease, and out of proportion to the amount of unconscious active voluntary motion.

It has been supposed that an anæsthetic will be an aid in the diagnosis of hysterical coxalgia, as the muscular spasm of both hysterical contraction and of true hip disease disappears at an early stage of the affection under an anæsthetic, and, in a later stage, after the muscles have become permanently shortened, some contraction remains in spite of an anæsthetic. It is true, however, that there is much less stiffness under an anæsthetic in neuromimetic coxalgia of long duration than in true hip disease with active inflammation and osseous changes; but the latter can ordinarily be recognized without difficulty.

A separation of the epiphysis of the femur at the hip needs here scarcely more than mention, it is a rare accident occurring only before puberty, and the symptoms are those of intercapsular fracture of the neck of the femur, except crepitus is not present, or is slight and cartilaginous.

Separation of the epiphysis from the diaphysis may occur in juxta-epiphyseal osteitis, *i.e.*, in hip disease. It would be recognized by the fact that the trochanter has suddenly become much higher on the affected side than on the normal.

The rare accident of partial rupture of the adductor muscles of the thigh need not be mistaken for hip disease. Although there is flexion of the thigh and adduction, and muscular stiffness less than is normal, yet the absolute limitation to motion is chiefly from the remaining fibres of the injured muscles, which are spasmodically contracted to prevent the torn fibres from being stretched—which is not the case in true hip disease.

Congenital dislocation of the hip-joint need not be mistaken for hip disease, as the clinical history of the former is one of continued limp since the child commenced to walk, while in hip disease the limping is not congenital. There are also no symptoms of muscular stiffness or limitation of motion of the hip in congenital dislocation—in fact no symptoms of hip disease except the limp.

The same may be said of shortening of the limb from retarded growth.[106]

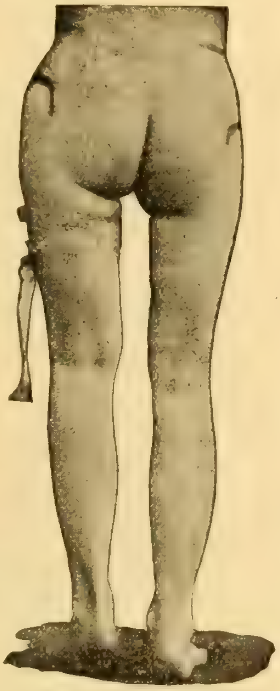

Fig. 4937.—Shortening in Congenital Dislocation of the Hip. (From a photograph.)

It is important, in an examination for hip disease, to determine the amount of permanent injury which the disease has already inflicted. The amount of enlargement of the acetabulum and absorption of the head of the femur which has taken place, may be estimated by determining the amount of subluxation. If the patient lie upon the well side, and a line be drawn over the suspected hip (the thigh being somewhat flexed), from the anterior superior spine to the most prominent part of the tuberosity of the ischium, it should pass just above the upper margin of the trochanter; if the trochanter is above this line, it is an evidence of subluxation.

The amount of abduction or adduction should also be determined. This can be calculated by means of degrees on the arc of a circle designed for the purpose; a more ready way is, however, furnished by means of the following table. The patient should lie straight on a table with the legs parallel. Real bone shortening should be estimated by a tape measure, and apparent shortening should also be estimated (by measuring from the umbilicus to each malleolus). If the apparent shortening is greater than the real, *adduction of the diseased limb is present*; if it is less, *abduction is present.* To estimate the amount of either present, measure from one anterior superior iliac spine to the other, and estimate in inches the difference between the real and the apparent shortening. Consult the table, and where the two columns opposite each of these figures intersect will be found the angle of the deformity.[107]

In a similar way the flexion of the thigh may be estimated as follows:[108]

Lay the patient on his back on a table or any flat surface, and then raise the diseased leg by the heel until the lumbar vertebræ touch the table. Having placed the child in this position, measure off two feet on the external aspect of the leg with a tape measure with the zero of the tape on the table at A, and note the point B; from here measure the perpendicular distance in inches to the table C. Consult Table I., and opposite the number of inches found by measuring B C, will be found the number of degrees representing the flexion of the diseased leg from the normal position.

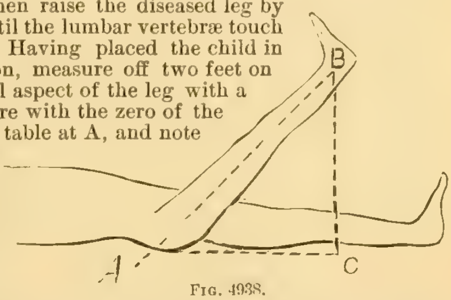

Fig. 4938.

Table II.

In.	Deg.	In.	Deg.	In.	Deg.	In.	Deg.

6.0	15	12.0	39	18.0	48	24.0	90

If the leg is so short that it is impracticable to measure off twenty-four inches, we can measure to a point on the leg distant twelve inches, from the table; ascertain the distance to the table in a perpendicular line just as before, double this distance, and look in the table as before.

A recognition of the existence of an abscess in the vicinity of the hip-joint is to be made by palpation. In acetabular hip disease, examination of the rectum will often reveal the presence of an abscess projecting into the pelvic cavity.

II. *Synovitis of the Hip-joint.*—Serous Synovitis of the hip-joint is not common. The existence of chronic tuberculous synovitis of the hip joint has been questioned, but there seems to be no reason why such an affection may not well exist and escape detection, for the opportunity for post-mortem examination does not occur until after the disease has involved the whole joint.

Chronic synovitis of the hip joint not extending to the bone is an uncommon affection. In a majority of cases, its existence must be an inference rather than a positive diagnosis. The writer has had under observation five cases with the usual symptoms of hip disease at an early stage, viz., limping gait, muscular atrophy, stiffness, limitation of motion at the joint, peculiar and characteristic attitude and slight pain persisting for months, and yet complete recovery took place. In one, death occurred from intercurrent disease six months later, and the remains of a synovitis in thickening and congestion of a part of the synovial membrane were found.

The course of acute, subacute, or chronic synovitis of the hip joint (if limited to the synovial membrane and not extending to the cartilage or bone) is not as protracted as that of epiphyseal osteitis.

Synovitis of the hip joint from traumatism may occur in sprains and contusions; the extent and course of such synovitis depend upon the nature and amount of the injury. In patients with tubercular predisposition, such injuries may produce tubercular disease. In certain cases, a synovitis of this sort passes away without permanent injury; in other cases, permanent disease or ankylosis results.

III. *Chronic Rheumatoid Arthritis of the Hip-joint*—morbus coxæ senilis, chronic rheumatoid arthritis—occurs chiefly in people of middle age or older; it may be limited to the hip, constituting morbus coxæ senilis, or may be combined with affections of other joints. The symptoms met are those already mentioned as encountered in an early stage of hip disease. The disease never leads to suppuration, but may to deformity and painful locomotion. In the lightest forms the disease may be a self-limited one, disappearing after a short subacute attack; but ordinarily, the course is long and frequently a permanent disability of the limb is left.*

Loose Cartilages in the hip joint are so exceptional as to be simply anatomical curiosities.

KNEE-JOINT.—The common chronic affections of the knee joint are the following: 1. Chronic synovitis with or without effusion; 2. hydrops articuli; 3. epiphyseal osteitis; 4. chronic rheumatoid arthritis. Besides these primary disease of the cartilage may occur. Displacement of the menisci, loose bodies in the joint, may give rise to joint inflammation. Charcot's disease is not uncommon in tabes dorsalis. Cysts connected with the knee joint should be also mentioned.

The knee joint deserves especial notice inasmuch as it is the largest and most exposed joint in the body, and the one most frequently attacked, if we may consider Schüller's figures (referred to above) as representative.

Anatomically, it should be noted that the joint surfaces forming it are nearly flat, and the facets in the tibia shallow. Owing to this fact the tibia is easily drawn backward and flexed by the hamstring muscles, the flexors of the leg being much stronger than the extensors, and also rotated outward, constituting the common and troublesome deformity which is the characteristic one after tumor albus, the result of the persistent muscular spasm. Certain cases of "internal derangement," as Hey called it, of the knee joint (and sometimes of others as well) have been reported since his original paper in 1803. The cause seems to be in certain cases the traumatic tearing away of one of the semilunar cartilages from its marginal attachments, and from having thus become able to slip backward or inward, it does so in certain movements of the joint, getting behind the condyle or into the intercondyloid notch, and giving rise to the symptoms described in the clinical history.

In other cases, owing to repeated attacks of synovitis, the attachments of the semilunar cartilages become loosened, and, allowing the cartilages to slip, cause the same symptoms.

Mr. Bradhurst reported a case where a laceration of the cartilage took place, and a piece of cartilage loosely attached caused the same sort of symptoms.

Dislocations of the semilunar cartilages are not uncommon.

The knee is the joint which is by far the oftenest affected by "internal derangement," but cases of it in the elbow and temporo-maxillary joint are on record.

Chronic Synovitis.—Simple chronic serous synovitis is often the sequel of the acute or subacute form. It may be rheumatic in origin, or possibly due to exposure to wet or cold. It occurs at any age, either in children or adults, generally under forty. It may occur at any time after an injury or strain. The earliest symptoms are usually impaired motion and pain; occasionally a loss of strength is complained of. The pain is not severe unless the joint is excessively used, and it is relieved by rest. Later, swelling, increased surface temperature, and redness of the skin appear. Tenderness may not be marked, except in the acute stages. If neglected, acute inflammation, even of a purulent type, may result. There may be moderate muscular atrophy. After a time, in some cases, the swelling slowly disappears with the absorption of the effusion. The patient no longer has pain or tenderness. The mobility of the joint is restored. In many cases this recovery is not permanent, for after a period of weeks or months a recurrence of the attack occurs, and ultimate recovery only follows after several such exacerbations. Generally, where no constitutional tendency to disease exists to change the character of the affection, the joint finally becomes normal.

Chronic synovitis presents itself in various forms. There may or may not be effusion; the effusion may be serous, sero-purulent, or completely purulent, according to the violence of the affection.

In tubercular synovitis suppuration is almost certain to occur, with thickening of the synovial, subsynovial, or periarticular tissues and the formation of abscess with spontaneous opening and the development of sinuses. The disease (tubercular synovitis) usually extends to the cartilage and bone, giving rise to a train of symptoms analogous to those to be observed in chronic epiphyseal osteitis.

Synovitis of the knee joint may, however, remain indefinitely in a subacute condition, with a slight amount of effusion and accompanied by thickening of the synovial membrane, which sometimes is gelatinous in appearance. A large amount of serous effusion may take place, with slight inflammatory symptoms, and the affection may resemble, clinically, the simple non-inflammatory effusion termed "water on the knee."

The clinical course of chronic synovitis necessarily varies as it does pathologically. It may be the result of an acute attack, or it may more commonly begin insidiously, the patient complaining at first of an impairment of strength and slight pain; presently there is a limping gait, with slight tenderness on pressure at the knee, usually over the inner condyle; impairment of motion at the knee is to be noticed; the limb is slightly flexed at the knee, and there is usually swelling apparent at the knee, to be demonstrated by measurement. Muscular atrophy of the muscles of the thigh and calf occurs, and the disease may progress gradually to complete stiffness, or there may be an intercurrent attack of acute synovitis with attendant exacerbation of symptoms.

Hydrops articuli differs clinically from the ordinary type of synovitis in that there is rarely any pain; the symptoms may develop gradually, there being no complaint except a slight, hardly noticeable one of loss of strength. The characteristic effusion gradually develops, disappearing slowly, or remaining for a long time unchanged. Sometimes, however, the effusion appears without premonition and disappears equally rapidly.

---

* For a case of [illegible] of the hip [illegible] in the Boston Medical and Surgical Journal, November 15, [illegible].

Muscular atrophy, impairment of motion, pain or tenderness, may all be absent, there being no evidence of trouble except the effusion in the joint.

Epiphyseal Osteitis. The commonest affection of the knee in children is the classical "white swelling" of the older writers. It may be either a diffuse osteitis or one limited to certain portions of the epiphysis, and the femoral or tibial epiphyses are attacked with equal frequency. In rare instances the patella has been primarily attacked.

Epiphyseal osteitis of the knee-joint begins, as a rule, insidiously, with stiffness and limp in gait. The disease may be limited for years, and be displayed by an enlargement of the condyles or head of the tibia, or it may extend and involve the whole joint; occasioning severe pain, swelling of the periarticular tissues, effusion in the joint, periarticular abscess, distortion of the limb, *i.e.*, flexion and subluxation; and ending in a natural cure with fibrous or bony anchylosis and a distorted limb, which may be more or less serviceable, according to the distortion; or the affection may result in so extensive suppuration as to endanger life from septic or amyloid changes. Sometimes an attack of severe pains supervenes, representing an acute stage, and the limb is flexed at the knee, hot and tender to the touch, and sensitive to any jar. This stage gradually subsides, and there is left impairment of motion, if not complete stiffness. Characteristic of chronic epiphysitis of the knee, if it persists for any length of time, is enlargement of the bone.

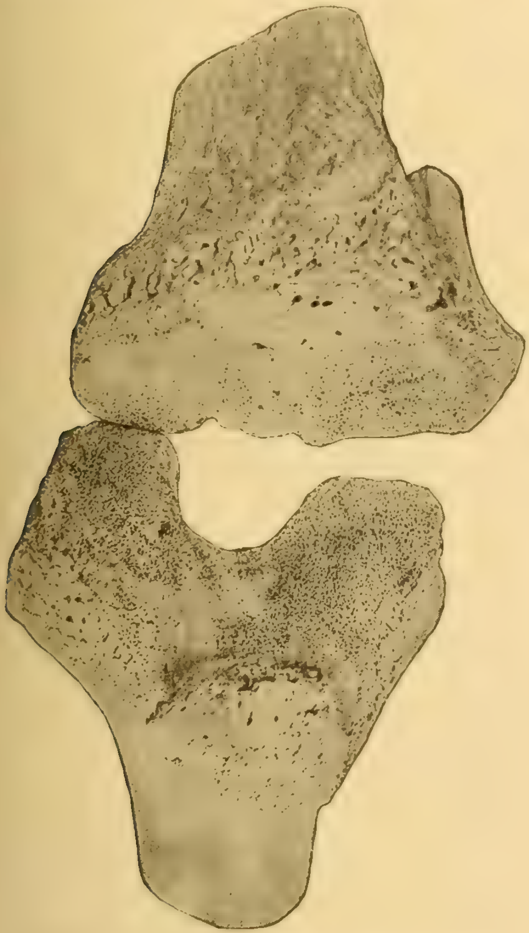

Fig. 4939.—Erosion of the Cartilages in Knee-joint Disease.

In some instances, one of the condyles is enlarged more than the other—usually the internal condyle—causing knock-knee. In the severer cases, suppuration follows, with the establishment of sinuses. The disease progresses to a cure with a stiffened limb, or the destructive process may become so extensive that excision or amputation is required.

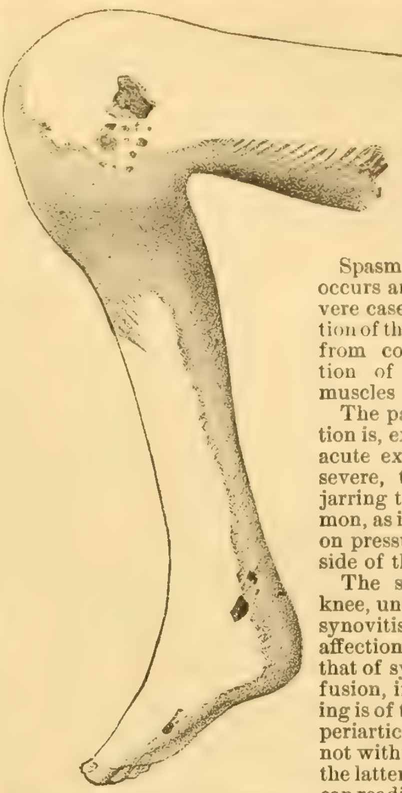

Fig. 4940.—Subluxation in Knee-joint Disease. (Schreiber.)

Muscular atrophy invariably occurs.

Spasm of the muscles occurs and results, in severe cases, in a subluxation of the tibia backward from constant contraction of the hamstring muscles (Fig. 4940).

The pain of the affection is, except during the acute exacerbations, not severe, though pain on jarring the limb is common, as is also tenderness on pressure at the inner side of the knee.

The swelling at the knee, unless suppurative synovitis be added to the affection, differs from that of synovitis with effusion, in that the swelling is of the bone and soft periarticular tissues, and not within the joint. In the latter case fluctuation can readily be determined by palpating on both sides of the patella, the limb being so placed that the quadriceps extensor muscle is reflexed. If the effusion is large, as in chronic serous synovitis, the patella, when the muscles holding it are relaxed, can be depressed on pressing on it, as it floats above the fluid within the joint. In effusion the shape of the swelling is characteristic. It is most prominent on both sides of the patella, being limited by the tendon of the quadriceps extensor muscle and by the ligamentum patellæ.

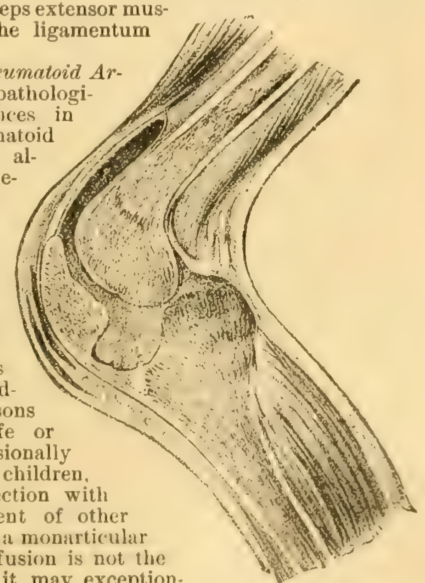

Fig. 4941.—Subluxation of Knee. Cross Section. (Schreiber.)

Chronic Rheumatoid Arthritis.—The pathological appearances in chronic rheumatoid arthritis have already been described. They are found more characteristically developed in the knee than in any other joint. The disease always develops gradually in persons of middle life or older. Occasionally it is seen in children, but in connection with the involvement of other joints, not as a monarticular affection. Effusion is not the rule, though it may exceptionally occur. Enlargement of the joint is almost constant. The symptoms are rarely acute, the most marked being a limping in gait, a sense of stiffness, especially after sitting for some time, limited motion, and eventually an irregular enlargement in the contour of the joint. The pain present is usually caused by motion or jar, and is absent when the joint is at rest.

The disease is chronic, and not subject to acute exacerbations.

It sometimes produces complete disability from contraction of the limbs, which are often strongly flexed.

The affection of the knee occurring in tabes dorsalis clinically differs from chronic rheumatic arthritis but little, except that the disease is often much more destructive, causing complete disability with practical destruction of the joint.

Diagnosis.—A diagnosis of affections of the knee joint is based on limp in gait, stiffness, change in contour of the joint, pain, tenderness; the prominence of these symptoms being dependent upon the activity of the affection. Limping may be considered a constant symptom, although in the mildest cases of hydrops articuli it is slight. The same may be said of limitation of motion at the knee. Pain or tenderness are not constant symptoms in the earlier stages and milder forms of affections at the knee.

Differential Diagnosis.—Gross errors in diagnosis in affections of the knee are not common, as a thorough examination of the joint is readily made. The distinction between a synovitis with effusion and a chronic ostitis, is based on the size and shape of the swelling. A diagnosis between a subacute synovitis without effusion and an epiphyseal ostitis, at an early stage, is difficult or impossible. It should be borne in mind, however, that in a pure synovitis there is thickening of the synovial membrane without enlargement of the bone, and in pure epiphysitis the reverse is true if the epiphysitis is well developed.

Periarticular disease (inflammation of bursæ, periarticular abscesses) is to be distinguished from true articular disease in that there is little or no stiffness, and the swelling, if present, does not bear the relation to the patella that occurs when there is fluid beneath the patella.

Functional disease (hysterical, neuromimetic) of the knee is to be recognized by the absence of objective symptoms, and the prominence of subjective symptoms.

Diagnostic Symptoms in Chronic Diseases of the Knee.

Loose Bodies.—The knee joint is the favorite seat for the cartilaginous bodies known as loose bodies, or floating cartilages. These vary in size and in number, being sometimes found in very large numbers. Billroth mentions one as large as the patella; ordinarily they are comparatively small.

They occasion suffering by becoming occasionally caught between the femur and the tibia, and occasionally they give rise to an attack of synovitis with effusion. These attacks vary in frequency. The pain is sometimes quite severe and the disability complete. It is relieved when the cartilage is freed from the position in which it has been caught, which will happen often after a slight twist of the limb which the patient learns by experience how to perform.

Ordinarily the trouble is only a transitory one, not recurring frequently, but in severe cases it may cause great disability from frequent recurrence.

Loose cartilages can sometimes be felt on palpating the joint.

Disease of the Menisci.—A few cases have been reported of primary disease of the semilunar cartilages, the disease was, however, only demonstrated after opening the joint.

Displacement of the Semilunar Cartilages.—Displacement of the menisci, though not a usual affection, may occur, and give rise to severe pain and synovial effusion. This is probably the cause of the obscure trouble which has been described as an "internal derangement of the knee joint." The symptoms resemble those occasionally seen following loose cartilages, viz., sudden severe pain, inability to use the limb, and often a troublesome synovitis.

Hey describes the affection of "internal derangement" of the knee as due to some alteration "which prevents the condyles of the femur from moving freely in the hollow formed by the semilunar cartilages, and articular depressions of the tibia. An unequal tension of the lateral or cross ligaments of the joint or some slight derangement of the semilunar cartilage," may explain the symptoms.

This affection has become more common since the prevalence of lawn tennis as a sport.

Cysts of the Joint.—Synovial cysts may be formed about the knee-joint as about other joints; they may enlarge and produce an unusual appearance in the shape of the joint. In many instances they are connected with the joint by a small opening; a common place for such cysts is in the popliteal space.

It should be remembered that a number of bursæ are to be found about the knee joint, and may become enlarged.

Slipping of the Patella.—Slipping of the patella to the side sometimes occurs as a sequela of a laxity of the ligaments about the capsule of the knee-joint, and a loss of tension of the quadriceps extensor muscle.

It is an annoying rather than a painful affection, though it may at times cause a synovitis.

ANKLE-JOINT.—The diseases of the ankle joints are either synovitis, ostitis, or the affections chiefly periarticular, involving the tissues about the joint, tendons, bursæ, etc.

Simple synovitis of the ankle-joint is not common. When it is present it is usually the result of injury. Owing to the anatomical relations of the parts, serous or purulent effusion can take place only to a limited extent. Periarticular swelling is a marked and early symptom,

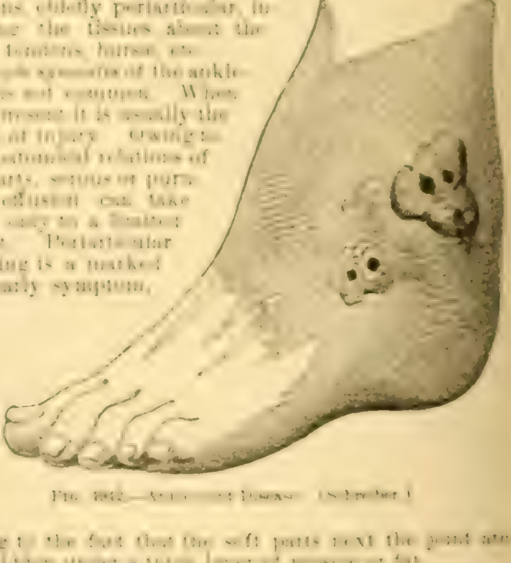

FIG. [illegible].—Ankle-joint Disease. (Schreiber.)

owing to the fact that the soft parts next the joint are not hidden under a thick layer of muscle or fat.

Pain on motion occurs prominently in acute synovitis.

but in chronic synovitis a certain amount of motion is possible without pain, but the motion of the joint is limited.

Swelling or puffiness of the tissues in front and behind the malleoli is to be noticed (Fig. 4942), and sometimes tenderness on pressure.

Chronic fungous synovitis may exist, but if it persists a long time, it extends to the cartilage and bone.

Osteitis.—In patients with tubercular diathesis, slight injury to the foot may develop an osteitis, either of the astragalus or of the lower end of the tibia. This may come from an extension of the disease from the synovial membrane, or it may originate in the bone; other adjacent bones may become involved, as the os calcis, and scaphoid, cuboid, or cuneiform bones.

The affection is usually painless, except where a large periarticular abscess has been developed; it is characterized by limping, a limitation to the motion of the joint, and a swelling of the ankle; this swelling is uniform around the ankle, except where an abscess is pointing on one side. The depressions in the contour of the ankle in front and behind the malleoli disappear in the swelling, and the foot is extended and slightly abducted. Some weight can be borne on the limb in the early stages, but if the disease becomes extensive the limb cannot be used to bear weight. The foot in affections of the ankle-joint usually assumes a position with the toes pointing downward, and in chronic cases with the foot slightly rolled outward (in the position of equino-valgus).

Chronic rheumatic arthritis rarely affects the ankle-joint.

Diagnosis.—The recognition of disease of the ankle is dependent on the usual symptoms of limping, limitation of motion of the joint, stiffness, swelling of the limb, pain, and tenderness. The prominence of these symptoms varies with the activity and extent of the disease.

Teno-synovitis gives rise to swelling around the tendons affected in functional, neuromimetic, or hysterical affection of the joint; there may be some puffiness of the skin, heat, hyperæsthesia and pain on movement of the foot; but extreme change in contour of the ankle is not present, and the pain is chiefly that of apprehension. A functional affection of the joint may result from sprains and fractures if treated too long by fixation. A diagnosis between synovitis without effusion and osteitis is not easily made, and is not necessary for treatment. Effusion is recognized by palpation of the parts of the ankle where the synovial capsule can be distended, that is, in front and behind the malleoli, and on both sides of the tendo Achillis and of the tendons in the front of the foot.

Periarticular disease is to be recognized by the localization of the tenderness, which is not to be found uniformly over the region of the most exposed portion of the joint, and by the fact that swelling, if present, is not uniformly diffused around the ankle.

A localization of the situation of the osteitis, *i.e.*, whether it is in the articular end of the tibia or tibial surface of the astragalus, is not possible, but in the earlier stages it is possible to recognize the fact if the disease is limited to the anterior surface of the astragalus (the portion articulating with the scaphoid), from the fact that in the latter case the motion at the tibio-astragaloid articulation is free. This is certainly the case where the os calcis alone is involved.

In cases of osteitis in the distal part of the foot the swelling when present involves this part of the foot entirely, or to a greater extent than the ankle.

SCAPHO-CUNEIFORM ARTICULATION. — Erichsen and Gosselin have described a rare affection of this complicated articulation. Motion at the ankle is free, but weight cannot be borne in severe cases by the foot. At a later stage the front of the foot becomes swollen.[113]

METATARSO-PHALANGEAL ARTICULATIONS. — These joints are occasionally attacked as a result of injury. In chronic rheumatoid arthritis they may also be attacked. Inflammation of the metatarso-phalangeal articulation of the great toe takes place as a result of the distortion of the toe called "hallux valgus," or in-toe, the result of imperfect shoeing, and also secondarily to the affection commonly known as bunion. A chronic rheumatoid arthritis of the joint is common, and it is a favorite seat for gout. An anchylosis of this joint occurs in adolescents, probably a sequela to a long-continued subacute inflammation. Nothing especial need be said of inflammation of the phalangeal articulations, except that they are not common.

SHOULDER-JOINT. — *Chronic serous synovitis* of the shoulder is a rare affection, most frequently met with in young children, either as a sequel of an acute attack, or as a slow, persistent process, beginning with slight symptoms easily disregarded.

Pain is either absent, or so slight as to often escape attention. The earliest symptom to attract notice is stiffness, observed particularly in forced movements, as in placing the hand on the head, etc. A slight fulness about the joint may be detected at this time, the humero-pectoral groove being indistinct, and the depression below the acromian obliterated. Although an increase of surface temperature may often be detected, its absence is of little importance, the joint being so thoroughly covered. As the disease progresses the case presents an exaggeration of the early symptoms, motion becomes more restricted, swelling increases as effusion takes place, the shoulder appearing broader, and elevations replacing the natural depressions. Atrophy of the deltoid and scapular muscles gradually occurs, but to a less extent than in the forms of osteitis.

As the joint is easily kept quiet, the symptoms gradually subside after several months, and the person recovers with a stiff joint.

Purulent synovitis may follow acute, subacute, and chronic synovitis, or develop in septic or pyæmic conditions.

Duplay has described as *periarthritis* of the shoulder-joint a condition of stiffness not infrequently seen after comparatively slight injuries. Pain accompanies motion beyond a certain limit. The amount of articular motion is apparently greater than is actually possible, owing to the mobility of the scapula, which moves with the humerus. Raising the arm above the level of the clavicle is difficult, as well as turning the arm behind the back. Atrophy of the muscles is present, and at times some spontaneous pain. The arm becomes of comparatively little use.

The diagnosis of periarthritis is not based on pathological evidence, and, judging from clinical analogy, it seems fair to infer that the affection may include the synovial membrane, constituting a chronic synovitis as well as a periarthritis.

Osteitis.—The general symptoms of osteitis of the shoulder differ in no way from those in the usual form of this disease in other more commonly affected joints; but stiffness at the joint is less noticeable on account of mobility of the scapula. The disease is insidious, extremely chronic, and prone to suppuration, and decided impairment of the joint is certain to result. Young children are most frequently the subjects, but adults are not exempt.

The forms of osteitis of the shoulder, whether beginning in the epiphysis or in the articular surfaces, or secondary to synovial disease, undoubtedly present more or less characteristic symptoms, but information is not at present sufficient to make definite distinctions easy. The more common varieties of this disease begin as an epiphysitis, or as a fungous synovitis. The history of a preceding injury is frequently obtained, but is by no means a necessary factor in a typical case. The earliest sign of this disease is pain, of a dull aching character, which is usually aggravated at night, and is referred either to the joint itself, or to the middle of the arm near the insertion of the deltoid. In many cases this symptom is absent, or very slight, and probably in these the origin of the disease is in the synovial membrane. About this time the child is noticed to use the arm much less, and upon examination a certain amount of stiffness is found. A slight increase of surface temperature may be detected, but the thickness of the coverings of the shoulder-joint renders this uncertain. The deltoid and scapular muscles early show signs of atrophy, even at this stage. There will usually be found a tenderness, frequently localized over a small area, and it is often a prominent symptom, especially in epiphyseal disease. The patient instinctively holds the arm at rest, and any attempt at passive motion provokes muscular spasm, and if this attempt be persisted in, the humerus and scapula are seen to move together.

Early in the disease a change in contour of the joint becomes apparent, and is due to enlargement of the head of the humerus as well as to muscular atrophy. This enlargement may not be symmetrical, perhaps more often presenting a localized swelling representing the situation of the disease.

The course of the disease is slow, the early symptoms, which were perhaps slight, become more pronounced; this is particularly true of the swelling and stiffness. The amount and character of the swelling depend upon the course of the disease. The stiffness may increase to complete, or almost complete, loss of motion of the humerus on the scapula. When the swelling is due to effusion within the joint, the shoulder appears fuller and rounder than normal; it is seen best by looking down on the patient; and the natural depressions in front and behind the joint become either obliterated or the sites of prominences.

In the epiphyseal form of the disease, suppuration is the rule, but it is not common in the other forms. The subsequent history depends on this result. When suppuration does not occur the symptoms gradually subside, the swelling disappears, and recovery takes place after several months, leaving a stiff joint.

If suppuration occurs, the patient complains more of pain, and the swelling increases. The prominence of the swelling will depend on the direction taken by the pus, but will be found collected in the axilla, under the deltoid, or along its anterior edge. When the pus breaks through into the cavity of the joint, the ordinary signs of a purulent synovitis supervene. The subsequent course is slow, the result depending on the extent of the carious process, which may terminate soon after evacuation of the pus, or continue to complete destruction of the head of the humerus.

The possible results are: recovery with a simple stiff joint; anchylosis, deformity, and impaired muscular power; entire destruction of the head of the bone; later, arrest of development of the humerus.

Chronic Rheumatic Arthritis of Shoulder.—Next to the knee the shoulder is the most frequent seat of this disease, which appears usually after the middle period of life.

Frequently there will be the previous or hereditary history of rheumatic tendency, but again, nothing of the kind can be traced. When one shoulder alone is affected a history of injury is the rule, but in the polyarticular forms this is not to be expected.

The disease may first manifest itself to the patient as a slight attack of joint pain, tenderness, and stiffness, and from this condition pass into the slow chronic course, with occasional exacerbations; or it may begin insidiously. The amount of pain varies, is more or less persistent, but not constant, and is dull and heavy, usually worse at night. Stiffness appears at this time with the pain; at first it is only slight, and is noticed in forced movements, as when the arm is raised above the level of the shoulder. Both pain and stiffness are more noticeable after a period of rest.

From the appearance of these symptoms the progress of the disease is slow, extending over months before marked change occurs. As the disease advances the muscles waste, and, in severe cases, to a very marked degree.

A creaking or crackling sensation on both active and passive motion is almost always found. It is best detected by placing the hand over the joint. The amount of this varies considerably in different cases, but does not seem to have any definite relation to the prominence of the subjective symptoms.

Later in the disease, when the characteristic osseous changes occur, the arm can be raised but a short distance from the side, and the loss of muscular power is very great. Swelling independent of bone enlargement sometimes occurs, and is due to effusion within the cavities of the synovial membrane, but is not a common occurrence, and usually appears late in the disease.

When these changes have taken place, a characteristic appearance of the joint is found. The head of the humerus is more prominent in front of the joint, while behind is a depression as if the head of the bone was displaced forward, while the shoulder droops, this being due both to ligamentous changes and loss of muscular tone.

Among the results which may occur from the change in the bone, is separation of the acromion, and displacement of the long head of the biceps from its groove, and its subsequent rupture.

The shoulder is not infrequently the seat of neural arthritis, that of Charcot's disease, but differs in no way in the course and symptoms from the same in the more commonly affected joints.

ELBOW JOINT.—A subacute synovitis of the elbow is not an uncommon occurrence after a blow or sprain. The symptoms are pain, swelling from the effusion within the joint, and stiffness. The disease continues several weeks or months, and may gradually subside, but is liable to leave considerable impairment of motion.

Purulent synovitis may appear in this as in other joints, from the usual exciting causes.

An ostitis frequently follows an injury to the joint, but in many cases appears with no apparent cause. It usually occurs in young children.

The disease may begin with pain, but this is not severe, and often is entirely absent. Limitation of extension of the forearm is a constant and early symptom, motion in this direction being distinctly restricted when flexion, pronation, and supination are free. A slight increase of surface temperature is usually found, but its absence does not exclude the disease.

Careful examination will reveal a slight amount of swelling even at this stage of the disease, shown by fulness and thickening on either side of the triceps; and, looking at the elbow from behind, the joint appears broader than normal. As in other joints, wasting of muscles occurs rapidly, and in severe forms of the disease is very great, especially on the forearm.

As the disease progresses the stiffness increases, motion in other directions is restricted and resisted by muscular spasm, and the joint is held at an angle of about 140°. Starting pains may be added to the other symptoms, and become the source of great discomfort. The whole joint becomes involved in the swelling, the enlargement assuming a fusiform shape, and displaying a greater prominence on the lower radial side of the joint. As the cartilages disappear, and the carious process in the articular extremities of the bone becomes established, the signs of abscess soon appear.

Chronic rheumatic arthritis of the elbow, in its course and symptoms, presents no difference from the same disease in the shoulder.

It is, however, a less frequent seat of the disease, and is one of the joints least liable to be affected alone. The position assumed is flexion.

Urethral arthritis is very prone to be located in the elbow, in this respect, perhaps, ranking second to knee only. A stiff joint, held in flexion, is the usual result.

WRIST JOINT.—Ostitis of the bones of the wrist occurs not infrequently as the result of injury by blow or sprain, and as a secondary affection to disease of the synovial membrane, or primarily from tubercular disease. Its onset is usually so insidious that the presence of the disease is often not suspected until considerably advanced. In other cases a slight amount of pain may call attention to the part, or some peculiarity in the manner of using the hand is observed. Examination will reveal a limitation to full extension. Other motions may be perfect. Wasting of the muscles of the arm will also be found.

If the disease is further advanced, deformity and swelling will be added to the other signs. The hand is held flexed on the forearm at an angle of one hundred and twenty to one hundred and thirty degrees. Swelling appears first in the depressions between the tendons. Later, measurement will show the joint to have increased in circumference, and there is a fulness of outline especially on the dorsal surface, and in destructive disease the swelling extends up on the forearm and down on the hand. Suppuration is very liable to occur, and the course of the disease is usually long and slow. Recovery may take place without suppuration having occurred, in which case the strength of the hand will suffer less. Flexion of the hand on the forearm is the usual position, and motion of the fingers is more or less interfered with.

Chronic Rheumatic Arthritis.—The wrist is a common seat of this affection, with the ordinary symptoms of pain, swelling, stiffness, creaking, etc. Weakness of the hand is frequently complained of. Stiffness is more marked in pronation and supination, motion in this direction being limited before flexion.

When deformity has occurred the wrist is generally flexed, and the distal ends of the radius and ulna are enlarged and project backward. Frequently the hand is adducted, this often being associated with a similar distortion of the fingers.

The wrist is one of the joints liable to the attacks of *urethral arthritis*. The joint is usually left flexed at about one hundred and thirty degrees, and considerable wasting of muscles of the forearm may remain.

Phalangeal Articulations.—Owing to their exposed position to sprains, blows, etc., the phalangeal joints are frequently found enlarged, slightly deformed, and stiff, extension being limited.

Chronic Rheumatic Arthritis.—The hand is a very common seat of this affection, the disease often beginning in one or two joints of one finger, and some time elapsing before others are attacked. The joints become much enlarged, and distortion usually occurs to the ulnar side, this adduction being chiefly in the metacarpo-phalangeal joint.

The fingers remain permanently distorted, becoming flexed or adducted or both; the second phalanges of the fingers, as well as of the thumb, are usually extended, giving a characteristic appearance to the hand.

Sterno-clavicular and Acromio-clavicular Joints.—Enlargement of these joints sometimes occurs in persons accustomed to hard work with their upper extremities. Inflammation of the sterno-clavicular articulation, followed by suppuration and caries, is occasionally observed, but it presents no unusual symptoms. Chronic rheumatic arthritis may occur in either of these joints, causing pain and stiffness, enlargement, and weakness of the upper extremity. The sterno-clavicular joint is not an infrequent seat of urethral arthritis.

Articulation of the First and Second Pieces of the Sternum.—Disease in this situation is rare, but has been described by Mr. Hilton. Symptoms were, pain about the sternum especially severe on forced or sudden respiratory exertion, and great tenderness over the joint. Recovery took place.

Temporo-maxillary Articulation.—By far the most common affection is chronic rheumatic arthritis; other diseases are rare.

Tuberculous disease may occur, secondary to disease of the ramus or ear.

Subluxation occurs from relaxation of the ligaments, usually in young people—frequently in women. The patient suddenly finds himself unable to close the mouth. If unilateral deviation from the median line be present, the jaw is unduly prominent. A tendency to this accident, once established, is usually permanent.

Chronic Rheumatic Arthritis.—Females are more prone to these affections than males, and young feeble subjects as well as old. One or both sides may be the seat of the disease. The usual symptoms of pain, stiffness, crackling, are present. There may be some general fulness about the joint, but deformity rarely occurs; local tenderness on pressure also occurs sometimes. A sensation of grating is sometimes complained of by patients. In extreme cases anchylosis is reported to result.

Vertebral Articulations.—French writers have described an acute or subacute inflammation of the vertebral articulations, but the affection must be an uncommon one. Inflammation of the vertebral articulations occurs in the course of gonorrhœal rheumatism. Chronic rheumatic arthritis of the vertebral articulations has been described by writers on the subject, particularly by Adams.[114] Rosenthal[115] mentions cases where peripheral neuralgic pains are apparently dependent on nerve-pressure consequent on rheumatoid alterations in the vertebral articulations. There is marked stiffness in the motions of the spine. Complete anchylosis of the spine may result, and accompanying this is usually to be found an anchylosis or limited motion at the articulations of the ribs with the vertebræ.[116]

Sacro-iliac Articulation.—For a consideration of disease of this joint the reader is referred to the article on the subject in Volume VI.

Symphysis Pubis.—Inflammation of this joint has been described. It occurs in pyæmia, and rarely idiopathically (see Holmes's "System of Surgery," Article, Diseases of Joints). A relaxation of this joint may occur in pregnancy.

Sacro-coccygeal Joints.—Inflammation of this articulation has been mentioned as following injury.

Treatment.—On the subject of treatment of chronic diseases of the joints, it may be said that in cases influenced by constitutional states constitutional treatment is manifestly indicated, and the reader is referred to the articles on Tuberculosis, Rheumatism, and Gout for details of appropriate medication. It is self-evident that the better the patient's health is, the better the patient's chances of recovery are, even in affections comparatively localized. In tuberculous joint affections the benefit of fresh air and exercise is particularly to be borne in mind.

The general methods for surgical and local treatment of chronic diseases of joints may be enumerated as follows: 1, local applications (counter-irritation, cauterization, inunctions, frictions, massage, subcutaneous injections); 2, compression; 3, fixation; 4, protection from jar; 5, distraction (extension). In addition to these the operative measures, aspiration, incision, excision, and amputation, are needed at times.

Local Applications.—The benefit to be derived from local applications comes chiefly from an alteration in the circulation of the parts and a relief of a condition of congestion, if such exist. Blisters, counter-irritation, and cauterization play less of a part in modern therapeutics than formerly, but in certain cases they appear to afford relief.

Friction and massage, in certain cases apparently, in improving the circulation, improve also the condition of the joint. It is probable that in this way galvanism is beneficial.

Ignipuncture in joint affections has been recently recommended by Kolomin, for epiphyseal osteitis, especially in the foot and wrist in children. In cases of chronic synovitis with absence of pain and tenderness, it is not recommended by the advocate of the method. An anæsthetic should be used, and a Paquelin cautery should be the instrument selected, and either superficial punctures, burning the soft infiltrated tissues round the joint can be used, or deep punctures extending to the bone and marrow, the latter after trephining the sound bone. Antiseptic dressings should be applied. Either a number of punctures can be made, or a few deep ones, according to the condition of the disease.[117] The method has also been used by Ollier, who divides the skin and sound tissues with a knife, and if necessary the bone should be exposed and thorough antiseptic cleansing should be carried out. Ollier and Vincent regard the method of more use in certain diffuse cases of tubercular epiphysitis than that by the curette.[118]

The benefit of inunctions is probably that of frictions generally, namely, the establishment of an improvement in circulation and the diminution of congestion. The application of moist heat, poultices, wet-pack, is often agreeable. And if there is inflammatory heat in the part, cold compresses, irrigation, or the ice-bag are advantageous; the cold douche or cold applied by means of Leiter's coil.

The subcutaneous injection of solutions of iodoform into tubercular granulation tissue has been recommended in fungous diseases of joints, but the results reported have not brought the method beyond the experimental stage.

In the view of imitating the spontaneous cure of fungous granulations in tuberculous joint disease by calcification, Kolischer has in a number of cases injected subcutaneously a concentrated solution of calcium phosphate at the seat of the disease. The solution is as follows: 75 grains of neutral phosphate of calcium are dissolved in twelve ounces of water, and enough phosphoric acid is added until a perfect solution is obtained. Nine minims of dilute phosphoric acid (Austrian Pharmacopœia) are added with 5 ounces more of water. The whole solution is sterilized by boiling and injected into the fungous tissue by means of a syringe with a platinum needle. The joint is dressed with gauze wet in a solution like the above, except that 90 minims more of dilute phosphoric acid should be added. There is a great deal of pain after the injection, and morphia is usually necessary. Fever and induration of the tissues follows. Kolischer and De Lone report successful cases.

The injection of solutions of iodine into the joint cavity is a remedy which was occasionally used in former times, but it fell into disuse.

Of late the irrigation of joints with aseptic solutions has been advised and practised. Solutions of carbolic acid, 1 to 20, or of corrosive sublimate, 1 to 1,000, are used. Hager reports the injection through a small trocar of such solutions with benefit in cases of relaxation of the shoulder and of the temporo-maxillary joint.

Compression.—Compression promotes absorption of fluid in œdematous tissues and effusion. It can most readily be applied to the knee by means of rubber bandages or other elastic compresses. Dried compressed sponges bandaged around a knee and then wet, will, by expansion, produce pressure in cases of chronic synovitis of the knee-joint or hydrops articuli, and are occasionally used. Elastic cloth or flannel bandages can be used, but sheet rubber bandages will be found best. In arranging compression, it is important that the pressure should be exerted chiefly on the synovial membrane and affected tissues, and not on the more prominent healthy parts of the bone. To arrange this rolls of cotton are sometimes needed, and the bandage is to be placed in the depressions of the joint, as at both sides of the patella or malleoli.

Fixation.—Fixation, *i.e.*, the prevention of motion at a joint, is indicated in all active inflammatory conditions of a joint. In subacute conditions of inflammation a limited amount of careful motion is not injurious, the amount of motion varying according to the state of the joint. Sudden, violent, or jerky motion is, however, injurious.

In cases of synovitis pure and simple there is manifestly greater indication for fixation than for protection, the reverse being true in epiphyseal osteitis. Passive motion, massage, active motion, and forcible motion of a joint all may be indicated in stages of convalescence, for the purpose of breaking up and stretching adhesions which glue the ends of the bones together or to diminish the thickening of the synovial membrane. Motion being a normal function of a joint, it is manifest that as much motion should be permitted as is compatible with the inflammatory state. The question when fixation should be interrupted and passive or active motion allowed, is one of judgment in each case. It should, however, be borne in mind that passive motion begun too early, or employed with too great force, is apt to increase the existing synovitis, and the ultimate recovery of the joint is retarded rather than hastened. It should also be remembered that the absence of pain or tenderness does not indicate the absence of osteitis and the safety of unprotected motion at a joint. Bone is not a sensitive structure, and there is comparatively little increase of sensitiveness accompanying a subacute localized osteitis. Verneuil has called attention to the danger of the frequent and early use of forcible passive motion, and has laid great stress on the undue fear of the formation of ankylosis (ankylophobia, as he terms it) from fixation of the limb. He claims that ankylosis results from inflammation, and that the best way to prevent ankylosis is to check inflammation, which is most readily done by rest and fixation. That ankylosis does not invariably take place simply from rest is shown by the fact that in the limbs of hemiplegics, where immobility is unavoidable, ankylosis does not result, except when chronic rheumatic arthritis is coexistent; but in the joints stiffness results after too long fixation in fractures, partly from traumatic inflammation, partly from periarticular contraction.

Passive motion is of more use in combating periarticular contractions than in cases of pure arthritis, and it is for the prevention of these chiefly that passive motion is advisable. But it is also true that motion is a normal function of a joint, and that its tissues are not in normal condition unless this function is brought into use.

Protection.—Protection from the jar incidental to locomotion is of importance in osteitis of the joints of the lower extremities, except in the latest stage of convalescence, and fixation, that is, prevention of flexion or extension, or the normal motion of the joint, is important in the acute stages of synovitis. The importance of protection is often overlooked in the supposition that if a knee or ankle is fixed by a stiff bandage, the patient can bear weight upon the limb, forgetting that the accidental jar to the inflamed epiphyses is more injurious even than motion. The simplest method of protection in affections of the lower extremity is by the use of crutches, but, as will be seen under the headings of individual joints, other more convenient means can be used. Protection from jar in joints of the upper extremity is readily effected by the means used for fixation.

Distraction.—The "distraction" of the bones forming a joint, that is, the pulling them apart, is manifestly desirable when the inflamed epiphyses are being crowded together either by jar or muscular pressure. Exaggerated pressure of two inflamed bony surfaces of a joint upon each other increases the danger of necrosis and the extent of the destructive osteitis, by diminishing from pressure the blood supply proper to the separation of the inflamed parts and the development of the formative or cicatricial osteitis, from which a cure is to be expected. In certain joints, as the elbow, sacro-iliac, symphysis pubis, distraction is impracticable, and in certain others, as the knee and shoulder, it is not difficult, and in the hip it is of great importance in cases of epiphyseal osteitis. In pure synovitis, where there is no danger of extension to the bone, there is little need of distraction. This, however, is a rare condition in the larger joints if extensively inflamed.

The operative procedures, aspiration, arthrectomy, and arthrotomy, will be considered severally under the headings of each joint where they are to be borne in mind as therapeutic methods.

The employment of these several methods varies not only in the different affections of the joints, but also in the different joints, certain methods being especially adapted to the anatomical conditions of certain joints; the subjects, therefore, will be separately considered under the heads of the various joints.

TREATMENT OF CHRONIC DISEASES OF THE HIP-JOINT.—*Chronic Epiphyseal Osteitis.*—Chronic epiphyseal osteitis (hip disease par excellence), the most formidable joint disease to be encountered, demands all of the surgical resources at command. The indications in treatment of hip disease are to furnish, severally, fixation, distraction (extension), protection for the benefit of the patient's general condition; to prevent and correct deformity; to allow locomotion as far as is compatible with the surgical indications; and to meet such complications as periarticular inflammation, abscess, and sequestra, as may arise.

Treatment, it is manifest, should be adapted so that it can be continued not only during the active and subacute stages of the disease, but also during the convalescent period, and until the affected joint is able to stand the jars incident to locomotion without fear of recurrence of the disease.

Fixation.—The means generally used for fixation are: 1. Plaster of Paris bandages, or leather and metal splints applied to the hip, pelvis, and thigh, for fixation. 2. The Thomas splint. 3. Gouttière de Bonnet, "wire cuirass," or some modification of it.

Plaster bandages. These furnish an imperfect form of fixation, as they do not firmly hold the trunk above the pelvis, and, owing to the possible motion of the lumbar spines, the pelvis is able to move within the bandage, thus allowing motion of the acetabulum and distortion of the limb. This is equally true of leather splints of this sort.

Thomas Splint. The Thomas hip-splint, introduced by Mr. Thomas, of Liverpool, is an appliance used in England, and has many points of usefulness. It does not, however, furnish complete fixation, nor does it prevent the occurrence of subluxation, or counteract the spasmodic muscular contraction of the muscles connecting the lower extremity with the pelvis—so important a feature in hip disease. The appliance, however, prevents motion of any noticeable amount, enables the patient to be lifted without jarring the hip, and prevents flexion of the thigh. In certain acute cases the pain may be increased by the Thomas splint, from the fact of the imperfect fixation furnished. The leg and thigh are firmly held by the appliance, *i.e.*, the flat rod, to which they are bandaged. This rod extends up the trunk, and cannot be so firmly fixed to the trunk but that some motion is possible at its upper end, as the patient turns in bed or moves. Motion of the upper end of the rod is, of course, communicated to the lower, and the joint may, in this way, be twisted and jarred by the long lever attached to the thigh.*

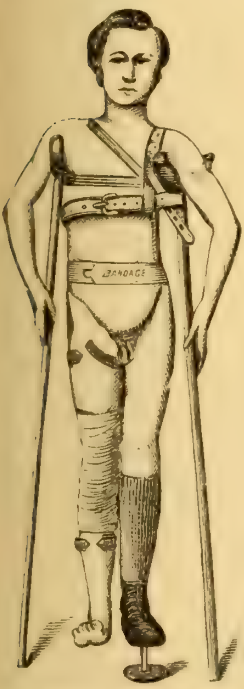

FIG. 4943.—The Thomas Splint Applied. Front view.

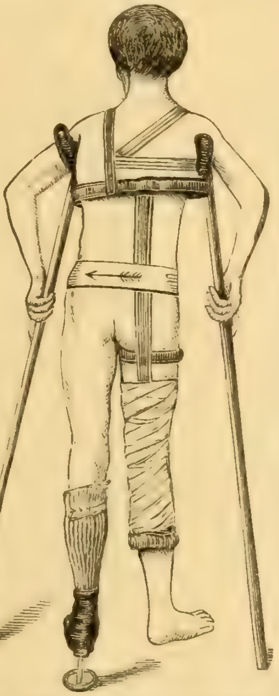

FIG. 4944.—The Thomas Splint Applied. Posterior view.

Wire Cuirass. The Gouttière de Bonnet, or wire cuirass, furnishes excellent fixation.† It is, however, cumbersome and expensive, and has the defect of not thoroughly giving the benefit which can be afforded by distraction, in relieving the increased intra-articular pressure.

Distraction.—All the above methods of attempted fixation overlook the injurious influence of muscular spasm of the muscles about the hip, in spasmodically jarring the hip-joint, and in exerting an undue pressure by crowding the inflamed epiphysis of the femur against the acetabulum. This reflex spasm of the muscles about a joint is constant in all inflamed joints surrounded by muscles. It is of special importance in hip disease, from the strength of the muscles about the joint. Such spasm prevents rest of the joint, increases the pressure on the inflamed bone, causes distortion of the limb, absorption of the head of the femur, enlargement of the acetabulum, and subsequent subluxation of the femur. The force of the pressure can be estimated if we consider the great strength of the muscles extending from the pelvis to the femur. A sudden spasmodic contraction of all these muscles drives the head of the femur against the acetabulum with the force of a sharp blow, and unless this is overcome, no attempt at securing rest of the joints is complete.

To counteract this injurious muscular force, a pull upon the femur away from the acetabulum is necessary. This is often instinctively attempted by patients, who press the foot of the well limb on the dorsum of the foot of the affected side, in the endeavor to force the limb away from the acetabulum.

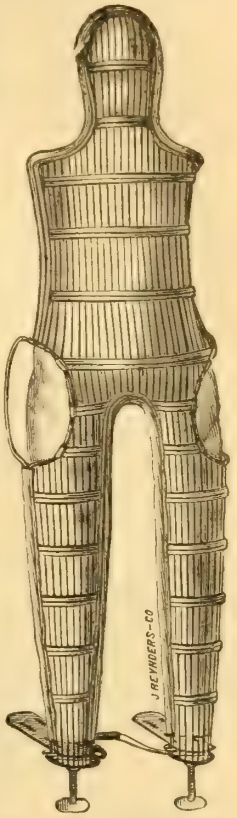

FIG. 4945.—The Wire Cuirass.

The influence of a distracting force has been denied by some writers, who claim that it is impossible to draw the femur away from the acetabulum. This is not only disproved by clinical experience, in the relief afforded by a distracting force properly applied, but the distracting effect of such force has been demonstrated by experiment.[56]

The head of the femur is held close to the acetabulum by the cartilaginous collar (cotyloid ligament), which is a prolongation of the acetabulum. In a healthy hip-joint, if all muscles are dissected away, it will be found difficult, if not impossible, to pull the femur from the acetabulum, if the pull is exerted in the line of the trunk; if, however, the limb is abducted, and a pull exerted in a direction not counter to the strength of the ligament, actual distraction takes place.

In a fœtus, or young child, distraction is easy from a downward pull in almost all directions, for the cotyloid ligament of a fœtus is not well developed. In hip disease the cartilage becomes softened and practically absorbed, and therefore cannot offer the resistance to distraction which is to be met in a healthy joint.

If a distracting force be applied with the limb strongly adducted, the head of the femur is brought against the rim of the acetabulum. This is not the case if the limb is slightly adducted, or if the acetabulum has not attained its normal adult development. But in well-marked hip disease in children, with softening of the cotyloid ligament and imperfectly developed acetabulum, distraction is as feasible as at the metacarpo-phalangeal articulation of the forefinger, where the bones of the joint can easily be separated by traction.

The effect of distraction can be readily estimated by any surgeon, if, in excision of the hip, before dislocating the head of the femur, the finger is placed on the head of the femur close to the rim of the acetabulum. If an assistant pulls upon the limb, the finger can be inserted between the head of the femur and the acetabulum. If the traction is discontinued, the pressure upon the finger will be found to be considerable. This pressure does not, of course, indicate the pressure due to muscular force, which is eliminated under an anæsthetic.

---

* A substitute for the Thomas splint, made of stout iron wire, introduced by Dr. A. T. Cabot, of Boston, will be found of use in the case of smaller children, and is more readily fixed than the ordinary Thomas splint.

† For a modified and improved wire cuirass, see Nicaise, Revue de Chirurgie, 10 Janvier, 1888.

A distracting force can be applied therapeutically, by means either of the well-known weight and pulley method, or of distraction splints.

The former method of distraction or, as it is commonly termed, "extension," is frequently employed and is often of great assistance, but it is often inefficiently applied.

The following mistakes are not uncommon:

1. The use of a weight too small to counteract the muscular spasm at the hip.
2. The neglect of a counter-extending force, or the use of an imperfect one.
3. Imperfect hold upon the leg and thigh.
4. Improper fixation of the patient's trunk and limb, allowing motion so that the distraction will fall upon the knee and not upon the hip joint.
5. The use of the pulling force in such a direction that the force is not exerted in the line of deformity.

(a) The amount of weight to be used should vary according to the case; the patient's sensation may be trusted in a measure. In cases of severe spasm as much as twenty pounds will be found to be well borne; in light cases and in small children four or five pounds will be ordinarily sufficient.

(b) The readiest counter-extending force is the weight of the body employed by raising the foot of the bed five or six inches, and causing a tendency of the body to slide in a direction opposite to the extending force. A perineal strap attached to a weight and pulley pulled in an upward direction, may be used, but it is not as convenient and no more efficient than the weight of the body applied as mentioned.

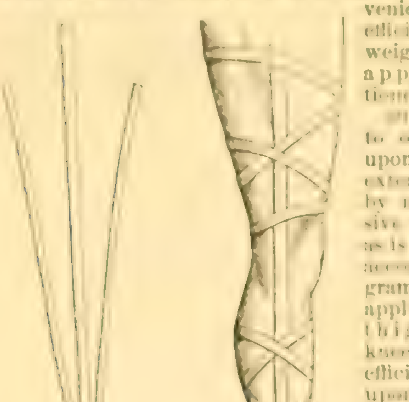

Fig. 4946.—Adhesive Plaster for Traction.

(c) The best way to obtain the hold upon the limb for an extending force, is by means of adhesive plaster applied as is indicated in the accompanying diagram. It should be applied firmly to the thigh above the knee, so as to secure efficient traction upon the condyles of the femur. If applied to the leg alone, distraction falls upon the knee and may cause relaxation of the knee joint. Efficient plaster should be used of a kind that will adhere readily without being heated. The prepared plasters furnished by Seabury & Johnson, and Grosvenor & Richards, answer the purpose best. The plasters should be changed every three or four weeks, or sooner if they cause irritation. They can readily be removed if the skin and plasters be thoroughly moistened with benzine. If any portion of the limb is chafed by the plaster, it may be protected by means of a cloth placed over the part, and the plaster is applied over the cloth and the whole limb; or if the chafing is extensive, the whole limb can be covered with vaseline and protected by a smooth bandage, and the plaster put on over the bandage to the limb. This will require frequent renewal, but will answer temporarily. It is usually the practice to apply a bandage over the plaster, but this impedes the circulation, and increases the danger of excoriation or chafing. If a bandage be applied, and worn for a few hours after the plaster is first put on, sufficient adhesion of the latter will be secured if proper plaster is used.

(d) If the patient be allowed to roll about in bed, or sit up, or to hold the limb flexed at the knee, it is useless that a proper distracting force is used. The patient, if restless, should be secured by the use of shoulder straps fastened to the bed, and by the use of sand-bags; or better still, he may be restrained by means of the bed frame to be described.

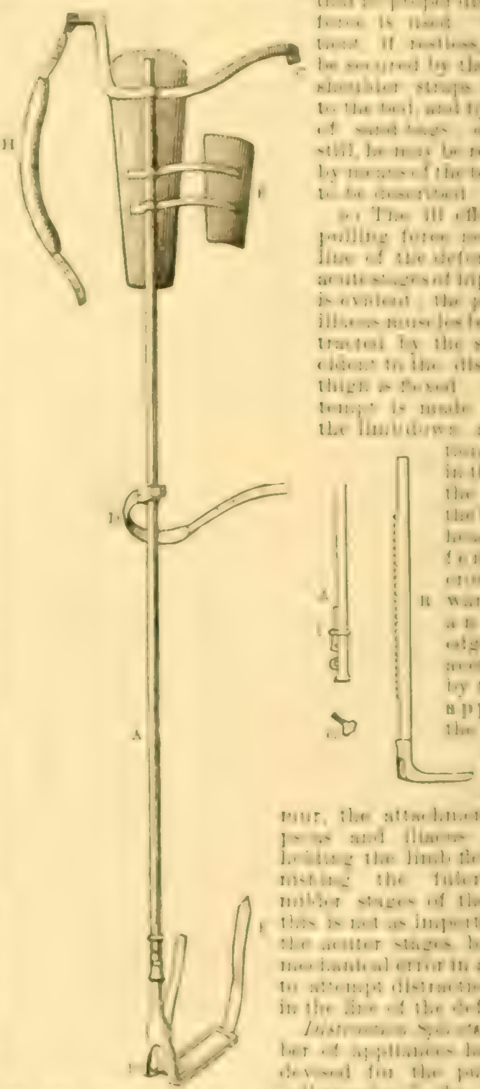

Fig. 4947.—Distraction Splint.

(e) The ill effect of a pulling force not in the line of the deformity, in acute stages of hip disease, is evident; the psoas and iliacus muscles being contracted by the spasm incident to the disease, the thigh is flexed. If an attempt is made to force the limb down, and traction be made in the line of the axis of the body, the head of the femur is crowded upward to the anterior edge of the acetabulum, by the force applied at the end of the lever, viz., the femur, the attachment of the psoas and iliacus muscles, holding the limb flexed, furnishing the fulcrum. In milder stages of the disease this is not as important as in the acuter stages, but it is a mechanical error in any stage to attempt distraction except in the line of the deformity.

Distraction Splints.—A number of appliances have been devised for the purpose of "distraction," the principle of which is practically the same, viz., perineal resistance with a pulling force exerted on the limb. As in most appliances, however, the details of the application of these principles are of so much importance that the efficacy of such treatment will depend on the details.

For efficient distraction by means of splints, it is important: (1) That it be possible to adjust the splint so that the amount of distracting force be regulated and properly applied. (2) That the perineal resistance be arranged so that great pain should not be caused in that way if efficient force is applied. (3) That a proper hold upon the limb be possible for some time. The latter has already been discussed in speaking of the weight and pulley method.

The perineal resistance should be so fixed that the perineal straps do not constrict the thigh. The straps should not be elastic and yielding, giving an uncertain resistance, and they should be made of proper material and padded, so that they do not wrinkle or cut at the edges. If the perineum be well anointed with vaseline, and the straps be properly made and padded, no serious trouble need be encountered.*

The first of the essentials above mentioned is easily accomplished, usually by means of a sliding rod moving within a tube, the amount of motion being controlled by means of a key (G) and ratchet (R), a spring securing the rod when in the proper position. This constitutes the well-known Davis Taylor extension splint, illustrated in Fig. 4947.

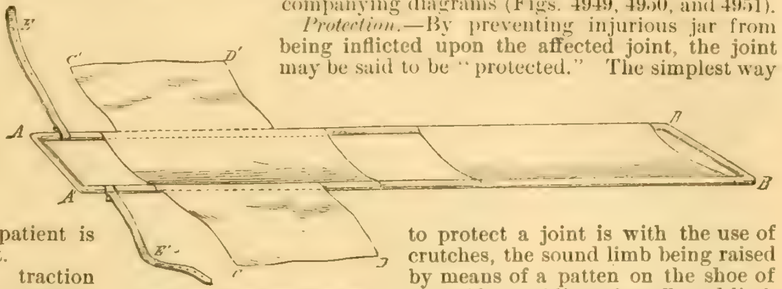

Fig. 4949.—Fixation Frame.

A traction splint manifestly furnishes certain advantages over the method of distraction by weight and pulley, in that distraction is possible while the patient is going about.

A short traction splint was at one time in use, but it cannot be relied on as efficient.

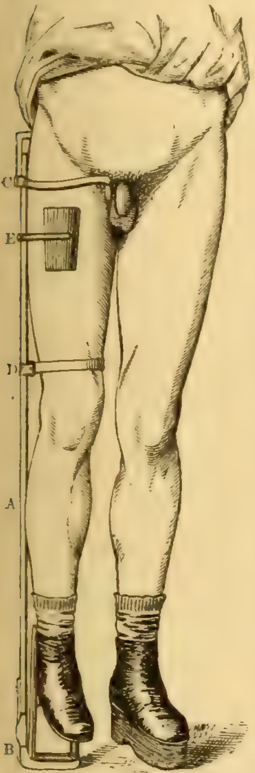

Fig. 4948.—Distraction Splint Applied.

The distraction splint consists of a rod, A, hollow at the lower part into which a rod, B, with teeth cut on the edge plays, by means of a key, G. The rod can be moved up and down, and it is caught and held in place by means of a spring, I, and sliding catch. The lower end of B is furnished with a broadened end, bent so as to pass under the foot, and through which a strap, F, can be slipped which is attached to buckles secured to the adhesive plaster on the patient's leg. To the upper end of A is secured an arm, C, which passes in front of the thigh, and to which a strap, H, passing under the perineum, can be buckled. A plate, E, in front of the thigh keeps the splint from slipping backward, and the arm D passes under the thigh and holds it firmly, and prevents the splint from slipping forward.

The arm C can be made longer, so as to pass around the waist, and hold a second perineum strap passing under the other buttock.

The splint is necessarily modified somewhat to fit different patients, but the above diagram illustrates the principle.

It has been claimed by some writers that if thorough distraction is employed, fixation beyond what is furnished by the distracting appliance is unnecessary.

Although this may be true theoretically, and practically many cases may be successfully treated without complete fixation, yet it cannot be assumed as a surgical aphorism that, where fixation is indicated, it can be furnished by a distracting force.

It is also true that thorough fixation of the hip is not possible without distraction. Efficient fixation can be furnished in the following way, illustrated by the accompanying diagrams (Figs. 4949, 4950, and 4951).

Protection.—By preventing injurious jar from being inflicted upon the affected joint, the joint may be said to be "protected." The simplest way to protect a joint is with the use of crutches, the sound limb being raised by means of a patten on the shoe of that side, enabling the affected limb to swing free of the floor. The weight of the limb exerts a certain amount of distracting force, and it was at first supposed that hip disease could be treated in this way alone.[122] Although this supposition has not been justified by facts, and it has been found that distortion of the limb and subluxation will not be prevented by this method, yet excellent protection can often be secured in this way.

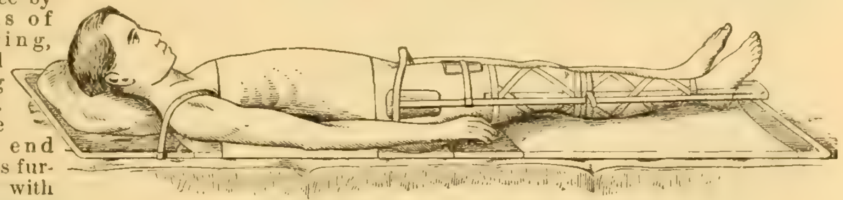

Fig. 4950.—Fixation Frame, with Patient in Position.

It will be found, however, that in many cases especially among children, it is difficult to prevent them from discarding crutches before it is safe to do so, or from kneeling upon the affected limb and in that way endangering the hip. Crutches also demand the use of the arms, and in adults the use of the arms for other purposes is desirable in the long period during which protection is needed. A protection splint is therefore of importance. The ordinary "extension" splint, as shown in Fig. 4947, is, in reality, a protecting as well as a distraction splint, as it is longer than the limb and passes under the foot, enabling the weight to be worn upon the splint instead of the patient's foot. Protection without distraction can be furnished by omitting the sliding rod, and continuing the upright rod below the foot, and expanding it at the bottom, as in the extension splint, or by inserting it into a socket in the boot. The rod should be long enough, and the boot so arranged that the patient's heel shall not touch the sole of the boot, though the ball of the foot may do so. The greatest jar in locomotion comes as the heel strikes the ground at the

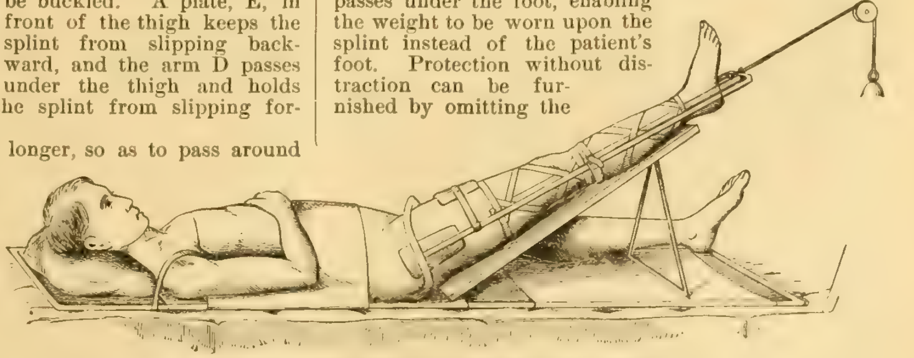

Fig. 4951.—Fixation Frame, with Inclined Plane Attached.

---

* An excellent modification of the perineal strap to be used, devised by Dr. Brackett, will be found described in the Boston Medical and Surgical Journal, October 6, 1887.

commencement of the step. If this gait is broken by the splint, the remaining use of the hip in the step will be diminished at the ankle and knee, and the hip will be sufficiently protected, except during the acuter stages of the disease.

A protection splint can be made hinged at the knee, and if properly adjusted patients can walk about readily with but slight discomfort. In this way reliable protection is secured during the long period of convalescence necessary for the thorough ossification of the affected epiphyses.

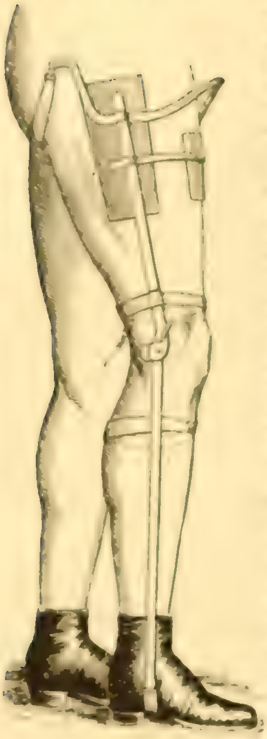

FIG. 1622.—Protection Splint Applied.

If proper protection is neglected and not continued for a sufficiently long time, the jar of locomotion, the whole weight being thrown upon the epiphysis previously carious, is sufficient to prolong the stage of irritability, to prevent complete cicatrization and ossification of the inflamed bone-tissue, to promote contraction of the limb and distortion, and in many instances to give rise to relapses.

An appliance which will not interfere with locomotion, which will readily allow walking and the free use of the **arms, which is not a great disfigurement, and can be** worn without discomfort for years if necessary, is of great use in the convalescent treatment of hip disease. It not only prevents relapse, but also prevents deformity. It is, of course, only indicated in the convalescent stage, and would be injurious in an acute stage.

Simple protection without distraction is not to be relied upon if muscular spasm is present; this point can be determined by palpation of the muscles of the hip. If muscular spasm is present, **protection and distraction should both be employed.**

Summary of Treatment.—The proper treatment of hip disease is not the exclusive use of any splint or method (i.e., of rest or extension), but the use of such means as may meet the indications that are present. During the acute stages the hip-joint should be fixed efficiently. This implies rest in bed, with fixation, and the use of efficient traction. Continued confinement to bed is not beneficial for the general condition of tuberculous patients except temporarily during the acute stage; and as soon as the acute symptoms have subsided the patient should be allowed to go about with the hip thoroughly protected against jar and spasm. This can be done by means of a distraction splint if efficiently applied.

At first, until patients become used to a splint (the **Davis-Taylor splint), crutches will be found an aid in** locomotion. If the acute symptoms return under this method, thorough fixation and rest in bed are again indicated. If the subacute symptoms diminish and there is less **muscular rigidity at the hip-joint, greater freedom** can be allowed, and eventually distraction discontinued, and the joint merely protected from jar. This should be continued as long as there is any danger of recurrence of active symptoms, or any tendency to contraction.

In brief, the hip should be fixed as long as it is sensitive, **should** be protected and distracted as long as there is muscular spasm, and protected as long as it is weak. The best results are attained only by great care for a year at least, and careful supervision and protection for two or three subsequent years. Distortions of the limb should always be prevented, and in many cases some motion can be saved at the hip-joint, if protection is not discontinued too soon.

Excision of the Joint.—In the severer cases of hip-joint disease, the question of excision demands consideration. The ultimate results after excision are not as satisfactory as at first supposed. The operation is in itself not a very dangerous one. If early excision is done, the percentage of recoveries is quite large, and excellent motion at the joint is often secured with the formation of a new joint (*Archiv f. Clin. Chir.*, Bd. xix., Heft 2, p. 409, and *Boston Medical and Surgical Journal*, April 23, 1885, p. 389). Yet the usefulness of the limb is claimed not to be as great as after the cure by conservative treatment. Holmes (*Medical Times and Gazette*, November 3, 1877) considers that the claim of the operation for adoption lies in its success in saving life where natural cure seems improbable. These cases are rare if care for years can be provided. Hüter (*Centralblatt f. Chirurgie*, No. 2, 1879) analyzed 288 cases of excision of the hip-joint; of these 134 died, 75 did not remain under observation; of the living, in only 61 were the ultimate results as to usefulness of the limb ascertained. Of these 41 were able to walk about without apparatus, 15 needed an apparatus, and 5 had no use of the limb.

A committee of the Clinical Society of London appointed to investigate the subject of the ultimate usefulness of the limb after hip-joint disease, reported the following result of their investigation of 320 cases. The percentage of mortality was forty, and of recovery forty-two. In fifteen per cent. death followed directly from the operation; in thirteen per cent., from phthisis; in six per cent., from albuminoid nephritis; in four per **cent.,** from other causes not connected with the hip affection. The treatment of those who recovered lasted one year and three-fourths; the duration of the affec**tion was three** years, and the average shortening of the limb was two and three-fourths inches. The indications for resection, as reported by the committee, were as follows: 1, Necrosis of the head of the femur and separa**tion into loose** sequestra; 2, firm sequestra of the head of the femur and the separation into loose sequestra; 3, **extensive caries of the femur or pelvis, with fistula**; 4, pelvic abscess with disease of the acetabulum; 5, chronic synovial suppuration, with disease of the cartilages of the acetabulum; 6, luxation of the femur on to the ilium, with chronic suppuration and fistula; a condition indicated by early suppuration and general symptoms.

Resection is also indicated in albuminoid degeneration, in cases with a great deal of suppuration and continued loss of strength in spite of care and rest, and also in pel**vic suppuration for the purpose of better** drainage.

Excision gives greater mobility than does conservative treatment, but the gait is much less certain and more limping.

Aseptic surgery has apparently reduced somewhat the mortality from excision at the hip-joint, but has not increased the usefulness of the limb after excision, nor in any way prevented a relapse.

The mortality also varies according to the stage at which the operation is done; during the first stage among children it is 0; in the second stage, 24.1 per cent.; and in the third, 67.5 (Grosch).

Yale's conclusions in regard to excision **of the hip-joint** represent well the present opinion of American surgeons. He says "that excision of the hip is indicated as a life-saving operation only," and that "as it has not been shown that it can save from any danger, except those consequent upon prolonged suppuration, it is, with rare exceptions, only indicated when the suppurative process has evidently reached a dangerous point and cannot be interrupted by any less serious operation."

For further details as to the procedure of excision, the reader is referred to the article on Resection.

As a substitute for excision, König, Volkmann, and **others** have advised, and successfully carried out in certain cases, a method of operative treatment by cutting down upon the bone and removing the diseased portion of the epiphysis by the chisel or curette, without sacrificing the joint. Such a method, however, is only possible in early cases, and in cases where the joint proper is as yet unaffected—cases with difficulty recognized.[129]

Amputation.—Of the still more radical method of amputation little need be said here (*v.* Amputation) except that, in cases of extreme hip disease, it is often to be regarded as a life-saving measure. The percentage of mortality of amputation for hip disease is not as great as that of amputation for injury or malignant disease.

Treatment of Complications.—Abscess. In certain cases of hip disease the epiphysitis is either so diffuse or so slight that the cicatricial process follows the inflammatory process of the bone without undue cell proliferation; but in others the tuberculous focus is neither encapsulated nor absorbed, but is sloughed out, and, causing an irritation, an abscess follows. This again may be absorbed or it may require treatment.

Simple cold abscesses secondary to hip disease can with safety be left to themselves, if not causing constitutional disturbance or increasing rapidly. It is desirable, however, that pus should be prevented from burrowing or extending in a great variety of directions. This can, in a measure, be done by bandaging the limb, and is done if an extension splint is worn efficiently; the pus being checked from extending along the sheath of the fasciæ by the resistance caused by the perineal strap and the pressure of the padded plates. If the abscess extends, it is well localized in a large majority of cases, and can extend only outwardly.

Aspiration is of assistance in many instances; in some, however, either the fluid contained in the abscess does not flow readily through the aspirating needle, or the latter is directly plugged by the caseous clots. In some instances abscesses have been entirely absorbed after one or two aspirations.

Injection of iodoform into an abscess cavity or hyperdistention by carbolic acid solution have been recommended. The latter involves the occasional risk of carbolic acid poisoning, which may be fatal.

Abscesses that are well localized, if allowed to open spontaneously, are often thoroughly evacuated, leaving a sinus which, discharging for some time, finally heals. Often, however, the abscess is not completely evacuated. Some residue remains, and, gravitating along the lines of fasciæ, gives rise to another abscess, and in this way several may be developed about the joint. It is better in such cases to open the original abscess freely, so that thorough drainage is furnished—large incisions being better than small. The pyogenic membrane should be dissected off or curetted. If that is done, with thorough asepsis, and proper dressings applied, it is not uncommon, when active disease of the bone has subsided, for such abscesses to heal up entirely by first intention, without recurrence or sinus. To gain such results two things are essential, viz., thorough drainage of the whole abscess and perfect asepsis. It is, of course, necessary that thorough treatment for the osteitis be not interrupted.

Nocturnal cries. A troublesome complication in the early stages of hip disease is often the nocturnal cry. This usually disappears after thorough fixation with distraction. In some instances, however, the cries persist for weeks or months. They are certain to disappear in the second stage of the affection; they can be checked by opiates, narcotics, chloral or chlorodyne, if not stopped by proper fixation. Stretching the sciatic, trephining the head of the femur, and direct incision of the joint have been advised and tried with success in aggravated cases of this sort.

Distortion. Distorted attitudes of the limb are incident to the clinical history of hip disease, and the correction and prevention of them form an essential part of treatment. In the earlier stages of the disease there is little difficulty in correcting the existing deformities due to abnormal muscular contractions or malpositions of the limb—the ordinary treatment of hip disease being sufficient to correct deformity. If distraction is applied in the line of the deformity, in the early stages of the disease, it will be found, in a few days, that the limb can be placed in a more nearly normal position until it eventually becomes straight.

The deformities occurring are flexion, abduction, and adduction. Flexion can be corrected by efficient traction in the line of the deformity, as already mentioned. It will be found that a traction splint is more efficient for this purpose than the simple weight and pulley; the patient should be fixed in bed, a traction splint applied, the flexed limb raised to the angle of deformity so that the back is flat, and, if necessary, the weight and pulley may be attached to the splint in order to give additional fixation to the limb. It will be found that each day the angle of deformity is less and the limb can be lowered. Flexion can also be corrected by means of the Thomas splint bent to fit the flexed limb and gradually straightened. In the severe cases rest in bed hastens the correction in this way.

Abduction usually corrects itself under the ordinary treatment for hip disease, or is changed to adduction in the natural course of the disease.

The same may be said of adduction, but this latter distortion is often more persistent. It can often be corrected by the ordinary weight and pulley method, with fixation in bed. The correction can be helped by counter-extension applied to the well limb, by means either of a perineal strap or of a weight and pulley arrangement attached to the sound limb, and pulling at the head of the bed in opposition to the force on the affected limb pulling at the foot of the bed. The result of the two forces is to correct the adduction. The most efficient appliance is one recommended by Dr. H. L. Taylor, of New York (Fig. 4953).[130]

In later stages of severer deformity forcible straightening under an anæsthetic, with or without division of the adductor tendons and the division of the fascia lata, or with division of all fasciæ by open incision, or osteoclasis, or osteotomy, has been advised,[131] and is of help.

Of all the operative procedures subtrochanteric osteotomy is the preferable one (see article in this HANDBOOK, Vol. V., p. 391) in bony anchylosis with deformity.

Osteoclasis has been used, but the fracture cannot be as precisely located as can be done in osteotomy, a procedure which has been so thoroughly simplified that it may be considered devoid of danger.

In cases of deformity with fibrous anchylosis, correction can be made by mechanical means, but in the severest cases much time and patience are required.

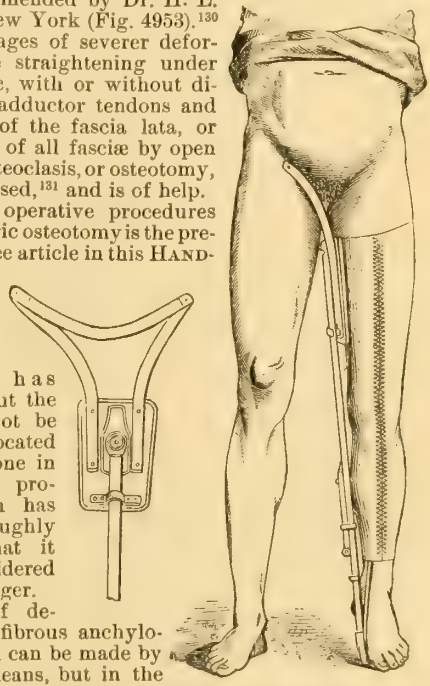

FIG. 4953.—Adduction Splint.

In cases with subluxation and absorption of the head of the femur and enlargement of the acetabulum the deformity entailed is necessarily permanent so far as the alteration of the bone is concerned, but the accompanying flexion and abduction can be corrected. Subluxation and the attendant distortion should not occur in the course of hip disease, as they are preventable, and their presence indicates a lack of thoroughness of treatment.

Shortening of the limb. Shortening of the limb after hip-joint disease and after excision occurs in a certain number of cases without satisfactory explanation; the shortening is not limited to the femur, but occurs also in the tibia and fibula and the foot.[132] Nothing can be done to prevent this arrest of growth. Prevention of the development of the disease and such use of the limb as is compatible with safety of the joint (inducing proper circulathat at the [illegible] may be regarded as the only means at our command.

Synovitis of the hip-joint.—Cases of chronic synovitis of the hip-joint are to be treated in the same way as cases of tubercular osteitis, if from the severity or duration it may be supposed that there is danger of extension of the disease to the cartilage and bone. The principles of treatment already enumerated—fixation, protection, and distraction—are to be considered in such cases. Cases of this sort do not require so long-continued treatment as those in which the epiphyses are attacked.

Chronic rheumatoid arthritis.—The treatment of chronic rheumatoid arthritis of the hip is the same as the treatment of chronic rheumatism in general. In the severer cases protection in the form of crutches, cane, or appliances will be sometimes needed. In the severest cases the deformities may need to be corrected by mechanical means, as in the earlier stages of hip disease. Massage, douches, hot and cold applications, and electricity alleviate the symptoms.

Functional affections of the hip.—Neuromimesis of the hip (hysterical affection of the hip, neuralgia of the hip) is not to be regarded or treated as a local affection. As a rule, it may be stated that the less local treatment given the better the result will be. For the mental management of the case it is sometimes necessary to assume the existence of irritation at the hip, but the treatment should be directed toward an improvement of the nervous system—either absolute rest, with general massage and forced feeding, or the reverse, viz., of diversion, with mental rest but physical and muscular exercise.

In some instances of hysterical contraction at the hip-joint an appliance is needed to correct deformity, but unless this is accompanied by management of the general condition such treatment will not be permanently beneficial. If thorough management is possible local treatment even in such cases is often unnecessary.

In cases of hysterical hypersensitiveness at the hip-joint crutches may be temporarily needed to enable the patient to go about. They should not, however, be used except as a means to give the patient confidence in locomotion in the early stages of treatment, and should not be used for a length of time.

PROGNOSIS OF HIP DISEASE.—Judging from the limited statistics at our disposal, the prognosis of hip disease in regard to life and to recovery of a useful limb is encouraging, but a long time is required in all cases. In 80 cases collected by Gibney,[133] where no particular treatment was adopted except constitutional measures, the results were as follows: In 33 the disease lasted three years; in 28 from three to six years; in 1 case fifteen years. In 48 of the cases abscesses had existed. Out of the 80 cases motion was reestablished in 12, in arcs of from fifteen to ninety degrees. In 71 cases the cure was accomplished before the fifteenth year. In only 8 of these was there such deformity as would interfere with walking. In a large majority of these cases there was only two inches of shortening; the amount of shortening varied between 1 and 3 inches.

Cazin reports that in 80 cases of suppurative hip disease treated at the hospital at Berck, in the course of five years, fifty-five per cent. were cured, twelve and one-half per cent. died, twenty-five per cent. were not cured, seven and one-half per cent. were improved when removed. Cazin has seen recovery in desperate cases. In 15 cases of suppurative coxitis with albuminuria, 5 died under conservative treatment, 2 were discharged improved, 6 not improved, and 2 cured.[134]

These cases of Cazin were all but 10 severe cases, sent from the Paris hospitals after they had ceased to improve there.

Of 288 cases collected by Gibney there was a mortality of twelve and one-half per cent. from exhaustion, meningitis, and amyloid degeneration.

In the Alexandra Hospital, London, there were 100 deaths out of 384, a mortality of twenty-six per cent.; of these, 260 were suppurating cases, and the death-rate of these was 33.5 per cent. Forty-two per cent. were reported cured.

C. F. Taylor, of New York, has reported 94 cases with only 3 deaths (1 by accident), and with recoveries in the remainder; of these 94, 24 were suppurating, and of these, 17 fully recovered.

Dhourdin reports fifty-three per cent. of recoveries in 257 cases of acetabular hip disease.

Hueter reports the mortality of hospital cases at twenty-seven per cent., and Billroth at thirty-one per cent.

Judson, of New York, in describing the treatment of 3 cases of hip disease of the third stage, has shown what can be done by careful treatment of these cases.

Shaffer and Lovett investigated 51 cases of cured hip disease which had been discharged from the New York Orthopædic Dispensary at least four years previously, and found that 41 had remained cured, some of the cases extending over ten years, and were all able to do a full day's work (although sometimes limping badly, only 1 used a cane). Of the remaining 10, 4 had died and 6 had relapsed, although 3 of the latter had been apparently cured a second time.[135]

In estimating the chances of an individual case, not only the severity of the disease has to be considered and the amount of resistance or recuperative power on the part of the patient, but also the amount of intelligent and skilled care possible in the case for a long time.

In few diseases is the benefit of thorough and long-continued treatment more clear, and in few surgical affections can the surgeon attempt to check the progress of disease and influence recovery with greater probability of success than in hip disease; but the surgical care and supervision should not be limited to the acute stages of the affection, but should be continued during the convalescent stage if the best results are desired.

KNEE-JOINT.—In considering diseases of the knee-joint, the varieties synovitis, osteitis, etc., have to be much more sharply borne in mind than is true of other joints, as these different diseases are clinically more easily distinguished and more common, and the differences more important. The methods of treatment common to all joints—viz., fixation, distraction, protection—are especially needed in affections of the knee. Fixation can be carried out in the knee-joint with much thoroughness. Effective fixation can be accomplished by means of stiff splints, by stiff bandages, plaster, silicate, starch, etc.

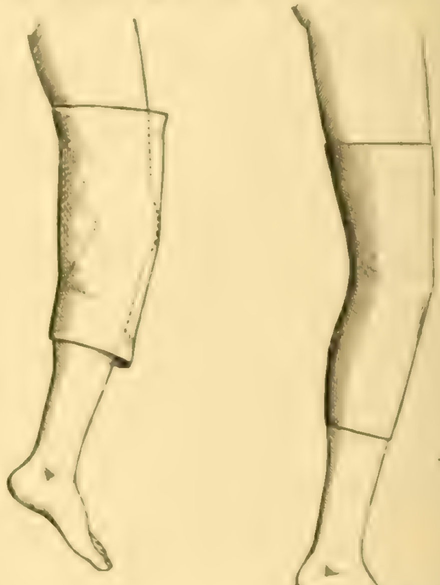

FIG. [illegible].—Incipient and Partial Flexion of the Knee.

The splint should be as long as possible in order to overcome the lever action of the segments of the limb above and below the joint. An additional reason for making the appliance of sufficient length is found in the fact that the thigh is well covered by soft tissues (Fig. 4954), and a certain amount of motion is possible owing to the yielding of the soft parts.

Distraction of the knee-joint is practicable in a relaxed condition of the ligaments and capsule. In a healthy knee-joint it is impossible to separate the tibia from the fibula owing to the strength of the lateral and crucial ligaments.

Counteraction of the reflex muscular spasm, so important in disease of the hip-joint, is needed in the knee chiefly to overcome the tension of the ham-string muscles, which tend to cause a subluxation of the tibia.

When there is a diseased condition of the epiphysis, and as long as that condition remains, the joint is incapable of bearing pressure or weight, and needs protection. Protection from jar is compatible with locomotion by means of crutches, or of an appliance longer than the limb, with arrangement for perineal support.

Compression is most readily applied to a knee-joint by means of a thin rubber bandage—Martin's bandage—wound about the limb; bandages of elastic cloth can also be used, but are not as efficient. Dried and compressed sponges, bandaged firmly about the limb, will expand when wet, and in this way compress the tissues of the joint effectively; or the knee may be thickly covered with sheet wadding and binders' board made pliable by immersion in hot water, and the whole bandaged firmly.

Innunction of fats, of oleates, and of medicaments, painting with iodine, etc., are remedies frequently used, but their value is questionable. The same may be said of cauterization.

Synovitis.—In chronic synovitis without effusion thorough fixation is needed in the early or acuter stages, with or without compression. The application of cold by ice-bags, evaporating lotions, cold douches, or the cold coil will often be a help, and in some instances hot cloths or poultices relieve pain. Counter-irritation, by means of tincture of iodine or blisters, and cauterization, are of doubtful value, except as expectants.*

In chronic synovitis with serous effusion the treatment is primarily to cause the absorption of the fluid by means of compression and fixation. Besides this, distraction and protection—one or both—are needed if there is danger of extension of the disease to the bone or cartilage, and fixation if there is any activity of disease; the choice of massage, of passive motion in later stages, or of fixation, is a question of judgment in each individual case, it being borne in mind that motion is a normal function of a joint, and that massage may be supposed, by temporarily improving the local circulation, to promote the absorption of synovial œdema or its results, and, on the other hand, that anything which increases the inflammation in a joint, like ill-judged motion, is an injury.

When the inflammatory stage is passed and there is no further danger of extension of the disease to the bones or cartilage, massage, as well as passive exercises, may be allowed. Twists and sudden jars are to be avoided, and protection (crutches or splints) is advisable in the stage of convalescence if the attack has been at all a severe or protracted one.

In synovitis with purulent effusion the joint should be thoroughly drained by incision and washed out. If the effusion is but slightly purulent, aspiration and thorough washing out will suffice. If, however, the pus is thick, or caseous clots are present, the joint should be freely opened by straight lateral incisions and well washed out with an aseptic fluid. The observance of strict aseptic precautions is of course necessary.

Hydrops Articuli.—In hydrops articuli (water on the knee) the treatment is such as would promote absorption or removal of the fluid. Besides friction and compression, which are often sufficient, aspiration is of great service. The procedure may be considered as free from danger. The best method of applying is as follows: after thoroughly cleansing the skin, the knee is bandaged with a rubber bandage to exert slight pressure, leaving a small portion uncovered for the insertion of the aspirating needle. This is best done at a little distance from the side of the patella. The size of the needle should depend upon the character of the fluid; if thorough asepsis is carried out a needle of large size or a trocar is free from danger. After the joint has been aspirated, the wound should be covered with a piece of aseptic gauze or cotton and a rubber bandage applied over the knee. If the fluid is again effused, the joint can again be aspirated.

When reproduction of fluid takes place, injection of iodine, as in the treatment of hydrocele, has been recommended and used, but sometimes the results have been disastrous. The injection of carbolic-acid solutions, or of corrosive sublimate solutions, is apparently efficacious, as well as thorough irrigation of the joint already mentioned.

Epiphyseal Osteitis.—In epiphyseal osteitis the treatment requires the greatest care to preserve the function of the joint as far as is possible, to arrest the progress of the disease, and to prevent and correct deformities. Fixation is demanded in the acute stages and should be thorough; in the subacute stages some motion is at times allowable, and in the stage of convalescence as much motion as is possible without direct jar to the joint should be allowed. Protection is demanded in all stages of the disease, and distraction in the acute and subacute stages. Aspiration of the joint, incision, injection into the joint, counter-irritation, may be all indicated, and in the severe cases excision or arthrotomy.

What was said in regard to the treatment of hip disease may be repeated in speaking of epiphysitis of the knee-joint. The treatment should be thorough, persistent, and should meet the indications. Fixation and protection are the most important indications in diseases of the knee, distraction being less so. The employment of protection should be continued until it is certain that the epiphysis is normal, a matter of judgment in every case. Protection should be discontinued gradually and tentatively; if discontinued too soon, recurrence will take place, or the deformity at the limb will increase. Fixation should be used so long as there is any activity of the inflammation; this is indicated by pain, muscular spasm, or tenderness. Efficient fixation of the knee does not require confinement to bed.

Protection can be furnished by means of crutches, raising the sound limb by a thick sole, and allowing the affected limb to swing clear of the ground. Better protection is furnished by means of a splint (with perineal support) longer than the limb and passing under the foot so as to

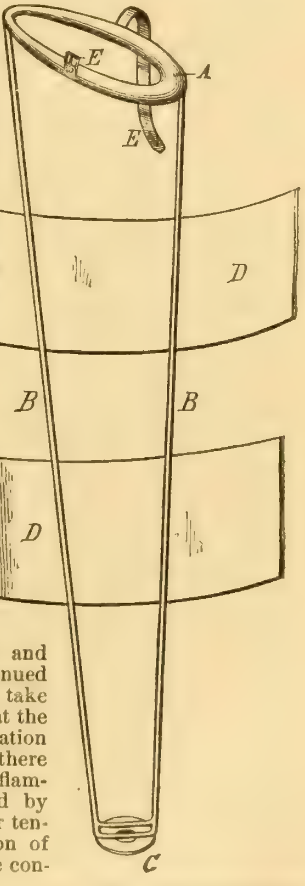

FIG. 4955.—Protective Splint for Knee and Ankle.

---

* For the treatment of acute synovitis the reader is referred to the article Synovitis.

take the part of locomotion. The best of these splints is one similar to that already described as a protective splint in hip disease (Fig. 2962). It can be readily set at the angle of flexion of the knee and straightened as the limb straightens, and distraction can be added to the splint if necessary.

A simpler appliance is the Thomas knee splint, which consists of a padded iron ring fitted so as to surround the thigh at the perineum, and fastened to two rods, one on each side of the limb, longer than the limb and secured at the bottom to a metal plate below the foot (Fig. 2971).*

In cases of extreme disease of the knee-joint amputation of the thigh is necessary as a life-saving measure. In less severe cases the limb may be saved by excision (for the details of this procedure the reader is referred to the article on Resection). As for the indications determining a choice between excision and amputation, it can be said that where the patient's reparative power is slight an amputation is to be preferred. The question is largely one of individual judgment.

One danger from excision in children is that of arrest of the growth of the limb from removal of the epiphyses. For this reason *arthrectomy*† has been advised in children as a substitute for excision. The joint is opened as in cases of excision and the whole synovial membrane as far as it is tuberculous should be dissected out. If carious spots are found in the bone these foci should be removed by the curette or chisel. If the whole epiphysis is diseased excision is of course unavoidable, but in many cases this is unnecessary. Schede, Volkmann, and others have reported excellent recovery with complete healing without suppuration in a few cases of this sort, and similar success has followed the procedure in two cases in the practice of the writer. Strictest asepsis is essential, as well as a thorough removal of all tuberculous tissue in the affected part, necessitating sometimes complete dissection and removal of all of the synovial membrane, as well as careful curetting of the bone. The patella should be removed or left according to its condition. Either two straight incisions, one median incision, or a cross incision may be used. The patella may be divided and subsequently wired, or the ligamentum patellæ cut across. All tubercular tissue should be removed by the chisel, curette, or scissors.

Müller has collected reports of 22 operations: 1 died of chloroform-poisoning, 1 died of iodoform-poisoning, 2 died of general tuberculosis from eight to eleven months after the operation on the knee, which had been successful, 15 healed by first intention without a fistula in from three to ten weeks, and in the others a small fistula remained after the first operation, and a subsequent curetting was necessary before recovery took place. No deformity followed the operation in 6; the knee remained stiff in all but 2, in which there was a certain amount of motion possible.[10]

Statistics in regard to the ultimate results of treatment of disease of the knee are unfortunately of little value as a guide in the consideration of proper treatment of disease of the knee-joint; it may be said that aseptic surgery has materially improved the chances of recovery after excision, and that conservative treatment in children gives most excellent results in cases which can be watched and treated for a long time. The following figures are given by Wilkens of cases treated in the course of seven years at the Göttingen Clinic (see *Deutsche Zeitschr. f. Chir.*, 1885, Bd. 21, Heft 5):—

The treatment was fixation by plaster-of-Paris bandage preceded by extension, and with or without incision of abscesses, curetting, etc., or by resection, partial or complete, or amputation. Of the cases not operated upon, in three years fourteen per cent. recovered, fifteen per cent. died, sixty-six per cent. were still under treatment. In four years twenty-six per cent. had recovered, seventeen per cent. had died, fifty-seven per cent. were uncured. At the end of five years, including all cases operated on or not, twenty-nine per cent. remained uncured, eleven per cent. had been amputated (with a mortality of sixty per cent.), thirty-seven per cent. had been resected (with a mortality of fifty-one per cent.), and thirteen per cent. were well without operation.

It should be borne in mind that these figures represent hospital cases, presumably cases treated under more or less unfavorable circumstances.

Periarticular abscesses are to be treated in the same way as cold abscesses are treated in connection with other joints.

The results of conservative treatment of the tuberculous knee-joint may be excellent, but in severe cases a long time is necessary. In adults the prognosis of the conservative treatment of severe cases is much less satisfactory. The reverse may be said of excision.

Prevention and Correction of Deformity.—The deformity most frequently accompanying chronic epiphyseal osteitis is flexion; this can, in the early stages of the disease, be easily corrected by manual straightening under an anæsthetic, by a pulling force with a weight and pulley, by a distraction splint, by bandages and a fixation splint, or by repeatedly applied plaster bandages. If the deformity, flexion, remains uncorrected for some time in severe ostitis of the knee-joint a subluxation of the tibia backward takes place, due to the contraction of the hamstring muscles. If an attempt be made to straighten the limb the head of the tibia is held in its subluxated position by the contracted hamstrings and the posterior capsular ligaments, and if the leg is brought into the direction of the thigh the head of the tibia will be found behind its normal position and an ugly deformity will have resulted. This can only be prevented by a forward force exerted on the head of the tibia, pushing it around the end of the femur as the limb is straightened. Various appliances have been used for this purpose, and by the use of long-continued and persistent effort correction can be effected by proper splints.

In angular ankylosis at the knee resection for correction of the deformity is not without danger. Pénières collected 77 cases with a mortality of eight per cent. This was, however, before the days of aseptic surgery, for the same writer collects 36 operations and no death where aseptic precautions were used.[11] For the correction of deformity which has persisted for some time, forcible straightening under an anæsthetic is often necessary, or, in cases of bony ankylosis, osteotomy or excision (see Osteotomy, Resection). In fibrous ankylosis the readiest way to correct is first to forcibly flex (in order to break up adhesions without increased danger of rupture of the artery) and then extend, dividing the hamstring tendons if need be beforehand. Mechanical appliances are often recommended for the purpose of straightening, but are unnecessary if the following procedure be carried out in difficult cases. The patient is placed upon the floor on his back, and the surgeon stands over him, holding the knee with both hands, the fingers being placed under the popliteal space. The patient's ankle is grasped between the surgeon's knees. The whole weight of the surgeon's trunk can then be thrown upon the end of the lever furnished by the leg, the hands of the surgeon pulling upon the popliteal space furnishing the resistance. After the limb is forcibly flexed and the adhesions broken, it can be straightened if the patient is turned upon the face, a downward force being applied to the heel and resistance being furnished by a cushion placed under the patient's knee. Where subluxation is present it must be corrected, and this can be done by means of an appliance which will, however, be needed only in extreme cases.

After correcting the deformity the limb should be well surrounded with soft cotton and a stiff bandage applied, the limb being held straight until the plaster has become hard. The procedure is sometimes followed by pain, and opiates are necessary for a few days. In the lighter cases no such force is required, but the limb can, under an anæsthetic, be brought into position by manual manipulation.

---

* In the figure of the protective splint (Fig. 2962) [illegible]

† The term "arthrectomy" has been applied to this procedure by some writers.

The dangers incurred by this procedure are not as great as would be supposed. Such a violent procedure should not be undertaken if there is inflammation present at the joint, but in the early acute stages little force is required to straighten the limb. The danger of rupture of the artery can be avoided by care. Separation of the epiphysis of the femur may take place, but is cured by the fixation requisite to treatment, and should not occur if the force is carefully applied. Fracture of the femur and tibia can be avoided by care.

The treatment of *chronic rheumatoid arthritis of the knee* is the same as that of the same disease elsewhere, as may also be said of syphilis and gout. In some cases of chronic rheumatoid arthritis protection is sometimes of use, distraction is not necessary, and fixation should be applied only temporarily. Massage, hot applications, and electricity may be of benefit.

Disease of Cartilage.—Three cases have been reported of circumscribed fungous disease of the internal meniscus. In one of these ignipuncture, and in two removing the granulations by scraping, resulted in recovery. Extirpation of the affected meniscus was followed by a cure with active motion of the joint. In another case the external semilunar cartilage was removed on account of chronic inflammation and a relaxed condition which interfered with locomotion. The operation resulted in healing by first intention.[138]

Loose Cartilage.—There are two methods for removal of loose cartilage at the knee: 1, The open incision, introduced by A. Paré, discarded by later surgeons, including B. Bell, who preferred amputation of the thigh, and revived again since the introduction of aseptic surgery; 2, the subcutaneous extraction, which is done as follows: the foreign body is pushed into the external upper cul-de-sac and held by the finger of an assistant under the triceps tendon, and by help of another kept from slipping up. An incision is then made with a tenotome in the subcutaneous tissue, directly under the synovial cavity, and in the synovial wall, directly under the foreign body, which is forced out into the cellular tissue: two weeks later the loose cartilage is removed by direct incision. The difficulties of the second step, namely, removal of the cartilage from the cellular tissue, are great, and several modern surgeons prefer the direct incision on account of the technical difficulty of the indirect method (*Revue de Chirurgie*, 1881, No. 1).

In removal of a loose cartilage by direct incision, an incision is made at the side of the patella, where the loose body is to be felt; the strictest asepticism is to be observed.

Displacement of the semilunar cartilage (internal derangement of the knee-joint) is the result of a sprain, and the symptoms and treatment are those of sprain at the knee with synovitis.

In the severest cases an anæsthetic is necessary in order to restore the cartilage to place, but after the cartilage is replaced by manipulating the joint immediately after the accident, the knee is to be flexed to its fullest extent, the tibia pulled upon as if to draw it away from the femur, and rotated; the limb is then suddenly straightened, the operator pressing upon the displaced cartilage at the same time. The cartilage sometimes returns to its place with a snapping sensation, but often without the patient's consciousness. Frequently the patient learns, by a sudden twist of the limb, to replace the cartilage himself. In some of the severest cases it has been necessary to remove the cartilage by direct incision.

Howard Marsh has used with benefit a steel clamp as a means of prevention of the slipping of the cartilage, when there is a tendency to recurrence. The clamp consists of two lateral pieces of thin steel, well padded and fitted to each side of the patella, connected by a spring passing behind the knee.[11]

Slipping of the Patella.—Occasionally, owing to an injury to the lateral fasciæ, or to a loss of tension of the quadriceps extensor muscle, the patella slips to the side, interfering with locomotion, and causing discomfort. Electricity applied to the muscle, with the idea of strengthening it, will sometimes be of assistance. The patella can be kept in place by a stout piece of leather moulded to, and covering, the knee, but with an opening into which the patella fits; this leather cap is then strapped behind the knee and held firmly in place.

ANKLE-JOINT.—In the treatment of the most formidable affection of the ankle-joint, viz., tibio-tarsal osteitis, protection from jar is especially indicated—as will be readily seen, if it be borne in mind that in locomotion the whole weight of the body is borne at each step upon the comparatively small surface of the articulating portion of the astragalus. Fixation of the ankle in a stiff bandage and allowing the patient to walk upon the limb, is a manifest error, occasionally made possible through confusion of a simple synovitis, which, at certain stages, needs fixation, with osteitis, which should be protected from jar at all stages. Protection can be furnished either by means of crutches, or, more thoroughly, by means of protective splints with perineal supports. Protective splints, described for the knee-joint, are needed in osteitis of the ankle.

Fixation is of advantage in the acuter stages of the affection, and is readily furnished by means of stiff bandages.

If abscesses form, they should be incised.

In cases of caries of the ankle, with extensive disease of bone, the decision to persevere in conservative treatment, or to resort to operative interference, is one which is based largely upon the patient's age, and the circumstances of attendant care.

In children, the results of conservative treatment are satisfactory. Satterthwaite reports 14 cures with useful limbs in 16 cases; the time of treatment being on the average two and one-half years; 2 of the 16 patients died (New York *Medical Record*, August 21, 1880).

In adults, however, the treatment is much less satisfactory in advanced cases of caries. Excision or amputation is not infrequently demanded in the worst cases.

Operative interference consists of curetting the sinuses or the removal of the diseased tarsal bones. It will be found that the latter procedure gives much the more satisfactory results where the osteitis has become so extensive as to have occasional sinuses; if it has involved a greater part of the astragalus, if the curette is unreliable as a means of removing all the disease.

Chronic synovitis of the ankle-joint is chiefly the result of sprains, and the treatment should be the same as that commonly used in the sprains of the ankle, viz., fixation, compression, massage, passive motion, occasionally protection; and the period of time required for the employment of these several methods varies according to the severity of the attack and the condition of the patient.

Fixation is readily furnished by the stiff bandages—silicate of potash or plaster of Paris—and compression by a rubber bandage. Care should be taken that the pressure comes upon the proper part of the ankle, and not upon the most prominent part, viz., the malleoli. The parts requiring pressure are the depressions in front and behind the malleoli, and these should be filled with pads of cotton, so that the pressure of the bandage should fall upon the capsule of the joint, and not chiefly on the malleoli; if there is much swelling at the ankle, this precaution is not necessary; but as the swelling subsides the malleoli become more prominent, and would bear the chief pressure of the constricting bandage.

Pure tuberculous synovitis not affecting the bones, an affection rarely encountered, should be treated with a view of preventing an extension of the disease to the bones—*i.e.*, in the same way as osteitis would be treated.

In severe chronic synovitis of the ankle-joint the indications are for rest, fixation, and, if swelling be present, compression. In cases where there is danger of extension of the disease to the astragalus or tibia, protection is advisable.

In the lighter cases of synovitis of the ankle-joint, or after the inflammatory stage has passed, the need of perfect fixation is not present, and massage, with protected or graduated motion, will be found of great benefit.

METATARSO-PHALANGEAL DISEASE.—In chronic affections of the joints of the anterior part of the foot and of the toes it is often desirable to allow locomotion without jar at the joint and to avoid the inconvenience of crutches or of appliances.

The shoe devised by Mr. Thomas, of Liverpool, seen in the accompanying diagram, will answer the indications of protection and fixation, at the same time allowing locomotion.

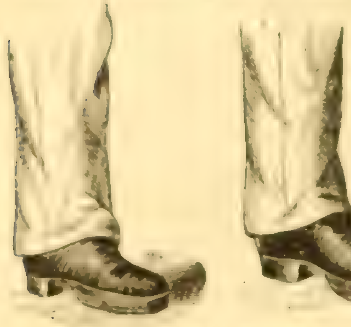

FIG. [illegible].—Shoe for Metatarsal Disease.

The shoe worn by the Chinese, with a thick stiff sole, cut away at a slant at the toes, answers the same purpose.

It is important, as a preventive measure, that shoes which are too short or which crowd the toes should be avoided; the foot should also be prevented from slipping forward, crowding the toes against the front of the shoe. This can be done by properly lacing the shoe against the instep and ankle, and furnishing a shoe of sufficient length.

SHOULDER-JOINT.—*Chronic Synovitis.*—In synovitis of the shoulder-joint with any active inflammation the indication is simply for rest and fixation. These are readily secured by means of a sling, and a bandage securing the arm to the side. Compression will be needed if there is swelling and effusion, and this is effected by surrounding the joint with cotton, and covering the whole by a felt or hard rubber shoulder-cap, which is firmly bandaged to the arm or shoulder.

Fixation should not be continued longer than there is subacute inflammation, and can be gradually discontinued; the bandage which holds the arm to the side being first discarded, and then, later on, the sling.

The question of the use of forcible passive motion in the convalescent stage is a vexed one. Where the adhesions are chiefly periarticular, or confined to portions of the joints, and are firm, forcible motion under an anæsthetic will be necessary, but in the majority of slight cases gradual passive exercises will suffice.

If the fixation is due to muscular spasm chiefly, forcible passive motion will be of no use, as the spasm reflex to the inflammation at the joint will reappear after the anæsthetic as long as the disease of the joint remains.

Local applications are to be used at the shoulder-joint for the same reasons and indications as at other joints.

Osteitis.—In tubercular osteitis at the shoulder-joints, the indications for treatment are practically the same as those present in chronic synovitis.

Distraction is not indicated in disease of the shoulder, as, owing to the laxity of the joint, the weight of the dependent arm, if kept at rest, is sufficient to separate the humerus from the opposing bone surface of the scapular articulation.

Abscesses are to be treated in the usual way.

In the severest cases excision of the shoulder is indicated, and excellent results are attained.

ACROMIO-CLAVICULAR AND STERNO-CLAVICULAR ARTICULATIONS.—Fixation and expectancy are all that can be done for these joints. Fixation can readily be secured by retaining the arm, as in disease of the shoulder-joint.

ELBOW-JOINT.—Synovitis of the elbow-joint recovers usually under fixation, which is readily obtained by fixation splints, internal angular splints, external angular splints, or a lateral splint to which the arm is strapped or bandaged. These splints can be made of thick pasteboard, reinforced with iron or wire (telegraph wire) or wood, and should be fitted to the arm bent to a right angle. Compression can be effected by surrounding the joint with cotton and bandaging it with an elastic rubber bandage. In time fixation by splints can be discontinued, and the support of a sling alone be relied on, with passive exercises and massage.

In cases of osteitis the treatment is the same, except that a much greater length of time is required, and abscesses requiring to be incised may supervene.

In the severest cases excision offers the readiest chance of cure.

WRIST.—The treatment of disease of the wrist-joint is to be conducted on the same principles as that of the other joints, and consists chiefly of fixation, by means of palmar splints, and compression. It may be mentioned, in regard to tubercular osteitis of the wrist, that excision, till recently rejected as an unjustifiable procedure, is of more usefulness than has hitherto been supposed. It is, of course, only indicated in the severest cases. Excellent results have been obtained by this procedure, chiefly in adolescents and young adults.

OTHER JOINTS.—Diseases of the sacro-iliac articulation, and of the temporo-maxillary articulation, have been already treated elsewhere in this work. (See under Sacro-iliac Disease and Jaws.) The treatment of the remaining joints requires no especial mention.

The writers are indebted to Drs. H. L. Burrell, H. W. Cushing, and E. G. Brackett for their assistance in the preparation of this article.

LARYNX, NEUROSES OF THE.—Strictly speaking, neuroses of the larynx are disorders or diseases of some portion of the nerve-structures supplying the larynx, or presiding over its functional integrity; but practically, all disturbances in laryngeal functions normally performed under neural influences are to be included in the term. There are various disorders of the muscular, vascular, and glandular structures of the larynx which produce objective and subjective results so similar to those of true neuroses that their differentiation is difficult and sometimes impracticable. Hence the most instructive method of studying laryngeal neuroses will be to include all impairments of function, whether neuropathic in origin or not.

The neuroses of the larynx, like disturbances of the nervous system in general, comprise disorders of nutrition—trophoneuroses; of sensibility—æsthesioneuroses; and of motility—kinesioneuroses; all presumptively attributable to cerebral, cerebro-spinal, and neural lesions, or to molecular disturbances, whether perceptible evidences of alterations of structure in cerebro-spinal or nerve-tracts be manifested or not. Neuroses that are so manifested are recognized as organic neuroses. Such as are not so manifested are termed functional neuroses, although the inference remains that some undeterminable change of tissue or of tissue relation must have taken place. It is sometimes impossible to determine whether organic neuroses originate in the cerebral, spinal, or peripheric portions of the nervous system.

TROPHONEUROSES: NEUROSES OF NUTRITION.—Disease being due to disturbance between equilibrium of nutrition and work, excess of nutrition and of work produce permanent hypertrophy; excess of nutrition alone produces hypertrophy with subsequent degeneration; lack of nutrition produces degeneration and atrophy; and excess of work and lack of nutrition produce atrophy. In studying these nutritive changes the condition of the trophic centres and of their lines of distribution is a matter of great importance.

Hypertrophy.—Hypertrophy of laryngeal tissues occurs most frequently in connection with an inflammatory disease. It has occasionally been noted without assignable cause, and may be attributed, at times, to increased functional activity of trophic supply. I am unable to refer to any recorded instances of hypertrophy as of presumptively purely neural origin.

Atrophy.—Atrophy of the laryngeal tissues is frequently observed in connection with chronic diseases of inflammatory origin, with anchyloses of the crico-arytenoid articulation, complete or incomplete, and with both spasmodic and paralytic disorders of the laryngeal muscles. In most instances the atrophy is to be regarded as a passive process, the result of disease or disuse of the nerve or muscle. In some it is the exhausting result of excessive innervation in resistance to tonic spasm (Jeleuffy)—prolonged catabolism. On the other hand, similar conditions may exist for years without producing atrophy. The rapidity with which atrophy, notably of the posterior crico-arytenoid muscle (Semon), sometimes follows paralysis, renders it likely that an active neurotic degeneration has been in progress. Active neurotic atrophy presupposes injury to the spino-neural mechanism, or irritation of the afferent fibre of a reflex arc (Ross). The association of trophic with motor paralysis renders it impossible to determine whether or not the nutritive changes are under the domain of special nerve-supply. Some observations by Türck ("Klinik der Krankheiten des Kehlkopfes und der Luftröhre," p. 440, Wien, 1866) as to atrophy of the crico-thyroid muscle without degeneration of the superior laryngeal nerve, led him to the inference that the trophic supply of this muscle must have come from the recurrent nerve and not from its own motor nerve.

While all the muscles of the larynx are subject to atrophy, none are so prone to atrophy from pathological lesions as the posterior crico-arytenoids. Great atrophy of these muscles alone has been observed after paralysis, independently of any microscopic evidence of alteration of either recurrent or pneumogastric nerves, as in an instructive instance reported by Riegel (cited in Ziemssen's "Cyclopædia of the Practice of Medicine," vol. vii., p. 961, New York, 1876). In most similar instances, however, degeneration of nerve-tissue has coexisted. Similar atrophy of the posterior crico-arytenoid has been observed likewise in cases of spasm of all the laryngeal muscles, possibly because of the forced inaction due to its having been overpowered by the combined force of the antagonistic muscles; probably because of cessation in the organic exercise of its special function, or perhaps because of loss of innervation from the respiratory centre, through other channels than those proceeding from the fibres of the recurrent nerve. Atrophy of the muscle has been recorded, as far as I know, only in cases in which the corresponding vocal band had been in phonatory, or in approximatively phonatory, position during life.

Treatment.—There is no special treatment that can be pursued with confidence. Probably systematic and long-continued electrical treatment offers the most reasonable prospect of benefit.

Changes in Secretion.—There is little reason to doubt that changes in the secretory products of the glands of the mucous membrane are often troublesome, especially when occurring in neurotic subjects and in the absence of marked pathological change of tissue. They may be, and most frequently are, associated with hyperplasia of the gland tissue, of the connective tissue or of the epithelium, or they may be associated with conditions of malnutrition and atrophy.

In many instances these are due to retention of products impairing nutrition, the result of improper diet and hygiene, and lack of elimination and exercise. Purgatives, diuretics, and sedatives, regulated diet, work, exercise, and sleep will do far more good in these instances than any topical treatment.

HYPERÆSTHESIA. NEUROSES OF SENSATION.—The term sensory phenomena is too broad and may well be subdivided. Krishaber[1] made a distinction between common and reflex sensibility. Bosworth[2] discriminated between three kinds of sensibility: 1, tactile, by which temperature and pressure are appreciated; 2, dolorous, by which pain is appreciated; and 3, reflex, by means of which muscular contractions, such as occur in cough, spasm, sneezing, choking, etc., are provoked, as are vasomotor, [illegible] vascular and secretory phenomena. Still further subdivision seems requisite, however, to include all varieties of sensibility; for distinction can be made by sensation between touch, or tactile sensibility; temperature, or thermal sensibility; weight, pressure, and resistance, or muscular sensibility; pain or dolorous sensibility; and a group of manifestations of reflex sensibility.

Sensory neuroses may affect all of these conditions, or any one or more of them. The degree of sensory excitability varies within great limits, not only in individuals but in the same individual under different conditions, normal and abnormal. The normal degree of sensibility in any individual may be augmented, diminished, obtunded, or abolished under the influence of hygienic or of toxic surroundings, and of overwork, innutrition, exposure, injury, and disease. Disorders of sensibility, dysæsthesiæ in general, may be due to appreciable structural lesion, to inappreciable structural lesion, or to either a want or an excess of stimulation in tissues both structurally and chemically intact. The latter division comprises the group of lesions of function, without appreciable lesions of structure, to which the term functional neurosis is applied. Disorders of sensation, dysæsthesiæ, occur as simple and as complex manifestations. They occur as primary and as secondary disorders. Primary dysæsthesiæ present as augmented, perverted, or diminished sensations of touch, body temperature, titillation (the analogue of cutaneous pruritus, Rossi), weight in the parts or mechanical restraint, irritability, discomfort, and pain. Secondary dysæsthesiæ present themselves as phenomena produced in the course of various diseases or disordered conditions of which they become part of the regular clinical train of symptoms, and to which affections their study is best relegated. Absence of these diseases usually stamps the neurosis as primary. The diseases and disordered conditions referred to, include inflammation, abscess, tumor, presence of a foreign body, tuberculosis, syphilis, lupus, carcinoma, [illegible], paresis from whatever cause, and diffuse cerebral and cerebrospinal lesions.

If special names be given to the various conditions, in accordance with modern neurological nomenclature, their classification would be somewhat as follows:

1. Neuroses of tactile sensibility, comprising (a) augmented sensitiveness to the touch, hyperæsthesia; (b) perverted sensitiveness, paræsthesia, including abnormal sensations of numbness, discomfort, tickling, itching, burning, tingling, pricking, of constriction, and of the presence of a foreign substance; (c) diminished sensitiveness, hypæsthesia (Eulenburg); (d) abolished sensitiveness, anæsthesia, including the anæsthesia produced by applications with ice or with drugs, such as preparations of cocaine, carbolic acid, menthol, eucaine, and the like.

2. Neuroses of dolorous or pathic (Rossi) sensibility, comprising (a) augmented hyperirritability, pain, algesia; or augmented sensation to painful conditions, hyperalgesia or hyperalgia, including painful sensations caused by the dread of an anticipated touch; (b) perverted sensation, paralgesia, constrictions, dragging; (c) diminished sensation, hypalgesia or hypalgia (Eulenburg), including [illegible]; (d) abolished sensation, analgesia; (f) paroxysmal painful sensations along the course of a sensory nerve, neuralgia.

3. Neuroses of thermal sensibility, comprising (a) augmented sensitiveness to heat or to cold; (b) perverted sensitiveness, sensations of heat, of burning, scalding, melting, of intense cold; (c) diminished, and (d) abolished sensitiveness.

4. Neuroses of muscular sensibility, comprising augmented sense of weight in the parts or pressure upon them, or of mechanical restriction in moving them, altogether independently of any condition of motor paralysis, as when distinct excessive muscular effort is required for phonation in fatigue from overuse or prolonged use of the voice. All these conditions occur usually in association with diseases in which they form part of the clinical pathological group of symptoms. Some occur independently of appreciable disease, or with such prominence as to become the leading feature of the disorder. The latter group are all that need any consideration in detail under the head of neuroses.

Hyperæsthesia.—Augmented tactile sensitiveness, abnormal hypersensitiveness of the laryngeal mucous membrane, is quite frequent in both catarrhal and ulcerative inflammatory disorders of the larynx. It is often associated with hyperæsthesia of the palate or of the pharynx. It often occurs as a manifestation of hysteria; often as a reflex neurosis. It is sometimes associated with spasm in these structures, and often gives occasion to spasm of the constricting muscles of the larynx, or to sensations of spasmodic contraction which are always distressing and sometimes alarming. In some instances it alternates with conditions of anæsthesia and of paralysis (Lisker, Gougenheim).

In one class of cases the use of the voice produces pain, and in some of these instances the annoyance to phonation from the sensations excited becomes so intense as to deter the patient from all attempts at using the voice. This condition has been termed phonophobia (Coen).

In another class of cases a peculiar intermittent hyperæsthesia sometimes occurs after bronchitis, commencing with sensations of burning and tickling, which are followed by paroxysms of dry or of moist cough, culminating in spasm of the larynx, which, in its turn is followed by vertigo, or by actual loss of consciousness, and is sometimes attended with convulsions of the face and even of the upper extremities, presenting, in fact, the condition to which the term laryngeal vertigo (Charcot) has been given.

With the cessation of the abnormal sensation in the larynx, the vertiginous seizure ceases, and the ordinary [illegible] condition of the subject pursues its accustomed course.

Pathology.—It is not likely that neuritis is present. Hysteria exists in many instances; in others there is a gouty diathesis, and especially a disposition to asthma.

Etiology.—A highly neurotic temperament is the main remote cause of hyperæsthesia. Gout and rheumatism are likewise remote causes. The immediate causes are varied in character, and are sometimes direct, sometimes reflex. Irritation in any portion of the alimentary tract, from the mouth to the anus, or in any portion of the respiratory tract, from the nostril to the pulmonary alveoli, may act as an exciting cause, or may keep up an hyperæsthesia of different origin. It is often due to influences, direct or reflex, from small neoplasms, retained secretions at the orifices of glandular ducts, and from various minute ulcerations, excoriations, or fissures in the pharynx, base of the tongue, tonsils, palatine folds, uvula, palate, or the intranasal tract. In some instances certain spots on the neck are especially painful (B. Fraenkel).

Treatment.—Both constitutional and topical treatment are required. In excitable or irritable conditions of the nervous system, nerve sedatives, such as bromides, [illegible], cannabis indica, hyoscyamus and its derivatives, chloral, and antipyrin, are indicated; in hysteric conditions, preparations of musk, assafœtida, or valerian; in debilitated conditions, nerve and blood tonics, such as arsenic, iron, quinine, strychnine, or their equivalents; in gouty and rheumatic conditions, colchicum, salol, and the salicylates. The condition of the digestive apparatus and of the emunctories requires strict attention that assimilation of nutriment may be as complete, and elimination of effete products as thorough, as possible. The liver, the kidneys, and the skin should be maintained in active performance of their respective depurative functions as far as practicable. The medical discipline and the medicinal agents to be employed for these purposes will vary with special indications, and must be selected in accordance with the principles of general therapeutics.

Topically, soothing or benumbing applications to diseased or disordered tissues are indicated, repeated once or oftener a day. These may comprise applications of morphine, of bismuth, or of aconite, in glycerine or water; of iodoform in ether or chloroform; or of cocaine, of thymol, or of menthol; sprays of opium, of bromides, of chloral, or of camphor in simple water or in peppermint water; sprays of iced water; inhalations of vapors of benzoin and similar drugs, changes being made from time to time as indications vary.

Permanent mechanical, traumatic, and plastic lesions producing the hyperæsthesia require to be combated, destroyed, or removed, according to the special indications.

Paræsthesia.—Paræsthesia denotes a condition of perverted or abnormal sensation, diffuse or localized, quite different from sensations of pain. It is most frequent in hysterical females. It is most usually described as a sensation as though a hair or other foreign body were present, or a sensation of tickling, burning, tearing, itching, or something not unlike. These sensations are sometimes provoked by phonation, and to prevent them the sufferer becomes disposed to speak in whispers only (phonophobia, Coën). In some instances the sensations are limited to the larynx; in others they extend into the pharynx in the one direction, or along the trachea in the other. Tracheal extensions cause considerable mental anguish and dread of suffocation.

Localized paræsthesias are frequently referred to the regions connecting the anatomical structures of the larynx, or the structures adjacent, as the regions of the hyo-thyroid membrane, crico-thyroid membrane, glosso-epiglottic fold, crico-thyroid articulation, or crico-arytenoid articulation. Paræsthesia is sometimes combined with anæsthesia (Elsberg, B. Fraenkel), and is sometimes followed by it. It sometimes causes considerable hypochondriasis, from the patient's dread that some incurable disease is in progress.

Its etiology and pathology seem closely allied to those of hyperæsthesia, if not identical; and the therapeutic measures would be much the same as for that condition.

Anæsthesia.—Anæsthesia of the larynx is the term used to indicate serious loss of sensitiveness of the mucous membrane, whether partial or complete, comprising likewise hypæsthesia or obtunded sensitiveness. It sometimes alternates with hyperæsthesia (Gougenheim), and is sometimes associated with paræsthesia. It may, or may not, be associated with motor paralysis. In cases due to diphtheria, motor paralysis coexists. The motor paralysis may, or may not, be in the domain of the same nerve-trunk. It is most frequently manifested in the constrictor group; the subjective symptom being dysphonia or aphonia. It occurs both unilaterally and bilaterally. In intensity it varies both with the cause and with the individual. It varies at times, likewise, in the same subject. It also varies in extent. In some instances it is confined to the epiglottis; in some to the supraglottic portion of the larynx, while in others it occupies the entire larynx; the extent varying according to the degree of participation in the lesion of the sensory nerve distributed to the regions indicated.

Laryngeal anæsthesia may be isolated, or may be associated with anæsthesia of the trachea, of the pharynx, of the palate, or of other organs and structures adjacent, contiguous, or at a distance; the special association being dependent upon the pathological or etiological lesion. Tactile sense may be in abeyance naturally, or can be placed in abeyance artificially, as by repeated manipulation with instruments, and by applications of cocaine hydrochlorate, menthol, and some other drugs. This abeyance is often associated with abeyance of reflex excitability, or with sufficient impairment to place that excitability under control; but sometimes the reflex excitability continues, so that spasmodic contractions ensue under its influence despite abolition of the tactile sense. Contrariwise it is asserted (Brown-Séquard) that anæsthesia of the entire body can be produced experimentally by irritation of the laryngeal mucous membrane.

Pathology.—Structural change, whether demonstrable or not, in the region of the origin or nucleus of the pneumogastric nerve, or in the tract of its superior laryngeal branch, is presumed to constitute the pathology of gross anæsthesia occurring in association with diphtheria, with syphilis of the cerebrum, or in bulbar paralysis.

Interruption in the transmission of peripheral impulses to the cerebral centre is the presumptive pathological condition in the anæsthesia occurring in hysteria. Should the anæsthesia be found to be limited to the upper portion of the larynx, ceasing at the margins of the vocal bands, the productive lesion will be presumptively attributable to disorder in the tract or nucleus of the superior laryngeal nerve from which sensory fibres are distributed to this portion of the larynx.

Anæsthesia extending beyond the margin of the vocal bands will be similarly attributable to disorder in the tract or nucleus of the inferior laryngeal nerve; and the lesion will be referred accordingly to the trunk of the pneumogastric, above the departure of the superior laryngeal, to its nucleus, or to its point of origin.

Symptoms.—Liability to access of foreign matter into the larynx during deglutition is the most prominent symptom. Lack of sensation to titillation and to irritation, and lack of reflex response by cough to irritation are additional symptoms.

Etiology.—Anæsthesia of the larynx is usually indicative of deeper lesion. The two chief causes are widely different in character, being hysteria and diphtheria. Then, but far less frequently, follow the lesions of bulbar paralysis (Krishaber) and of cerebral syphilis (Ott*). Anæsthesia has been noted in the asphyxic stage of cholera (Romberg), and is similarly present at times during the death agony. Hysteria is a far less frequent cause of anæsthesia of the larynx, or at least of the epiglottis, than was generally supposed a number of years ago; the mistake having been due to want of recognition of the fact that the epiglottis is a far less sensitive structure in some subjects than in many others. An anæsthetic epiglottis cannot be regarded, therefore, as pathognomonic of hysteria.

Among other causes to which laryngeal anæsthesia seems to have been attributable may be cited, severe forms of sore throat, epilepsy, plumbism, alcoholism, syphilis, and even carcinoma and tuberculosis (Krishaber).

Anæsthesia from diphtheria is often associated with paralysis of the depressor muscles of the epiglottis which are innervated by the superior laryngeal, the same nerve which supplies sensation to the supra-glottic portion of the larynx. Paralysis of the crico-thyroid muscle, supplied by the same nerve, may, or may not, exist. In occasional instances there is paralysis also of some of the phonatory muscles, indicating implication of the inferior laryngeal nerve. Anæsthesia is sometimes associated with neuralgia (anæsthesia dolorosa) (Schnitzler, Elsberg).

Sequelæ.—Laryngeal anæsthesia, especially when complete, and associated with anæsthesia of the trachea, of the epiglottis, and of the pharynx, has been noted as a precursory formation of [illegible] laryngeal paralysis ([illegible], 1877, No. 48).

---

* For a marked instance of right-sided anæsthesia in association with right-sided paralysis of the vocal band in the cadaveric position, in a case of extensive hereditary syphilitic disease, which had involved the origin of the vagus, from which all traces of medullary fibres had disappeared, thus destroying all communication with the larynx, centrifugal and centripetal, see Ott, Prager Med. Woch., 1881, No. 4.

Diagnosis.—Passage of food or drink into the respiratory channel, larynx, in the absence of motor paralysis and of mechanical lesions, such as morbid growth, wound, or foreign body, is presumptive evidence of anæsthesia. Palpation by probing or electric stimulation, however, under laryngoscopic inspection, is the proper method of making the diagnosis, and will reveal the intensity and extent of anæsthesia. Diphtheritic anæsthesia is usually associated with paralysis of the depressors of the epiglottis. Entire loss of sensitiveness will be indicated by absence of any sensation of touch, or of pain, or of any evidence of reflex movement. Partial sensitiveness may, or may not, be associated with voluntary suppression of the reflex movements of cough, and of spasmodic closure. The most sensitive portion, normally, is the internal or intra-laryngeal surface of the interarytenoid fold, the touching of which, with the probe, usually excites titillation and cough.

To determine whether apparent want of sensitiveness be abnormal, the mucous membranes of other structures, adjoining or at a distance, should be examined, for individuals will be found with general obtuse sensitiveness. Limited patches of cutaneous anæsthesia at the anterior portion of the neck, above and below the hyoid bone, have been indicated as frequent and peculiar concomitant signs of laryngeal anæsthesia.

Prognosis.—The prognosis will vary with the nature of the lesion. It is of the gravest character when present in association with bulbar paralysis. It is serious in all cases of central origin.

In diphtheria the prognosis is good provided that means are available during treatment to prevent the entrance of food into the larynx; an accident that may be followed by suffocation on the one hand, or by fatal pneumonitis on the other.

In cerebral syphilis the prognosis will be dependent upon the extent of the lesion, which will therefore be an unknown factor, unless amelioration follow the institution of antisyphilitic remedies.

The condition is always rendered serious in the presence of catarrhal inflammations, in which the product of secretion may accumulate in dangerous and even fatal quantity without exciting the reflex movements of cough for their expulsion.

Treatment.—The treatment will vary with the nature of the case. Preparations of phosphorus and of strychnine, or its equivalent, are usually indicated constitutionally. Induced electrical currents topically are often additionally serviceable in cases of diphtheritic origin.

Feeding by the œsophageal or even by the stomach tube is indicated when attempted deglutition drives food into the larynx. The condition of anæsthesia calls for especial care to see that the tube is not introduced into the larynx. It should be guided along a finger placed behind the epiglottis or at the entrance of the larynx, or should be introduced under laryngoscopic illumination. Hysterical anæsthesia is sometimes promptly relieved by the emotional influence of the laryngoscopic examination. It may subside under the influence of mere probing, of painting with silver nitrate or other reagents, or of the application of the electric brush, according as its intensity may warrant.

Constitutional syphilitic disease will require the usual constitutional antisyphilitic measures.

Sclerotic conditions of the nervous structures, and bulbar paralysis, must be met by the measures indicated by neurologists: internal administrations of silver nitrate, gold and sodium chloride, etc.

Hyperæsthesia.—Neuralgia of the larynx usually occurs in a series of paroxysmal darting pains of irregular recurrence, radiating from one side of the larynx, most frequently the left, or from both, to the ear. Similar pains occur in cases of ulceration of the epiglottis, and in some unrecognized cases of syphilis and carcinoma.

Sensations of tickling from irritation of the terminal filaments of the sensory fibres of the pneumogastric, and especially of those of the superior laryngeal division, leading to reflex irritative laryngeal cough to relieve them, are not to be regarded as evidences of neuralgia.

The treatment is constitutional, as for all forms of neuralgia.

KINESIONEUROSES.—These comprise the groups, hyperkinesis (spasm), and akinesis (paralysis).

HYPERKINESIS.—*Spasm of the Larynx. Laryngismus.*—Spasm of the larynx is a spasmodic closure of the glottis by contraction of all the constrictor muscles, or of all the muscles of the glottis, both constrictor and dilator, the predominant effect by the dominance of the constrictors producing closure just as surely as though the dilators were unaffected. The latter condition is sometimes mistaken for paralysis of the dilators.

Spasm of the constrictor muscles of the glottis is sometimes associated with paralysis of the dilator muscles, the contracture following the paralysis. Spasm of individual muscles also occurs in which the constriction of the glottis does not take place.

Spasm of the larynx occurs in three forms: tonic or fixed, clonic or mobile, and contractile or [illegible]. The spasm is respiratory in some instances, phonatory in others. The respiratory spasm may follow either the expiratory or the inspiratory phase, the latter variety being usually the severer. Inspiratory spasm is familiar to all who have practised initial cauterization upon the interior of the larynx. This manipulation produces a series of painful stridulous inspirations through a glottis that has become spasmodically closed; the expirations remaining efficient, noiseless, and free from cough. The spasmodic phenomena subside in a few minutes, although the pain from the cauterization continues. An expiratory spasm occurs when a foreign substance enters the larynx suddenly, as when a drop of water goes the wrong way during speech or laughter. The spasm, at first often inspiratory as well, is essentially an expiratory, stifling spasm of cough; and the cough continues until the foreign matter has been expelled, or until the uncomfortable sensations it has produced have in a great measure subsided. These examples, while serving to illustrate the phenomena of spasm, do not enter into the category of essential neuroses.

One form of spasm, a true laryngismus, occurring during a paroxysm of cough which has been spontaneously provoked by tickling or other abnormal sensation in the larynx, is marked by sudden arrest of the muscles of respiration, with dizziness or vertigo, and partial or complete loss of consciousness for a few seconds, so that the patient may fall to the ground if erect. Consciousness returns in a few seconds, and the patient is usually as well as ever, without stupor or other morbid symptoms. The term laryngeal vertigo (Charcot) has been ascribed to this variety, but it appears to me without sufficient reason, inasmuch as giddiness or even momentary loss of consciousness is not rare after prolonged coughing spells, and occasionally attends prolonged efforts of forced expiration during auscultation of the lungs. This form of laryngismus occurs far more frequently in males, and after middle life, and in individuals who are gouty, or who are the subjects of asthma and bronchitis. Convulsive movements of the limbs and of the face have been noted in some instances. The attacks may occur at irregular intervals of days, weeks, or months, or as frequently as several times a day.

Spasm with aphonia occurs occasionally as a professional hyperkinesis in persons who have been compelled to make great use of the voice. While the muscles respond normally in respiration and in voluntary efforts of expiration and inspiration, in coughing and in laughing, spasm occurs, as in histrionic spasm, writers' cramp, and so on, whenever an attempt is made to use the muscles for phonation, and the act becomes impracticable. To this condition the term spastic aphonia (Schnitzler) has been applied.

Fatigue of the cerebral centres has probably been produced, so suppressing their functions as to develop a latent contracture of the muscles in connection with them, which becomes augmented into spasm when the power centre in the medulla is put into action as in the explanation given (Hughlings Jackson) for writers' cramp; which is, that the lower centres, being in a condition of "hyperphysiological activity," are "let go," just as the spinal centres are, in hemiplegia, accompanied by slight rigidity.

When the individual attempts to speak, a spasmodic hypercontraction of the muscles of phonation brings the vocal bands into such close approximation that the phonatory current of air cannot pass between them.

Aphonia spastica has been found associated with dyspnœa, as in a very interesting instance described by Michael ("Aphonia und Dyspnœa Spastica," Wiener Med. Presse, 1885, Nos. 41 and 42). In this patient, a married woman, thirty-two years of age, with hysteria, there were in addition globus hystericus, muscular contractures of the face and of the extremities, intercostal neuralgia, and occasional paroxysms of hystero-epilepsy. The diagnosis was made during narcosis preliminary to tracheotomy, when subsidence of the spasm, restoration of free respiration, relief from cyanosis, and resumption of voice occurred. Return of the spasm, as consciousness revived, rendered the tracheotomy imperative. It was necessary to retain the cannula permanently, no change in the laryngeal neurosis having taken place at the date of the report, three years after the operation.

Hysterical spasm may manifest itself in the inspiratory or in the expiratory phase of respiration, or in both phases. Inspiratory spasm is characterized by stridor, feebleness of voice, and shallow respiration.

Expiratory spasm is phonal, and is characterized by a series of convulsive barking or other explosive coughs repeated many times a minute; continuing many minutes or hours during the day, and recurring daily for many days, months, or even years. It is not manifested during sleep. The term laryngeal chorea has been given to this variety of spasm, owing to the irregular or choreic movements of the vocal bands during the attack; a term which should be confined to such laryngeal choreic movements as are associated with genuine chorea (Schreiber).

Pathology.—Spasm of the larynx in the adult occurs as a result both of direct and of reflex irritation. Chronic hyperæmia of the larynx, ulcerations of the mucous membrane, morbid growths, or foreign bodies may be the source of direct irritation. In these cases spasm of the larynx is a symptomatic feature merely—sometimes of serious and even of fatal import.

It exists also, occasionally, as a true neurosis in disease of the nerve tissues or tracts. It is often one of the early symptoms of locomotor ataxia (Fereol), and sometimes for a long period is the only premonitory symptom of that affection (Krishaber). It occurs likewise in ascending spinal sclerosis, in multiple neuritis, in hysteria, and in hystero-epilepsy, though rarely in true epilepsy; it has been observed in the subjects of hydrophobia, plumbic poisoning, and of pressure of various kinds upon the pneumogastric and recurrent nerves; and after inhalations of irritant gases, prolonged sojourn of foreign bodies, the titillations of pedunculated laryngeal neoplasms, and in œdema of the larynx. The vertiginous form of the affection has been attributed to some peculiar irritation of the centripetal laryngeal nerves (Charcot) and to epilepsy (Gray). It has been excited by intranasal irritation from a polyp (Knight). Knight attributes the vertigo to direct disturbances of cerebral circulation by compression of the large vessels, and even of the heart, in consequence of forced expiration against a glottis closed in spasm. It is probable that constant cough may produce turgescence in the cerebral arteries which have undergone or are undergoing the usual changes which occur after the age of forty.

Symptoms.—Sudden dyspnœa with laryngeal stridor are the main symptoms of bilateral spasm. They relax in clonic spasm, and are more or less continuous in tonic spasm. Unilateral spasm is often unattended with subjective symptoms, unless there is exertion of some kind.

Etiology.—Functional spasm may be attributed to molecular changes unassociated with structural disease, and therefore without any objectively perceptible lesion.

Organic spasm may be due to changes in the nerve-centre, especially in the nucleus of the pneumogastric or of its superior laryngeal division. It may be due to compression of the superior or of the inferior laryngeal, or the pneumogastric nerves by an abscess, enlarged glands, or morbid growths. Compression thus occasioned, especially when neuritis is present, will sometimes produce spasm, with occlusion of the glottis by bilateral action, even though the compression involve one nerve only.

Reflex spasm may be occasioned by irritation in the nasal or in the pharyngeal mucous membrane, the external auditory meatus, or in more distant mucous membranes, or in ovarian irritation.

Diagnosis.—This is based on the sudden dyspnœa and stridor. The condition is recognized in the laryngoscopic image by approximation of the vocal bands when bilateral, and sometimes by approximation of the ventricular bands. The arytenoid cartilages are drawn backwards, a position which serves as a discriminating feature from bilateral paralysis of the dilators (Jeleuffy). In unilateral spasm the vocal band is drawn to the middle line or the phonatory position.

Prognosis.—Life may be lost in an initial bilateral spasm. Should the spasm relax the prognosis will depend upon the curability of the exciting cause. Unilateral spasm is not menacing to life, unless for some reason the sound side should become subsequently involved.

Treatment must be directed not only to the spasm but to the constitutional malady underlying it. Rest—physical, mental, and emotional—is an important element in the treatment. All sources of excitement must be avoided. Systemic remedies suited to the malady are to be employed, to which antispasmodics should be added with sedative inhalations. Topical treatment is imprudent, and is liable to excite spasm during moments of quiescence, or to increase it when in progress. Inhalations of chloroform or of amyl nitrite may be employed during moments of exacerbation. In cases of continuous tonic spasm, and of frequent clonic spasm, tracheotomy is indicated either as a permanent therapeutic measure or as a prophylactic one. Its performance becomes imperative in the presence of even moderate inflammatory swelling.

Laryngismus Stridulus—spasm of the laryngeal muscles in infants—*Clinical History.*—A child with impaired nutrition, and in most instances a subject of craniotabes (Elsässer), especially when the affection begins during the first year of life, is suddenly seized with an alarming arrest of respiration, most frequently in its expiratory phase, and is unable to get his breath. The seizure may occur while the child is awake, whether he be quiet or excited, or it may awaken the child from sleep by day or by night. In from ten to twenty seconds, sometimes not until after the lapse of sixty or more, a prolonged shrill crowing or stridulous inspiration takes place, and respiration becomes re-established; a spell of crying or coughing, or both, usually following. The attacks are slight in many instances, severe in some, and occasionally are immediately fatal by apnœa.

Mild attacks frequently occur without exciting alarm or even attention. In cases of severity the attacks may recur at intervals of a few hours or of a few days during a period of several weeks or of several months. They sometimes recur with gradually increasing frequence, in some instances with gradually increasing severity also.

Pathology and Morbid Anatomy.—While cases occasionally occur as examples of a special neurosis, the majority are of reflex origin. Some of these are due to irritations of the trifacial nerve in dentition, of the pneumogastric in malnutrition, and of the spinal nerves in intestinal disorders (Marshall Hall). Some are due to irritation from enlarged scrofulous glands along the tracheo-bronchial tract, and along the tract of the pneumogastric nerve and its subdivisions. The majority are due to craniotabes (Elsässer) in rachitis, a condition in which hyperæmia of the meninges or of the encephalon is readily produced by fits of laughing, crying, holding the breath from fright, and other slighter causes of exditions. Congestion and thickening of the meninges have been observed in the dead subject, but by no means frequently. Similarly, changes in the consistency of the pneumogastric nerves have been sometimes noted, as well as caseous degeneration of the bronchial glands. The condition of the thymus gland, to which much importance was formerly attached, has been found so variable as to eliminate disease of that structure from special pathological significance. No special lesion has been traced in the larynx.

Symptoms.—The characteristic symptom is sudden, spasmodic dyspnœa, terminating in relaxation from spasmodic closure of the glottis with a reëstablishment of respiration at the end of ten or more seconds after one prolonged, sibilant, crowing inspiration, or after a succession of shallower ones, unaccompanied by expiration. During the attack the face is first pale, then flushed, and finally livid or cyanotic. The limbs are cold, the head is thrown backward, and the mouth is open, or gasping for breath, as it were. The patient may grasp at the throat as though to tear away some obstruction, or the extremities may lie flaccid or stiff. In severe cases there are convulsions of the diaphragm and of the intercostal muscles, and even of the extremities.

Etiology.—The remote causes of the affection reside in the constitutional condition; the immediate ones in the irritability of the nervous system and in the exposure to irritation of the sensitive surfaces from which the reflex manifestation is started. Rachitis is by far the most common of the remote constitutional causes, and the more acute this disease the more frequent are the paroxysms. Scrofulous affections, particularly enlargements of the lymphatic glands along the course of the pneumogastric nerve and its subdivisions; imperfect nutrition and lack of proper hygienic conditions are other remote factors. Irritation of the mucous membranes in the mouth, throat, and intestinal portions of the alimentary tract are the more immediate factors. These favoring conditions being present, slight excitation may provoke the paroxysm; anything, in fact, which frightens the child or disturbs its equanimity; in patients of great nervous irritability even the dread of a touch.

The age at which the affection is most frequent comprises the period between the fourth and twenty-fourth month. It has been observed in the new-born child and in children from three to eight years of age. Boys are far more subject to it than girls. It is most frequent during the cold and wet season of the year, and more frequent in northern than in southern latitudes.

Diagnosis.—This is easy, and is based on the sudden onset of the paroxysm, the stridulous character of the respiration, the cyanotic condition, the attendant spasms elsewhere, and on the freedom from evidence of laryngeal disorder in the intervals between the paroxysms.

Prognosis.—The prognosis must be guarded in almost all instances, for quite a large proportion of cases terminate fatally during a paroxysm. It has been estimated that nearly one-third of all cases perish in this way. The older the child, the slighter the paroxysm, the milder the complications, the better the nutrition and surroundings, and the more amenable to treatment the constitutional disease under which the patient is laboring, the better the prognosis. Treatment is often protracted, this depending chiefly on the general health of the patient and the hygienic character of his surroundings.

Treatment.—An attack of laryngismus having been recognized, the treatment will be prophylactic to ward off future paroxysms as far as practicable, and corrective as regards the causal factors. Little can be done during a paroxysm, as the attack usually subsides before any remedy can be given. The child must be raised at once, and its head be bent backward to facilitate respiration, by placing the airway in the most favorable position. Efforts are to be directed to relax the glottis and avert suffocation. Various methods are recommended, any one of which there is usually time to execute. These comprise dashing cold water upon the face, loosening all constricting clothing, flagellation to the trunk and extremities, passing the finger into the larynx to release or to mechanical appliances to provoke gagging, tickling the nose (Sneezing) so as to force an involuntary effort at respiration, seizing the tongue and pulling it forward. If time permit, chloroform may be passed before the mouth in hopes that a few whiffs may be inhaled and thus relax the spasm; but usually there is no time to secure the chloroform, far less to prepare a hot bath, as is often suggested. Immediately after the paroxysm has subsided, efforts should be directed toward allaying any irritation or source of irritation that may exist in the mouth, stomach, intestines, anus, vagina, prepuce, or elsewhere. The prophylactic treatment against future paroxysms will consist in the administration of bromides, chloral, camphor, asafœtida, or musk, according to the preference or experience of the physician, or the special indications. The corrective treatment of the causal condition will include proper attention to diet, clothing, ventilation, sleep, exercise, and general hygienic surroundings; with the internal administration of cod-liver oil, malt extract, ferrous iodide, or potassium sulphate, as indications may dictate. Suitable appliances should be kept at hand to carry out whatever procedure may be selected as the most appropriate to execute during any future paroxysm.

Should the attacks of laryngismus become frequent and increase in severity, tracheotomy may become necessary in order to secure an avenue for respiration through the artificial opening during the closure of the glottis. The cannula having been introduced, the patient must not be allowed to go about without the tube as long as any disposition to spasm remains. An unnecessary loss of life has been the penalty of disregarding this precaution.

AKINESIS.—*Paralyses of the Larynx.*—Under the head of paralyses of the larynx it is necessary to include all impairments of motion, whether neurotic, myopathic, or mechanical in origin; as it is often difficult, and sometimes impossible, to distinguish them by their laryngoscopic image; and post-mortem examination sometimes fails likewise to show any anatomical lesion to indicate whether a paralysis has been neurotic or myopathic in origin. In many cases the distinction can be made only after microscopic examination of the nerves and muscles, and in some instances not even then. In some cases paralysis of the laryngeal muscles is unassociated with paralysis elsewhere. In many it is associated with paralysis elsewhere, and presents itself as one phenomenon only of the disease by which it has been produced. As already mentioned, paralysis is sometimes associated with the other neuroses.

Lesions of the nerve-nuclei usually produce bilateral paralysis on account of the close proximity of the origins of the nerves; and central lesions and derangements generally are likewise usually productive of bilateral paralysis. Lesions of the nerve-tract are commonly unilateral in their effects; but when a lesion is of great extent, as a large aneurism, or when it is multiple, as in some instances of morbid growth and aneurism, the two tracts on the two sides may become involved and the paralysis become bilateral.

Paralyses of individual muscles, of two or more muscles, and of groups of muscles, occur unilaterally and bilaterally as effects of lesions apparently limited to them; and also of lesions attributable, as far as is known, to myopathic causes only.

Pathology.—In myopathic paralyses the paralyzing disorder, whether disease or injury, is located in the muscular apparatus. Disease or injury to the centre or tract of innervation of the laryngeal muscles is the essential pathological feature of neuropathic paralysis. Secondarily degeneration of the muscles may follow, so that paralysis may remain from that cause even though recovery may take place from the neural lesion. This degeneration, when the result of disease, is most frequent in the posterior crico-arytenoids (Semon). The pathological lesions may involve the cerebrum, the medulla, the pons, the cord, or the trunks of the spinal accessory, pneumogastric, superior laryngeal, or inferior laryngeal nerves, or their peripheral filaments. When the central lesion extends beyond the nuclei of the laryngeal nerves there will be paralyses of muscles and organs innervated from the entire seat of the lesion, and thus of the tongue, face, lips, palate, pharynx, trapezius and sterno-cleido-mastoid muscles. The muscles of the eyeball and the muscles of the extremities may be paralyzed likewise, according as the lesion has implicated the roots or nuclei of the nerves distributed to the regions involved. Even the olfactory, ophthalmic, and auditory nerves have been implicated in very extensive lesions.

Laryngeal paralysis is less common in cerebral disease than are paralyses in other regions, a fact familiar in the clinical history of ordinary hemiplegia. This is accounted for, according to Broadbent, by reason of a relative immunity from paralysis possessed by muscles bilaterally associated in their action, because the muscles of each side are connected anatomically with the cortical centres in both cerebral hemispheres, and thus a compensatory nervous influence performs the duty on the two sides when one side is diseased.

A lesion of the recurrent should affect all the laryngeal muscles except the crico-thyroids and the depressors of the epiglottis, their further relations being identical. But the constricting muscles are phonatory muscles. They are not necessary for respiration and they are for phonation; hence, neuropathic paralysis affecting them alone implies a lesion beyond the origin of the recurrent trunk in the accessorius nucleus—at the phonic centre or in the tract leading from the centre to the nucleus. In hysterical paralysis, a molecular disturbance preventing passage of the will-current, there will be inability to will to phonate, and hence paralysis of the muscles of adduction.

When bilateral paralysis follows a unilateral lesion, the sensory fibres of the pneumogastric or of the superior laryngeal convey the peripheral irritation to the nucleus, whence in consequence of the crossing of nerve-fibres, the motor centres on both sides may become affected (Johnson). Hence, if the inferior laryngeals be purely motor nerves, injury to one recurrent alone cannot be productive of paralysis on the other side, inasmuch as the effects of injuries to motor nerves can be transmitted toward the periphery only. Any instance to the contrary would be proof presumptive that the recurrent nerve contained sensory as well as motor fibres. This is maintained to be the case by some observers, who contend that this nerve supplies sensation to the subglottic portion of the larynx and to the trachea. It has been claimed, however, that such sensory fibres may be derived from the superior laryngeal nerve through the communicating branch. Thus laryngeal paralysis occurs as a phenomenon of a number of diseases. It is occasionally congenital. When of central origin, it is most frequently observed in diseases of the medulla oblongata and of the pons, as in bulbar paralysis and progressive muscular atrophy, which Kussmaul, Charcot, and others have maintained to be identical; in multiple or disseminated cerebro-spinal sclerosis; in locomotor ataxia, and in general paralysis of the insane.

It is occasionally observed in other diseases and in disorders of the cerebrum, such as occur in apoplectic hæmorrhage, epilepsy, general neuroses, and especially hysteria, in syphilitic lesions of the cerebrum, in malignant and other morbid growths, and in ectasia of the blood-vessels. It occurs in diseases and injuries of the trunk of the pneumogastric nerve or of its spinal accessory reinforcement, or of the subdivisions of the nerve, the superior and inferior laryngeals. In some of these instances the lesion has been very high up, even within the skull, as in malignant growth involving the posterior fossa and the foramen lacerum (Türck).

Aneurism of the arch of the aorta, compressing the recurrent nerve, is the most frequent lesion producing paralysis of the laryngeal muscles. Compression of the recurrent or the pneumogastric likewise occurs from aneurism of the innominate and subclavian arteries, and compression of the pneumogastric may occur in aneurism of the carotid (Mackenzie). In these lesions the nerves being stretched, as well as compressed, and adhesions being often formed, it is difficult to determine the exact mechanism of the paralysis. One and the same lesion may compress both the recurrent laryngeal and the pneumogastric nerves. Occasionally bilateral paralysis is produced by separate aneurisms.

Similar compressions occur from enlarged thyroid gland, enlarged cervical and tracheo-bronchial lymphatic glands, and malign growths of these structures; malign growths of the neck, of the pharynx, of the œsophagus, and of the mediastinum, carcinoma of the œsophagus being the most frequent. Pericardial effusion, pleuritic effusion, chronic pleuritis, chronic pneumonia, and tuberculosis are cited as occasional causes of compression. In these lesions chronic neuritis of the injured nerve, with atrophy and degeneration, is the usual result, and degeneration of the muscles often ensues.

Traumatic lesions are occasional causes of paralysis by injury to the nerve. These include gunshot, punctured, and operation wounds, inclusion of the nerve in a ligature thrown around the adjacent artery, hypodermic injections, interstitial injections into tumors, infiltrations with blood or serum after contusions, and pressure or injury from a foreign body in the pharynx, œsophagus, or larynx.

Toxic paralysis occurs in poisoning by lead, opium, belladonna, stramonium, and cannabis indica. Septic paralysis sometimes occurs in infectious diseases, as in diphtheria, enteric fever, relapsing fever, cholera, variola, pertussis, erysipelas, dysentery, syphilis, tuberculosis, and malaria.

Paralysis occurs in various diseases of the larynx, including superficial or catarrhal laryngitis and perichondritis, and in inflammations from operative procedure, including tracheotomy. It may be produced also by the pressure of a foreign body within or outside the larynx, or as a result of the destruction of tissue by trichinæ or by overstrain from loud and continued singing and shouting. It sometimes proceeds from colds producing a rheumatic paralysis directly; and sometimes from mental excitement or emotion. Reflex paralysis occurs in some cases of disease of the nasal passages, pharynx, tonsils, intestinal tract, genito-urinary tract, uterus, and ovaries.

Rheumatic paralyses are presumed to be due to peripheral neuritis or to other disorders in the terminal nerve-filaments, occurring as the direct result of exposure to lowered temperature, or to fatigue in use of the muscles when infiltrated with the products effused during catarrhal laryngitis from similar exposure. In an instance narrated by Holz (Semon's notes to the German edition of Mackenzie) there was a rheumatic paralysis of the spinal accessory nerve alone, as shown in relaxation of the right trapezius and sterno-cleido-mastoid muscles, deviation of the uvula to the right, relaxation of the right half of the soft palate, and immobility of the right vocal band in nearly the median position.

Degenerations or other changes in the nerve-tract are sometimes not noticeable, although considerable impairment of function had been noted in the muscular territory of its distribution, and although degeneration of the muscle had ensued from the injury to the nerve. Degeneration of muscle also occurs independently of any appreciable lesion which could exert a deleterious influence on the nerve-supply. In these cases it is not improbable that peripheral changes exist which elude detection.

Symptoms.—The symptoms of paralysis of the laryngeal muscles consist in modifications in the functions of voice, cough, respiration, and deglutition. The voice is abolished in complete bilateral paralysis of all the muscles of the larynx, in bilateral paralysis of all except the crico-thyroids, paralysis of the recurrents, which is by far the more common, and in bilateral paralysis of the adductor groups only. In paralysis of the crico-thyroid muscles, paralysis of the superior laryngeal, the voice is tremulous and uncertain through lack of tension of the vocal bands; and it is harsh and deep, with inability to produce tones high in pitch. In some instances of hysterical paralysis of the adductors, the singing voice is unimpaired though the speaking voice is abolished. In the unilateral paralyses the voice is muffled, hoarse, or thrill, according to the muscles affected, the tendency of the sound side being able to force the corresponding vocal band beyond the median line so as to approach the paralyzed or immobile band sufficiently to produce vocal sounds. In unilateral paralysis of the recurrent laryngeal, the character of the voice in some instances will vary with the position of the head and neck. In some cases there is no modification of voice. Phonal cough is usually impaired in complete bilateral paralysis of all the muscles, and in many instances of complete unilateral paralysis. Approximation of the ventricular bands is sometimes observable, and this suffices for cough. It can be produced in nearly all cases of paralysis of the adductor groups of muscles only, which are due to hysteria. It is normal in complete paralysis of the abductor muscles whether unilateral or bilateral. In irritative lesions of the pneumogastric nerve spasmodic cough is often a characteristic manifestation. Inspiration is difficult and accompanied with stridor in complete bilateral paralysis of the abductors. Moderate stridor occurs on deep inspiration and on great physical exertion in complete bilateral paralysis, and to a less degree in unilateral paralysis of an abductor muscle. There is, of course, no stridor in paralysis of the adductors. Expiration is difficult on exertion in bilateral paralysis of the abductors, but is not impaired in the other forms of paralysis. Deglutition is difficult in paralysis of the depressor muscles of the epiglottis, food and drink falling into the cavity of the larynx from lack of closure of the vestibule by the epiglottis, which remains erect or semi-erect. Cough is thus excited to expel the foreign matter.

Etiology.—Neuropathic paralyses of the larynx are due to disease or injuries to the nerve-paths of the pneumogastric and spinal accessory nerves, to their branches, superior, median (Exner), and inferior laryngeals, or to their terminal filaments after their separation from the main trunks. The character of the initial lesions that produce the changes in the nerve-tissue which cause the paralysis has been discussed under the heading of Pathology. While anatomists are mainly in accord in the opinion that all the motor fibres innervating the laryngeal muscles proceed from the spinal accessory; that the superior laryngeal division of the pneumogastric supplies motor innervation to the crico-thyroid, and to the aryteno- and thyro-epiglottic muscles, and that the inferior or recurrent laryngeals supply motor innervation to all the other muscles of the larynx, it must be borne in mind that recent researches of German investigators, as well as some clinical observations (Türck, Dehio, etc.), point to the fact that the various muscles are often supplied by both laryngeals, and that the muscles of one side are often innervated by nerves from two sides. Hence, probably, arises much of the obscurity evinced in certain interpretations of paralyses of the larynx as revealed to laryngoscopic inspection.

Destruction of the nucleus of the spinal accessory nerve in the medulla, or of the continuity of the trunk of the pneumogastric above the point at which the laryngeal nerves separate from it, paralyzes all the muscles of the larynx of that side; and immobility of the corresponding vocal band, with relaxation of tension in the ordinary cadaveric position, follows.

Destruction of the continuity of the superior laryngeal nerve, or of its motor (the external) branch, paralyzes the crico-thyroid muscle of that side, producing impairment of the longitudinal tension of the corresponding vocal band in phonation, and depression in level, rendering its edge elliptically concave, and impairing its vibration in phonation. It also paralyzes the aryteno- and thyro-epiglottic muscles, so that active depression of the epiglottis is prevented or impaired.

Destruction of the continuity of the inferior laryngeal nerve paralyzes all the muscles of the larynx of the same side except the crico-thyroid and the thyro- and aryteno-epiglottics, so that the corresponding vocal band becomes immobile in the ordinary cadaveric position as in paralysis from similar lesion in the upper portion of the trunk of the pneumogastric. The unimpaired crico-thyroid is unable to contract from lack of fixation of the arytenoid cartilage, and hence presents no objective indication of its integrity.

Destruction of the filaments proceeding from the laryngeals to the various muscles produces paralysis of the muscle or muscles to which they are distributed. Peripheral neuritis will likewise produce paralysis of limited regions. Myopathic paralyses are due to changes in the muscular apparatus by infiltration, thickening of connective tissue, or otherwise. It is extremely difficult in many instances to separate myopathic lesions from neuropathic ones; and in some instances of apparently myopathic lesion it is safe to infer that peripheral neuropathic lesion exists also.

Diagnosis.—While the significance of laryngoscopy is nowhere more beautifully demonstrated than in the diagnosis of paralyses of the laryngeal muscles, great discretion is often necessary in interpreting its revelations. The two sides of the larynx may be normally asymmetric. The normal positions of the vocal bands in rest and in all phases of function are by no means alike in all subjects. Even the normal cadaveric position is not uniform after death, and hence the pathological cadaveric position cannot be uniform during life.

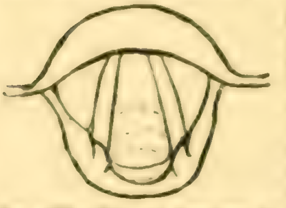

FIG. 4957.—Bilateral Paralysis of the Recurrent Nerve. [illegible]

The subjective symptoms in some instances are sufficient to indicate the existence of paralysis and its character.

Accuracy in diagnosis is secured only by inspection of the laryngoscopic image. The association of paralyses in other regions, and the symptoms of the case with its clinical history, serve to differentiate the disease or injuries which give rise to similar images.

In complete paralysis of the recurrent nerve, the vocal bands are relaxed in the position which is observed in the dead subject, the cadaveric position (Fig. 4957), and no movement takes place in respiration or in attempted phonation, although the crico-thyroids are not paralyzed; for these muscles are unable to render the vocal bands tense unless their posterior attachments to the arytenoid cartilages can be fixed in position by the action of the posterior crico-arytenoids. There is also anæsthesia of the subglottic portion of the larynx.

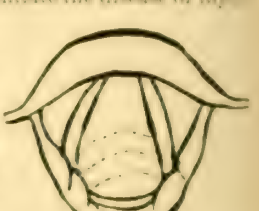

FIG. 4958.—Left-sided Recurrent Paralysis; Deep Inspiration.

In unilateral paralysis, the vocal band of the affected side will remain immovable or nearly immovable in the cadaveric position, but the vocal band of the sound side will move normally in respiration (Fig. 4958), in phonation (Fig. 4959), and in cough, and will even pass the middle line in phonation so as to come sufficiently near the immobile band to produce vocal sound. The action of the unparalyzed half of the arytenoideus muscle will in some instances produce slight motion or tremor in the posterior portion of the vocal band, or bring the tips of the arytenoid cartilage toward the sound side. In some instances the tip of the arytenoid cartilage of the sound side will be drawn in phonation beyond the median line and in front of the corresponding structure on the paralyzed side, thus giving the glottis an oblique direction toward the paralyzed side from before backward (Fig. 4960).

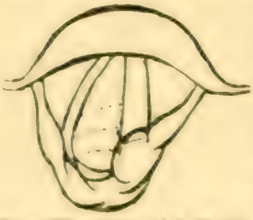

FIG. 4959.—Unilateral Paralysis of Recurrent. Phonation.

The anæsthesia of the subglottic portion of the larynx will be unilateral. Marked longitudinal relaxation of the vocal bands indicates, in addition, paralysis of the superior laryngeal innervating the crico-thyroids, and the lesion is located at a point anterior to that at which that nerve leaves the trunk of the pneumogastric.

Bilateral paralysis of the adductor groups of muscles will be indicated by continuous gaping of the glottis, with little or no motion, in respiration or on attempted phonation (Fig. 4961). In slightly paretic cases there will be initial approximation with sudden recession before phonal proximity is accomplished.

In unilateral adductor paralysis, which is exceedingly infrequent, the vocal band of the paralyzed side will remain at the lateral wall of the larynx, while the movements of the other will remain practically unimpaired.

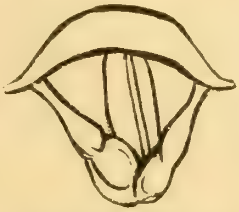

Fig. 4960.—Paralysis of Left Recurrent. Phonation with Crossing of Supra-arytenoid Cartilages.

Bilateral paralysis of the abductor muscles is recognized by the permanent location of the vocal bands quite near to the middle line (Fig. 4962), or at some point between that line and the lines of the cadaveric position. From this position they do not recede on the strongest effort of inspiration. On the contrary, they become more closely approximated and pushed downward by the atmospheric pressure of the inspiratory current of air, so that every inspiration is rendered prolonged, loud, and stridulous. The mucous membrane sometimes is forced down over and beyond the structure of the vocal bands. On expiration, the vocal bands are thrust upward and aside by the expiratory current of air, enlarging the elliptic or triangular orifice, so that expiration is comparatively quiet and easy. The physical signs of intense dyspnœa are present; sometimes to an alarming extent after exertion or agitation. This is especially prominent in a group of cases in which the vocal bands are nearly or actually in contact at the posterior vocal processes; conditions attributed to spasm of both abductors and adductors, or to secondary contractures of the adductors. The vocal bands then occupy the position for phonation. Phonation requires fixation of the arytenoid cartilages by the posterior crico-arytenoids, before the crico-thyroids can stretch the vocal bands (Jelenffy).

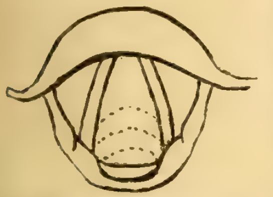

Fig. 4961.—Bilateral Paralysis of Adductors.

Voice is unimpaired, inasmuch as the vocal bands are continuously in a position to favor the action of their unparalyzed tensors. Immobility from spasm, from mechanical restraint by morbid growth, or from false or true anchylosis of the crico-arytenoid joint, must be carefully discriminated when practicable. Differentiation is often difficult, and its solution is dependent upon other manifestations than those observed in the laryngoscopic image. Sudden onset of the inspiratory dyspnœa, and temporary relief under anæsthesia, are both indicative of spasm, and may usually be relied on in differentiation, except in cases of contracture of very long standing, and in which other mechanical factors are present. Spasm due to compression of the nerve does not relax under anæsthesia.

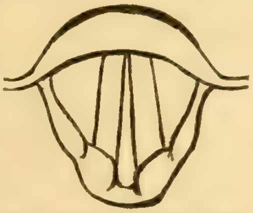

Fig. 4962.—Bilateral Paralysis of Abductors.

Unilateral paralysis of an abductor (posterior crico-arytenoid muscle) is recognized by the unilateral position of a vocal band, as indicated in Fig. 4963), and its immobility in inspiration. In the absence of any subjective symptoms it may exist for a long period without detection.

Paralysis of the depressor muscles of the epiglottis, the thyro- and aryteno-epiglottics, is indicated by erection of the epiglottis, which does not become depressed under attempts to perform so much of deglutition as can be accomplished with the mouth open. Its most frequent cause is diphtheria, and it is associated with anæsthesia of the supra-glottic portions of the larynx. The paralysis is attributed to lesion or disorder of the superior laryngeal nerve.

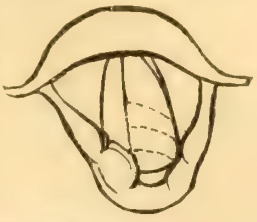

Fig. 4963.—Right-sided Abductor Paralysis. Deep Inspiration.

Paralysis of the crico-thyroid muscles is shown in marked cases only by lack of longitudinal tension of the vocal bands in phonation, efforts at which usually produce some congestion. Sometimes irregular undulation of the surface is seen. In most instances laryngoscopy shows no abnormal condition, and the diagnosis is inferred from the character of the voice and the absence of vibrations on palpation of the crico-thyroid membrane.

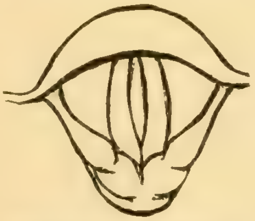

Fig. 4964.—Bilateral Paralysis of Thyro-arytenoids; Phonation.

This paralysis is due to lesion of the superior laryngeal. Nevertheless, so accurate an observer as Türck has found degeneration of these muscles with that nerve apparently intact, whence he inferred that the innervation in some subjects may be derived from the inferior laryngeal. Paralysis of the thyro-arytenoid muscles is recognized by approximation of the vocal bands posteriorly without longitudinal approximation, so that the glottis is rendered elliptic in phonation when the paralysis is bilateral (Fig. 4964), or bow-shaped when unilateral (Fig. 4965). The paralysis is most frequently limited to the inner portion of this muscle. When the outer portion is paralyzed the image of the vocal band shows want of adduction posteriorly, because the vocal process of the arytenoid cartilage is not thrown inward by the action of the muscle upon its attachment to the muscular process of that cartilage. It is extremely difficult of diagnosis. When both portions are paralyzed, there is a lack of adduction of the vocal bands posteriorly, with a concave curve to the internal border.

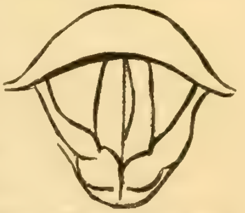

Fig. 4965.—Left-sided Paralysis of Thyro-arytenoid; Phonation.

Paralysis of the arytenoid muscle is shown by gaping in phonation of the posterior or arytenoidal portion of the glottis behind the posterior vocal processes (Fig. 4966); the closure in front being normal, or modified by other conditions as in combined paralysis of the arytenoid and thyro-arytenoid muscles (Fig. 4967). A slight gaping of the arytenoidal portion of the glottis in phonation is observed as a normal condition in many subjects, even in good singers, and this fact must not be lost sight of in making the diagnosis.

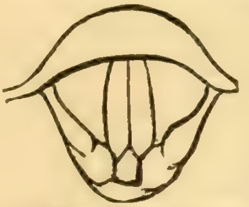

Fig. 4966.—Paralysis of Arytenoid Muscle; Phonation.

In paralyses affecting several muscles, the laryngoscopic picture is more complex than in paralyses of individual muscles; but it can usually be analyzed into combinations of the simpler forms which have been detailed.

The better to comprehend the changes in paralyses, three outlines are appended of the positions of the vocal bands respectively in normal phonation, deep inspi-

[illegible] and [illegible] [illegible] (Figs. [illegible], [illegible], and [illegible]).

Prognosis.—Two factors enter into prognosis: the danger to life, and the prospect of relief from the paralysis. The danger to life is very great in all incurable diseases involving the paths of innervation from the cortex to the nerve-trunk, apart from any direct influence of the paralysis. Two forms of paralysis are very menacing to life, independently of the lesions causing them. These are bilateral paralysis of the posterior crico-arytenoid muscles, and bilateral paralysis of the thyro- and aryteno-epiglottic muscles. In the former, death by suffocation is imminent from inability to breathe. In the latter the fatal issue may be caused by suffocation or by traumatic pneumonitis from escape of food into the air passages. The unilateral paralyses of these muscles are not dangerous. In bilateral paralysis of the abductors of hysterical origin the prognosis is better, though grave for the time being.

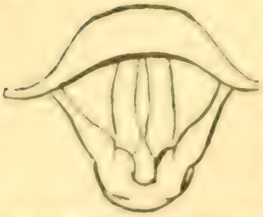

FIG. [illegible].—Bilateral Paralysis of Thyro-arytenoids, with Paralysis of Arytenoid Muscle. (Mackenzie.)

Bilateral paralysis of the entire group of muscles innervated from the recurrent, is far less serious, though sometimes quite grave.

Other paralyses offer no inconvenience to life, although the lesions producing them may be of fatal significance.

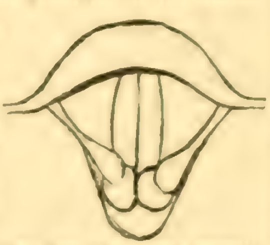

FIG. [illegible].—Phonation (normal).

Relief from paralysis is not to be expected in cases due to serious lesion along the nerve-path, unless the injury has been very slight, and the primary disorder be one susceptible of cure or of amelioration. It is, therefore, in syphilitic diseases that most benefit is to be expected; while reasonable hopes of relief may be entertained in many instances of simple compression of the nerve by enlarged lymphatic glands, by tumors susceptible of removal, and sometimes by foreign bodies. Lesions from traumatic injury cannot be relieved, as a rule.

FIG. [illegible].—Deep Inspiration (normal).

Relief from the paralysis may be justifiably expected in bilateral paralysis of the adductors of functional or hysterical origin: the voice becoming restored by treatment in the vast majority of cases, even when of several years' duration. A few cases resist treatment.

Paralysis of the crico-thyroid muscle is sometimes curable when not due to surgical injury or to degeneration of nerve-fibres.

Isolated paralysis of the thyro-arytenoids is curable in cases due to exposure to unfavorable climatic influences, to laryngitis, and to simple overuse of the voice; but the termination is doubtful in cases due to overuse of the voice during the period of sexual change at puberty.

Isolated paralysis of the arytenoid muscle is usually curable.

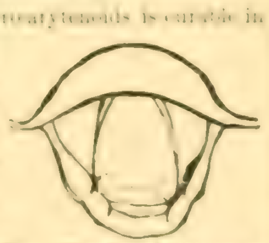

FIG. [illegible].—Bilateral Recurrent Paralysis. Vocal bands motionless, [illegible].

Treatment.—The treatment of laryngeal paralysis varies with the cause and with the effects of the lesion. Except in so far as special conditions may require, treatment is unavailable in paralysis from degenerative disease and injuries of the medulla, of the spinal accessory, and of the pneumogastric; and but little can be expected in cases due to aneurism and malignant morbid growths pressing upon the laryngeal nerves. In other cases treatment must be directed to the pathological lesion, and when this is remediable, as in the removal of a foreign body, enlarged glands, syphilitic lesion, etc., the paralysis may be relieved if the nerve has not suffered permanent injury.

Bilateral paralysis of the abductors requires tracheotomy to relieve the dyspnœa and avert the danger of death by suffocation. Its neglect is criminally hazardous and reprehensible, although the risk is sometimes taken with impunity, especially in hysterical cases.

Bilateral paralysis of the adductors, when of functional or hysterical origin, is often curable by any irritation whatever applied within the larynx, a manœuvre which excites spasm and thereby overcomes the paralysis. The induced electrical current is the most reliable agent, and a spark of static electricity drawn from the larynx externally is often strikingly effective; but even so simple a manipulation as the introduction of the laryngoscopic mirror and an order to say *ah*, will suffice in many instances. These manœuvres may require repetition at intervals of a few days for several days or weeks. Strychnine internally is the best medicinal remedy, and is usually indicated in addition. Constitutional treatment suitable to the systemic condition is to be instituted as a matter of course, whether the remedies be medicinal, hygienic, moral, or psychical.

Paralysis due to toxæmia, to acute infectious disease, to rheumatic influence, to want of exercise of the voice, as occurs in the paralyses of some [illegible], or to too much exercise of the voice, are usually amenable to treatment by electrization, the primary or induced current being applied as directly as possible to the muscles affected or to the nerve-fibres supplying them, at the most accessible or superficial region; and it is probably a matter of indifference in most instances whether the source of electricity be taken from the battery, from the induction coil, or from the magneto-electric machine. Appropriate constitutional treatment is required to avert or restrain relapses. The laryngeal muscles may be subjected to the electric influence through the medium of their motor nerve supply, or through currents passed through some portion of the bodies of the muscles.

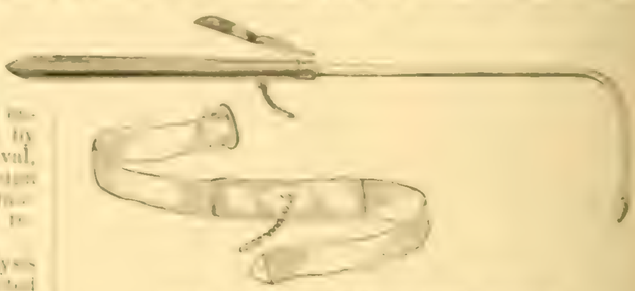

FIG. [illegible].—Mackenzie's Intra-laryngeal Electrode.

The negative electrode should be placed over the part which is to be especially subjected to the current; the other electrode being placed in proximity or at a distance, as may be. When placed at a distance the positive electrode, preferably a disk covered with moistened sponge or flannel, may be held in the hand of the patient, or be applied to the neck. The superior and inferior laryngeal nerves and the crico-thyroid muscle can be influenced from the exterior of the larynx. Direct influence upon the other muscles requires a small curved electrode, with a handle so bent as to facilitate its easy introduction into the larynx. The form adopted by Mackenzie (Fig. [illegible]) is probably the best. It has a spring key controlling the current, which is very easy of manipulation. When it is desired to confine the faradic current as much as possible to one muscle or to a group of muscles a double intra-laryngeal electrode is used, of which one of the best is that of Ziemssen (Fig. 4972). For use externally, small-sized ordinary electrodes suffice. The superior laryngeal nerve can be influenced by placing the electrode on the side of the larynx over the superior horn of the thyroid cartilage, and the inferior laryngeal nerve can be influenced by placing the electrode over the inferior horn between that structure and the sterno-cleido-mastoid muscle (Gerhardt). If allowed to pass through the muscle, the current may influence the pneumogastric disastrously, and produce slowing of the pulse and syncope (Duchenne, Türck, Gerhardt, *et al.*). The crico-thyroid muscle is reached by placing the electrode to the side of the crico-thyroid membrane.

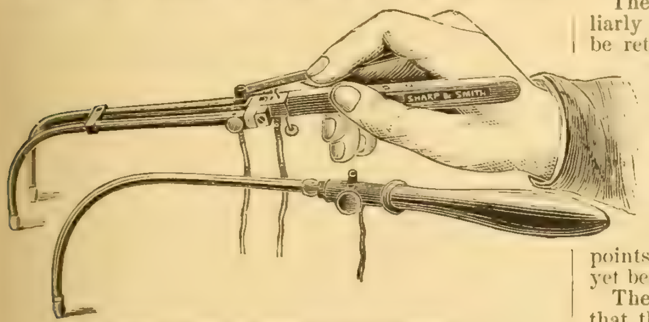

FIG. 4972.—Ziemssen's Double Laryngeal Electrode.

The thyro-arytenoids are best reached by placing the intra-laryngeal electrode upon the corresponding vocal band, and the external electrode over the crico-thyroid membrane. The arytenoid is reached by placing the electrode on the posterior surface of the larynx; the posterior crico-arytenoid, by placing it upon the outer surface of the cricoid cartilage a little to the side of the middle line; the lateral crico-arytenoid at a point considerably further forward than that last mentioned, to the side of the cricoid, and deep down in the pyramidal sinus between cricoid and thyroid cartilages; and the aryteno- and thyro-epiglottici are reached at the sides of the epiglottis. When the electrode is placed upon the posterior or postero-lateral surface of the larynx, that is, between that structure and the tissues of the pharynx and œsophagus, the electrode should be insulated on one side, if it be desired to prevent electrization of the pharynx or œsophagus. Intra-laryngeal electrization should be performed under laryngoscopic inspection, and the strength of the current be regulated according to the effects observed. A current strong enough to move the extensor muscle of the thumb is sufficient in any instance, as a rule; much weaker currents suffice in many. Each application may be continued for ten seconds or a little longer, with one or more interruptions by the use of the key. Two or more repetitions can be made at each sitting, and the sittings may be renewed daily, or at intervals of two or three days, as long as there remains any indication that electricity will continue to be useful.

In paralysis of the thyro- and aryteno-epiglottic muscles from diphtheria, it is often requisite for a considerable period that nourishment should be administered artificially through an œsophageal or a rectal tube, as the case may be. Strychnine is of advantage internally or hypodermically. Little benefit results from topical electrization; for the restoration of tone in the nerve-centre must be awaited, and this does not appear to be at all accelerated by electrization. A spontaneous cure during a course of electrization is often incorrectly accredited to that procedure. *J. Solis Cohen.*

LEPTUS. A parasite of the human skin known popularly as the "harvest mite." Riley considers that there are two species, *l. americanus* and *l. irritans*. Geber, however, considers these as, in all probability, the female and male respectively, and includes both under the designation "*l. autumnalis*."

The mite, which averages 0.3–0.5 mm. in length, and is visible to the naked eye, has a reddish or yellowish-red color. On the head, which is small, compared with the size of the body, is a proboscis, on each side of which are the stylet-formed strong mandibles (Fig. 4973, *m*).

The palpi (*p*), situated a little further back, are peculiarly strong. These are jointed like the limbs, and may be retracted or thrust out; they terminate in a sharp claw. The feet are six in number, three on each side, setting into a socket. Each limb is composed of three parts: a coxa (*c*), a five- to six-jointed tibia (*t*), and a tarsus (*ta*), with two club-shaped terminal bristles. Similar bristles are found along the tibiæ. The abdomen is relatively large, broad, and striated. Thorn-like processes project from the dorsal surface. On the head, on either side of the palpi, are two sharply defined points, the so-called "eyes." Sexual organs have not as yet been discovered upon the leptus.

The negative sexual appearances, as well as the fact that the animal has only six legs, caused Siebold to regard the leptus as a larva of some probably unknown form of mite. Geber, however, suggests, as was before mentioned, that the two "species" or "varieties" are probably male and female.

The *leptus americanus* of Riley is found upon the scalp, in the axillæ, and on other parts of the body, and more frequently upon children than upon adults. It does not completely bury itself in the flesh, but insinuates the anterior portion of the body only beneath the skin, causing a small inflammatory papule.

The *l. irritans* (Riley) is the better known of the two varieties, and is considered by Duhring to correspond to the *l. autumnalis* of foreign writers. It gives rise to considerable annoyance, burying itself in the skin, and causing irritation and inflammation, characterized by the appearance of papules, vesicles, and pustules. It attacks especially the ankles and legs. It is met with in the summer and autumn in corn-fields, upon low bushes, in the grass and weeds along the banks of rivers, and in swampy places. It is said to be very common along the Mississippi River. The little red mite encountered in the swamps and on the low ground of Pennsylvania, New Jersey, and Delaware, especially about blackberry bushes, is in all probability the same species (Duhring).

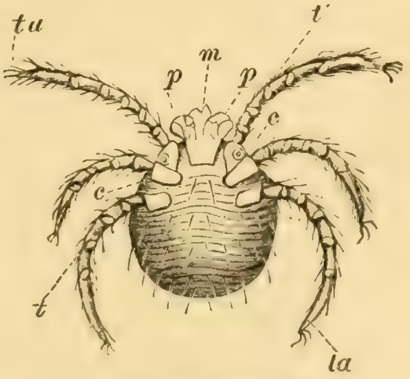

FIG. 4973.—The Harvest Mite.

The disease is best treated with mild parasiticides, as, for example, a weak sulphur ointment employed in the same manner as for scabies.

LYMPHATIC GLANDS, DISEASES OF THE. In entering upon the study of the pathological processes which take place in the lymphatic glands, it is evident that the field of investigation is materially restricted by the fact that these organs constitute only a part, and that a subordinate one, of a system, the more important members of which are the lymphatic vessels. For this reason, nearly all the diseases of the glands are of a secondary or "sympathetic" nature, due to pathological processes in other organs or tissues with which the radicles of the lymphatic vessels, which convey lymph to them, are connected. The only exceptions to this rule, outside of those diseases due to direct traumatism, are lymphadenoma, or Hodgkin's disease, and tuberculous affections of the glands. As both of these are treated of elsewhere in this work, it is not our province to discuss them here.

The lymphatic glands are collections of lymph-follicles, surrounded by connective tissue, scattered in clusters throughout the course of the lymphatic vessels. Their function is now believed to be a double one, viz., to form lymph (or lymphoid) corpuscles, and to act the part of filters or strainers of the lymph.

In the performance of the latter function, the glands of course show that they possess the power to retain and store up within themselves insoluble particles, which, being foreign to the organism, would act as irritants if allowed to gain access to the general circulation. This power is most strikingly shown in cases of the operation technically known as "tattooing," in which the smaller particles of the substance introduced into the skin, usually vermilion, may be found a few hours later in the glands through which the lymph, coming from the injured part, flows, most abundantly in that portion of the gland nearest the afferent vessels. Here it remains permanently, and has been discovered as late as fifty years after the operation.[1]

During the absorption of extravasated blood, red blood corpuscles have been found in the glands outside the blood-vessels, and that at a very early period. Thus Müller[2] found them, within forty minutes after the subcutaneous division of the tibial artery of a dog, in large numbers in the inguinal glands of the side operated upon. As regards the ultimate fate of these corpuscles, it has been found that some of them undergo pigmentary metamorphosis in the lymphoid corpuscles, while the remainder pass unaltered through the lymph channels and find their way back into the blood.

Fat, also, in passing through the lymphatic system, is largely retained by and deposited in the glands, whether it comes from the medullary canal in cases of fracture, from contused fatty tissues, or from exudations undergoing the process of fatty degeneration. In the glands it can readily be recognized collected in large and small drops, within and between the lymphoid corpuscles.

If substances arrested within the glands be intrinsically of an innocuous nature, they produce no structural alteration in them unless they be present in very large quantities. If this be the case, the number of lymphoid corpuscles in the glands decreases, because crowded out by the foreign elements, and because the meshes of the reticulum and the capsules of the glands take on hyperplastic thickening. In consequence of this change, portions of the glands may become transformed into dense fibrillary connective tissue, dotted, in time, with pigment granules. The foreign elements have not been found to penetrate, as a rule, farther into the gland than the outermost cortical layer, at which point in such cases the follicles have been found to be filled with young connective tissue.

While inert substances thus produce no other alteration in the glands than simple hyperplasia of the connective tissue, the case is far different with the invasion of specific agents, e.g., such as are present when the glands become secondarily involved in cases of malignant neoplasms. According to the view now held, the first demonstrable alterations in the glands in such cases consist in dissemination of corpuscular elements which penetrate into the protoplasm and nuclei of the lymphoid cells.[3] The nature of these corpuscular elements can be certainly recognized only in the case of melanotic tumors. They are, according to Gussenbauer, to be regarded as fructifying germs which transmit certain qualities to the constituent elements of the glands, so that the secondary neoplasm takes the type of the original tumor instead of that of the gland tissue.

These corpuscular elements are at first arrested in the lymph channels of the cortex, but later penetrate into the follicles themselves. Early in the disease the microscope demonstrates the presence of small collections of epithelial cells, scattered throughout the cortex of the gland. These proliferate and gradually supplant the normal cells of the gland, until finally the entire organ has undergone a cancerous degeneration, and the new growth begins to invade surrounding tissues. The cells of the reticulum and the endothelium of the vessels also undergo an active hyperplasia, instead of becoming atrophied and degenerating into fat as they would do under the pressure of indifferent foreign elements, and ultimately form the connective-tissue framework of the new growth.

This circumstance, that the tissues of the lymphatic glands undergo proliferation and hyperplasia as a result of their invasion or infection by foreign elements, or in consequence of being irritated and stimulated by the absorption of fluids of a virulent nature, furnishes the type of the changes which these organs experience in the diseases of a simple inflammatory nature which we are now considering. Hyperplasia, induration, fatty degeneration, and sometimes atrophy, are the most common alterations which are met with in inflamed glands.

It is a fact established on the authority of many good observers that every pathological product which has the power to infect the system always excites, when absorbed, a swelling of the glands of that lymphatic territory with which it is brought into contact. This we have on the authority of Bergmann,[4] whose writings have been freely drawn upon in the preparation of this article. This swelling may be acute, subacute, or chronic, and at first always consists in hyperplastic changes within the glands. A striking illustration is furnished by the effects of inoculation with the virus of chancroid, which is invariably followed by enlargement and tenderness of the glands nearest to, and in communication with, the seat of the original lesion. The process is usually an acutely inflammatory one, terminating in suppuration and furnishing a pus capable of exciting suppuration and ulceration when inoculated. In this instance the contagious element, whatever be its nature, penetrates into the gland and there develops its specific action, for the pus from the middle of the gland is just as virulent as that from its periphery.

The hard chancre also is, as is well known, always attended by swelling of the lymphatic glands, in this case of a chronic and indolent type. The first to be affected are those of the groin, when the chancre is seated upon the genital organs, of the elbow and axilla when upon the hand, and of the submaxillary region in cases of chancre of the lip. Later in the disease the swelling involves successively other groups of glands, until none remains unaffected. Swelling and tenderness of the glands nearest the seat of operation also occur after vaccination, and usually terminate in spontaneous recovery.

A sympathetic affection of the glands is common in certain [illegible] diseases, e.g., in erysipelas. In this affection it is often possible to make a diagnosis before the pathognomonic redness of the skin has appeared, from the high fever and the swelling and tenderness of the glands of the affected region. To this tenderness, in fact, the patient generally calls the attention of the physician. In many cases of the disease of a severe type, all the superficial glands of the body become involved.

Swelling of all the lymphatic glands of the body may be said to be characteristic of all constitutional infectious diseases, a phenomenon peculiar to, and an essential part of, them. It is true that this swelling is usually so slight as to escape detection unless a very careful examination be made, which is seldom the case. It can very readily be found to exist in variola, scarlatina, and typhus and typhoid fevers. In scarlet fever a true hyperplasia of the glands, of limited extent, is a constant phenomenon,[5] which may result in suppuration or gangrene. This is especially liable to occur in scrofulous subjects. It is probably the result of septic absorption.

This involvement of the whole lymphatic glandular system is susceptible of two explanations. First, it is possible that the noxious agents may affect the tissues of the glands directly from the blood, as they may do with all the other tissues, as in the well-known instances of typhus and typhoid fevers, in which fatty degeneration of the muscles, heart, liver, and kidneys, is very common. Secondly, it seems not improbable that the swelling may be secondary to the affections of other organs which the disease induces. If the former hypothesis be accepted, the affection of the glands is a specific one, whereas if the latter be regarded as correct, the swelling is purely secondary and sympathetic. In the latter case, in consequence of degenerative processes in the affected organs, a variety of products entirely distinct in nature from the virus which caused the primary disease, may have been carried from the tissues to the glands by way of the absorbent vessels. In cases of mammary cancer the axillary glands may become swollen, either as a result of the immigration into them of specific cancer-cells, or in consequence of the absorption of inflammatory septic products which are never wanting in suppurating growths.

A strong light would be thrown upon this question by positive proof that in cases of swelling of the glands in infectious diseases the micrococci which have, in given instances, been demonstrated to be the causes of the maladies, can be traced into the glands. In malignant pustule, for instance, the cause of which is now known to be the bacillus anthracis, the glands whose lymphatics originate at the point at which the pustule is seated, are always softened, swollen, and of a deep red color, as if infiltrated with blood. The discovery in these glands of the bacillus anthracis would prove that the glandular affection was specific and not sympathetic. In diphtheria, in which the glands are much enlarged in consequence of cellular hyperplasia, while the periglandular cellular tissue is œdematous and often the seat of capillary hæmorrhages, micrococci *have* been found in the glands by numerous observers, especially by Oertel[6] and Barth.[7] No specific micrococcus has, however, been as yet shown to be the cause of diphtheria.

Some help toward the solution of this question is furnished by the experiments of Gaffky.[8] This author succeeded in producing in mice and rabbits, by the inoculation of a micro-organism cultivated outside the body, a disease which usually terminated fatally, within twenty-four hours. The autopsy always showed marked enlargement of the spleen and lymphatic glands, without discoverable changes in other organs. The microscope, however, detected in the blood in all parts of the body a morphologically very distinct form of bacterium, which was recognized as occupying a position midway between a micrococcus and a bacillus. Examination of the swollen glands showed these bacteria inside their blood-vessels, but not in the lymph-channels. Similar conditions were found in the glands by Koch, in his experiments in the production of septicæmia in mice by the inoculation of another form of bacterium. Also in animals which had died of the so-called "malignant œdema" Bergmann found the glands invariably enlarged, and dotted here and there with extravasated blood. He regards it as probable that in these cases the micro-organisms were carried to the glands by the lymphatics and not by the blood-vessels.

Another fact which goes to support the belief that the swelling of the glands in infectious diseases is due to the presence within them of the micro-organisms peculiar to the affection is this, that when fluids rich in the bacilli of decomposition are injected into the abdominal cavities of rabbits, these structures can be found in the reticular lymph spaces of the rapidly swelling glands even before they can be discovered in the blood. This fact was demonstrated by Fehleisen and Soubbotine.[10]

Whichever view of this question is adopted, and it must be admitted that in the present state of knowledge it is a difficult one to answer positively, the fact is at all events established that every artificial disease produced by the inoculation of bacteria, regardless of the location of the parasite, whether in the blood or in the connective tissue, is attended with an acute swelling of the lymphatic glands.

Not only is the swelling of all the glands of the body the result usually of an infection of the organism, but also that of a single group of glands is often, in a certain sense, of infectious origin. It has long been taught, and is still believed, that every swelling of a gland is the result of an inflammation at the point of origin of its afferent vessels. This inflammation, it may be confidently stated, is in all instances of an infectious nature, using the adjective "infectious" in the broader sense which it now conveys. Formerly the soft chancre, the "chancroid," was regarded as the type of a local affection which was capable of causing swelling and suppuration of the communicating glands. The hypothesis of the penetration of some infectious material from the infiltration upon the genitals into the glands was a natural one, since there could be no doubt but that the primary disease was transmissible and infectious. But a careful examination of other somewhat similar cases showed that in all those affections of the skin and mucous membranes which are usually attended with swelling of the glands there is, as a common feature, a something which is the first and most important requisite to the penetration into the body of foreign organisms, viz., a solution of continuity in blood-vessels or lymph spaces. In all diseases of this nature there occurs a removal of the protection which the epidermic and epithelial coverings furnish to the underlying tissues, a barrier which must first be overcome before we can inoculate any disease. We know that the inflammation of the glands is not dependent upon the nature or extent of the injury, but solely upon the question whether or not the skin or mucous membrane is broken or lacerated, and whether or not infecting germs come into contact with the lesion. The results of modern antiseptic surgery go to prove every day that if wounds are kept in an aseptic condition no inflammation (with its glandular swelling) will occur. Since also open wounds, in comparison with subcutaneous injuries, are especially prone to take on suppurative action, the conclusion seems justified that certain noxious agents present in the former (and necessarily absent in the latter) are the direct causes of suppuration, and as it is the teaching of every-day observation that suppurative inflammations are, as a rule, attended by glandular swelling, we are warranted in stating that lymphadenitis, both acute and chronic, is a disease which is directly caused by the penetration into the lymph channels and glands of infectious materials coming from without the body.

Suppurative inflammations which give rise to glandular swellings may conveniently be divided into two classes, superficial and deep. Of the former are inflammations of the skin and catarrhal affections of mucous membranes; of the latter, subcutaneous phlegmonous inflammations, local and diffuse, furuncles, onychias, burns and frost-bites, and all gangrenous and deep ulcerative affections. Catarrhs of the gastro-intestinal and pulmonary mucous membranes are the most common causes of affections of the former class. Here the lymph follicles seated in the mucous membranes are first affected, and later the glands connected with them. Thus a very close relationship is noticeable between diseases of the bronchial tubes and their lymphatic glands.[10] The affections of the glands here vary, with the duration and intensity of the bronchial affection, from simple hyperæmia or hyperplasia to chronic inflammation, with pigmentation, cheesy degeneration, or calcification. If they have acquired such a size as to compress the larger bronchi, or nerve or arterial trunks, they may even produce bronchial stenosis with its usual results.

In such cases the most plausible explanation of the adenitis is that the delicacy of the inflamed epithelial stratum affords no obstacle to the passage to the deeper layers of the membrane of the noxious organisms always present in the inspired air, or in the contents of the intestinal canal, as the case may be.

Similar conditions prevail in the superficial affections of the skin and in certain forms of eczema, which disease has been regarded by some as the analogue of a catarrh of a mucous membrane. In these the resisting or protective power of the epithelial layer is much lessened or entirely overcome, and in consequence of this the integrity of the rete Malpighii is impaired, and the passage of irritating organisms into the subcutaneous connective tissue permitted. For this reason there are but few cases of chronic eczema which are free from symptomatic affections of glands. In fact, swelling of these organs is a necessary attendant upon all itching, excoriating, and crusty diseases of the skin, including the prurigo of Hebra, scabies, and phthiriasis capitis. In all these instances the cause of the swelling is doubtless the same, viz., the penetration into the subcutaneous tissue of noxious agents deposited upon the surface, access being gained through the lesions of the skin produced by the fingers of the patient; and their transportation into the lymphatic vessels and thence into the glands.

Having reached these organs the foreign organisms act as irritants, causing a swelling of the glands which stands in an exact relationship with the specificity and intensity of the original local process. If the original lesion be, for instance, a soft chancre, an acute suppurative adenitis is developed which may become diphtheritic or gangrenous if the chancroid itself take on these changes. If connected with more indolent or less virulent lesions, the affection of the glands is also sluggish and indolent.

In its development, also, the swelling of the glands keeps pace with that of the primary disease. This can often be observed during the course of an erysipelas or of an impetiginous eczema of the scalp, or of an acute stomatitis. As the original disease grows worse the glands become more swollen and painful, and decrease in size and become less tender as the patient's condition improves.

In the case of a circumscribed affection of the skin, or of a mucous membrane, the swelling is for a time confined to a few glands, but later in the course of the disease the entire group in connection with the affected region becomes involved. If recovery do not take place the swelling invades the next group of glands in the direction of the lymph current. Matters remain in such a state, however, that the first group is always most severely affected, the swelling becoming gradually less the further from the original seat of disease the glands are situated. (This fact furnishes an additional illustration of the retentive power of the glands already spoken of.)

While the penetration into the glands of noxious germs or fluids from without, must with our present knowledge be regarded as the main cause of their swelling in the immense majority of cases, it may also be said to be the sole cause of their suppuration. Exceptions to this statement may, perhaps, be furnished by those cases in which glands suppurate in consequence of traumatism directly applied. Thus cases are not very uncommon in which glandular abscesses are met with in the axilla in consequence of the pressure of the head of a crutch. As regards the first part of the statement just made concerning the cause of the swelling of glands, it cannot be doubted that the practitioner meets now and then countless cases of acutely enlarged glands in children, in which the most careful investigation fails to detect any possible cause. Such swellings usually occur in the glands underneath the angles of the jaw, and are neither diphtheritic, nor are they the result of catarrh of the ear or throat, nor of scrofulous origin. Fortunately the swelling rarely suppurates, so that their importance is of a scientific rather than of a therapeutic nature.

The statement that the presence of noxious germs from without must be regarded as the sole cause of suppuration of glands, is borne out by the study of cases in which hyperplasia takes place without it being possible for such agents to have penetrated into the glands. In [illegible] blood-clots, e.g., the nearest glands are sometimes found to be swollen and tender. Here it seems not unlikely that certain ferments have developed in the clot which have been carried into the glands, and have stimulated them unduly.

It has been asserted that long-continued muscular exertion may cause swelling of glands, and that those of the axilla are generally enlarged in laboring men. If this be true, it is readily explained by the fact that men of this class are very often the subjects of slight lesions on the hands, which may permit access to the lymphatic system of external irritants. It is also not improbable that the excessive use to which such persons put their muscles leads to a constant increase in the quantity of lymph passing through the glands, a lymph richer than usual in the products of tissue metamorphosis, and hence capable of stimulating the glands to a physiological hypertrophy similar to that which the muscles undergo.

The first noticeable change in a diseased gland is an increase in size. In infants it is usually impossible to discover the glands by palpation or any other means. They first become recognizable at the age of from five to six years. At this time of life they may be felt as small isolated nodules of an oval shape, not sensitive to touch, and capable of being displaced under the skin. Their outlines are distinct, their consistence firm and elastic, and their surfaces smooth. They are always arranged in groups made up of glands varying greatly in size, from that of a pin-head to that of a bean, and are disposed in two sets, superficial and deep. The former are most numerous in the folds of the flexures of the large joints, and around the great vessels of the neck and limbs. The deep-seated are most abundant around the vessels coming from the large glandular viscera. At the period of second dentition some of the glands in the submaxillary region become appreciable to the touch, and at puberty those in the inguinal region. They usually become more distinct as the person grows older, for the reason that they increase in size with the rest of the body, and also because they are often subjected to slight disturbances of nutrition from the injuries and diseases to which they are liable. The enlargement of the glands along the lower edge of the lower jaw, which is so common at the period of second dentition, is due to the swelling which they undergo as the result of caries of the first teeth, inflammation of the gums, alveolar periostitis or stomatitis, affections which are so common at this period. Traces of the (usually temporary) swelling remain in the shape of slight permanent enlargement and induration. This fact explains why it is usually easy to make out the location of these glands in the majority of adults.

The discovery of enlargement of lymphatic glands should always lead to the suspicion of the existence of some pathological process in the region from which their afferent vessels originate. Thus enlargement of the glands under the angles of the jaw should lead the practitioner to suspect the presence of nasal or pharyngeal diphtheria. In some cases the presence of an enlarged and indurated gland in the median line of the neck, just above the thyroid isthmus, has furnished the first sign of the existence of a malignant neoplasm in the interior of the larynx. It must not be forgotten that in many epidemics of mumps the inflammation and swelling are confined exclusively to the subauricular and submaxillary lymphatic glands, the parotids not participating in the trouble to any appreciable extent; and yet that the disease is undoubtedly mumps is shown by its contagiousness and by the occasional occurrence of a typical parotitis during the course of the epidemic. Such an epidemic has been described by Penzoldt and one has recently been watched by the present writer.

In acute lymphadenitis, the most important alteration in the glands is an acute hyperplasia. This affection has been made the subject of careful study by Yeo and Lassar[17]. The latter excited acute inflammation in the glands of a dog by injecting oil of turpentine into them, and invariably found that only a portion of the parenchyma was affected, the rest remaining normal. The glands were soft, moist, and succulent on section, and of a much redder color than natural, due to active hyperæmia. This had also produced numerous small extravasations of blood. Microscopical examination showed marked swelling of the follicles, those of the cortex seeming to be filled full of lymphoid corpuscles with indistinct contours. In the dilated lymph-channels, besides normal lymph-corpuscles, many larger ones of irregularly oval shape, with several nuclei, could be seen. The trabeculæ of the gland and the finest reticular tissue showed no alteration. If the inflammation progressed these changes became more marked, and the vessels greatly dilated and distended to bursting with blood-corpuscles. The large multi-nucleated cells were probably lymphoid cells undergoing transformation into pus-corpuscles. Proliferative changes were also recognizable in the endothelia of the smaller blood-vessels.

The swelling of the glands in acute inflammation is therefore due to a numerical increase in the number of the lymphoid cells, with dilatation of the capillaries and retention of lymph. That the last is a factor in the causation of the swelling is shown by an observation of Lassar, who found an enormous increase in the quantity of lymph flowing from the vessels coming from the inflamed glands, whereas, under normal conditions, but one small drop flowed at intervals of about ten minutes. The amount could be greatly increased by passive motions of the limb to which the inflamed gland belonged.

Whether or not, in cases of septic adenitis, micro-organisms are present in sufficient numbers to materially contribute to the production of the swelling, must at present be left undecided, since careful microscopical investigations of this subject have not yet been made. In diphtheria, however, as has already been stated, numerous colonies of micrococci have been found in the glands by a number of authors.

According to the doctrine of the essential nature of inflammation now generally taught, the source of the lymphoid cells, whose increase in number and size is so marked a feature of the swelling of glands, is the blood capillaries. Although this may be true to a certain extent, it also seems probable that a part of them, at least, may originate from the reticulum of the gland as the result of proliferation. This is believed by Billroth, Yeo, Hansen, and Ranvier. Still another possible source of the new cells is from pre-existing lymphoid cells. Hyperplasia of the connective tissue of the trabeculæ is at all events the invariable result of inflammation of the glands.

Pus first shows itself in the gland in the form of distinct, scattered collections in different portions of the parenchyma of the organ. On section of a suppurating gland, yellow spots of the size of a pin-head are visible, containing thick creamy pus, and bearing a marked resemblance to follicular abscesses of the intestinal wall. Later these increase in size, spread and become confluent, the entire gland ultimately becoming transformed into an abscess, with shreds of tissue traversing its cavity, the remains of the parenchyma.

The surrounding connective tissue has by this time become the seat of a phlegmon, a "cellulitis," of greater or lesser extent. This participation in the inflammatory process of the periglandular tissue is doubtless due to the presence in the vasa afferentia of the affected gland of the materies morbi which caused the original trouble. The great number of these vessels is perhaps best seen in the mesentery in some fatal cases of typhoid fever. In many such these vessels are found to be enormously distended with large and small cells within and between which may be found extensive masses of the short, thick bacilli of Eberth.

These complicating inflammations of connective tissue are modified by the nature and intensity of the original irritation and also by the anatomical peculiarities of the planes in which they are developed. For the latter reason acute suppurative inflammations of the glands sometimes lead to very serious and even fatal results, as, *e.g.*, when suppuration sets in underneath the deep fascia of the neck, the pus burrowing downward and breaking into the mediastinum.

The extravascular accumulation and growth of cells in the parenchyma of the gland may be so great that the vessels are not only partially but wholly obstructed. In consequence of this the substance of the gland may become in spots pale from anæmia, and even gangrenous. This condition is often encountered in typhoid-fever cases, and may result in cheesy or calcareous degeneration of the necrosed mass, or in its removal by absorption, as is fortunately generally the case. Similar changes may take place in the glands beneath the angles of the jaw in diphtheria.

If the inflammation of the gland is destined to terminate in resolution, as is usually the case, the accumulation of lymphoid corpuscles is arrested at an early stage, and the greater part of them is carried back into the circulation. Another portion undergoes fatty and granular degeneration, and is reabsorbed. But as the progress of an acute lymphadenitis is always associated with increased growth of the fixed connective-tissue cells of the reticulum, an absolute restitution to the normal condition does not occur, and a permanent alteration in the framework of the gland always remains. This consists in a thickening of the connective tissue of the septa and reticulum, leading to induration and chronic enlargement of the gland. At a very late period the gland may undergo partial atrophy, but the induration remains through life.

In all acute infectious diseases it is the rule for the swelling of the glands to terminate in resolution. Exceptions to this are, however, quite common, especially in scrofulous subjects. The result of the swelling depends, in fact, to a large extent upon the nature of the cause of the original disease. Thus the bubo attendant upon chancroid ordinarily suppurates, whereas glands enlarged from constitutional syphilis never do so. It may be said that the tendency to suppuration is most marked in glands inflamed as a result of localized affections.

Etiology.—In the axillary region acute lymphadenitis may develop either with or without a preceding lymphangitis, or, at least, without discoverable evidence of it. It is much more common in adults than in children, because the hands and fingers of the former are much more exposed to those injuries in whose train the glandular affection is apt to develop. Children do not have the callous spots on the hands, collections of pus under which are frequently the cause of adenitis. Direct traumatism is a not infrequent cause of axillary adenitis, as the pressure of the head of a crutch. In children onychias, the so-called "run-rounds," often excite glandular inflammations in the axilla, and deep eczematous fissures or ulcers over chilblains may cause the same trouble in the axillæ or groins of adults. Itching pustular eruptions, *e.g.*, scabies, may cause lymphangitis, and subsequent adenitis. Bergmann once saw an acute suppurative inflammation of an axillary gland follow an acute suppurative mastitis in a child.

Lymphangitis from dermatitis is very common in those who walk a great deal in improperly constructed shoes, and is often attended with a rapid swelling of the inguinal glands, which, however, but rarely suppurate. Injuries to the hands or fingers of a special kind, such as those from insect-bites, contact with the poison of cadavers, or certain infectious diseases of wounds, often lead to rapid suppuration of the axillary glands. In all cases of this nature this is preceded by lymphangitis, characterized by the development of red lines running up the arm, and attended by great constitutional disturbance. The involvement of the glands sometimes occurs with surprising rapidity. Thus Hunter relates that a patient once called his attention to the fact that he felt pain in the axilla five minutes after his (the patient's) finger was accidentally punctured with a needle. On examination, Hunter was able to recognize a distinct enlargement of the glands in that situation.

The knowledge that the glands act as filters of the lymph flowing through them long ago gave rise to the belief that the swelling of these organs was a salutary one, protecting the system against infection. According to the same belief the suppuration was also advantageous, as the poisonous material which the gland stored up was supposed to be discharged with the pus. The fact that constitutional disturbance and pain always rapidly decline after the breaking through the skin or the artificial opening of a glandular abscess, and also that constitutional infection does not occur after suppurating buboes of venereal origin, also seem to lend weight to this view. It is, however, doubtless incorrect. It is much more probable that the character of the infecting micro-organism alone determines whether or not its action remains restricted to the lymphatic system and consecutive tissues, or passes into the blood and infects the whole organism. If the inflammatory bacteria are capable of vegetating in the tissues as well as in the blood, as in malignant pustule and diphtheria, the glandular affection does not afford the slightest defence against general infection. In chancroid, on the other hand, the poisoning material limits its action to the local destruction of tissue at the point of inoculation and the glands, but cannot continue to live and reproduce itself in the blood, and for this reason alone systemic infection does not take place. The same is true of lymphadenitis which follows most suppurative processes on the fingers. The constitutional disturbance which attends them owes its origin to the blood-changes produced by the taking up of inflammatory material from the focus of disease.

Although the glandular swelling may develop early in the course of the lymphangitis, its further course toward suppuration is usually slow. Five or more days usually elapse during which the gland grows steadily larger and more tender, but may still be displaced under the skin. If the swelling do not subside the gland becomes still more sensitive and fused together with the overlying skin and adjacent similarly affected glands, if such there be, and its contours become lost in the inflamed periglandular connective tissue. The entire groin or axilla, as the case may be, seems filled with a large, doughy mass. The skin is tense and glistening, and finally becomes oedematous. Careful examination shows harder, alternating with softer spots, and finally fluctuation is detected. The spot at which this is observed is usually surrounded by a dense wall of infiltrated tissue, and the skin over it soon becomes reddened and thinned, and finally bursts. The pus escapes and leaves an ulcerous cavity with undermined and overhanging edges. While quick healing is the rule if the opening be free, it is usually slow when the case is left to the unaided powers of nature.

The same glandular suppuration may also take place without the intermediary of a lymphangitis. Here also the swelling occurs early and suppuration is delayed. For this reason the original cause of the trouble, the pustule, or fissure of the skin, may long since have healed and been forgotten before attention is drawn to the glandular inflammation. These are the cases which are spoken of as illustrations of acute idiopathic suppuration of lymphatic glands, an affection which, probably, never occurs.

In children acute lymphadenitis is much more common in the neck than in the axilla. A connective lymphangitis can here almost never be demonstrated. Acute inflammation of the submaxillary glands follows as a rule diseases of the lips and mouth, especially of the gums and teeth. It is analogous in all respects to the chronic swellings of the same glands, so that it is often difficult to decide why an inflammation of these glands should be acute rather than subacute or chronic, as it usually is. It is doubtless dependent upon the intensity of the original inflammation and its cause.

Acute inflammation of the submental glands is ordinarily due to fissures of the angles of the mouth so common in scrofulous children. These fissures become inflamed and may induce suppuration of the gland under the anterior belly of the digastric muscle. Ulcers formed during dentition or pertussis may also give rise to the disease. The deep location of the gland renders the swelling impalpable, so that a correct diagnosis is often difficult.

A simple nasal or oral catarrh may also be the exciting cause of a gradual swelling of the neighboring glands, usually terminating in resolution, however. Many a case regarded as scrofulous in origin from the presence of a [illegible] chronic swellings of the lymphatic glands may be readily interpreted by the discovery of a chronic nasal catarrh or eczema of the buccal mucous membrane.

Chronic lymphadenitis, being usually of a syphilitic or scrofulous nature, constitutes a phenomenon of these diseases and shall not therefore engage our attention.

Treatment.—Acute lymphadenitis developing in the course of diphtheria, scarlatina, chancroid, or any of the essential fevers is a part of that particular disease, and its treatment is described under the particular headings in other portions of this work and need not detain us here.

When it is secondary to diseases other than those named above, the situation and nature of the original trouble should, of course, be determined, and the appropriate treatment instituted. If a patient present himself stating that he has a lump in his groin which causes pain, the physician should at once suspect herpes, chancroid, or some injury of the foot, either an infected wound or bunion, or an ingrowing toe-nail. Thorough cleansing of the latter, with the proper use of antiseptics, will usually at once arrest the inflammation of the gland in the groin, which will rarely require any other treatment than rest in bed and the application of tincture of iodine, or of a warm poultice. Fortunately sympathetic inguinal glands rarely suppurate, this result occurring only in badly nourished or scrofulous subjects. In such persons, of course, iron, cod-liver oil, and other appropriate tonics are indicated.

Children are often brought to physicians for treatment of enlarged and painful glands in the back of the neck, on either side of the occipital protuberance. Such swellings are always due to the presence of lice in the hair, or, rather, to the artificial eczema which they excite, and the glandular inflammation requires no other treatment than the destruction of the parasites. Suppuration almost never occurs in such cases.

When there is marked constitutional disturbance in acute glandular inflammation, absolute rest in bed should be prescribed, with the administration of a brisk cathartic and sufficient opium to relieve pain. In robust subjects the local treatment should be at first vigorously antiphlogistic, viz., the application of two or three leeches around, not over, the gland, rubbing the skin over it with a moistened stick of silver nitrate, the application of the tincture of iodine, or the continuous use of the ice-bag. In some mild cases of acute swelling of the glands under the angles of the jaw in children, the writer has seen marked subsidence of the tenderness and swelling after the application of a one to three solution of tincture of lobelia in water, on a compress covered with oiled-silk, a therapeutic application originally obtained from extra-professional sources.

If suppuration be inevitable, antiphlogistic treatment should of course be abandoned, and hot applications, either water as hot as can be borne, or poultices, should be resorted to. Here, of course, free incisions are indicated, even before fluctuation can be detected, that a free discharge may be given to all pus and tissue debris. In some cases of suppuration of glands underneath the sterno-cleido-mastoid muscles, with alarming [illegible], numerous incisions through the deep fascia must be made in order to release the compressed tissues and to obviate burrowing of pus, which may become very dangerous in this situation.

LYMPHATIC SYSTEM. Synonyms: Absorbent system; Latin, Systema lymphatica; French, Système lymphatique; Italian, Sistema linfatico; German, Lymphsystem oder Saugadersystem. The lymphatic or lymph vascular system consists of the vessels and spaces containing lymph or chyle (colorless or white blood), and of the lymphatic or conglobate glands situated in the course of the vessels, and through which the lymph must percolate something as if passing through a sponge. This system is an appendage of the blood vascular system, its two terminal trunks, the thoracic duct, and the right common lymphatic trunk, ending in the great veins at the base of the neck.

A tolerably correct pictorial idea of the entire vascular system may be formed by considering the blood vascular part as made up of a great tree, the heart forming a short trunk and the arteries, veins, and capillaries, the branches; but there is present the untree-like character of the direct union of the terminal twigs of the arteries and veins, that is, the venous and arterial capillaries are continuous. The lymphatic system may then be represented by two vines of unequal size, but which together follow all the blood-vessels to their ultimate ramifications, and in many places even send minute twigs beyond them. The analogy with a vine is further borne out by the lymphatic vessels, as they remain of a more uniform diameter than the blood-vessels; and finally the terminal twigs, like those of a real vine, end freely or blindly, often in slight expansions like leaves, thus forming a marked contrast with the terminal twigs of arteries and veins, which cannot be properly said to terminate at all. In a word, the blood vascular system forms a complete circle or circuit in itself, while the lymph vascular system joins the blood vascular system at its central or trunk end, but ends blindly at the periphery.

Historical.—Perhaps it is not to be wondered at that the lymphatic system should not have been discovered and investigated before the circulation of the blood and the general relations of the blood vascular system had been investigated and understood, and yet, from the prominence of the lymphatic glands they were seen by Hippocrates; but, having no notion of their true relations, he classed them with the other glandular structures of the body; so, too, there is strong reason for believing that the lacteals were seen in animals by the two famous Alexandrian physicians, Erasistratus and Herophilus; but their significance was not comprehended. About the middle of the sixteenth century (1564), Eustachius found the thoracic duct in the horse, and traced it, both to its beginning in the abdomen, where he became bewildered, and to its termination in the great veins in the neck. He did not profess to understand the significance of this vessel, but named it, from its color and position, *vena alba thoracis*.

It was not until 1622, when Asellius saw the lacteals in a dog, that the real significance of these vessels was appreciated. The whole scientific world was about this time aroused by the epoch-making discovery of Harvey on the circulation of the blood, and everything like a vessel was scrutinized with inquiring eyes. The story of Asellius in connection with the discovery and comprehension of the significance of the lacteals will never lose its interest as long as the human mind is striving to comprehend the universe, either in its details or in the ensemble. Having opened the abdomen of a living dog, to show to some friends the arrangement of the nerves and the working of the diaphragm, Asellius saw in the mesentery some white cords in addition to the nerves and vessels with which he was familiar, and upon cutting one of them and seeing a white liquid exude, he immediately recognized that they were a new kind of vessel. Most fortunately for him and for science, the dog, killed on the following day to find out still more about these curious white veins, showed none of them. Fortunately, because it led Asellius to consider the conditions under which they appeared in the first dog, and wherein the conditions differed in the second. With the sure comprehension of a scientific mind, he saw that the only essential difference lay in the presence of partly digested food in the first case, and in the absence of food in the second. When this condition was realized in a third dog, the lacteal vessels reappeared, and the relation between the products of digestion and these vessels was fully established for the dog.

Not content with the experiments on the dog, Asellius examined many other animals, showing in every case that there was a constant relation between digestion and the presence of the white fluid in the lacteal vessels. Owing to the powerful influence of the prevailing opinion that all matter must first go to the liver to be assimilated, Asellius supposed that the newly found lacteals extended to the liver. It is difficult to comprehend how a mere hypothesis could blind the eyes of so skilled an anatomist, but so it was, and the belief that the lacteals passed to the liver prevailed for nearly twenty-five years, till about 1650. It may be said in passing, that when the facts concerning these new vessels were presented to Harvey, he did not welcome the newly acquired knowledge. Doubtless the weight of years had quenched the enthusiasm of investigation, and he may have been troubled lest these newly discovered vessels might in some way prove a stumbling-block to his simple and easily comprehended explanation of the blood vascular system.

About 1650, the great facts concerning the lymphatic system, as they are understood at the present day, were discovered by four men in different quarters of Europe. In France, Pecquet showed that the *venæ aquosæ hepatici*, or lymphatic vessels connected with the liver, were not the continuation of the lacteals to the liver, but were vessels extending either to the lacteals, or with them into a common reservoir into which both opened, and that the reservoir was continued as a somewhat smaller vessel (the thoracic duct) through the thorax, to terminate in the great veins in the neck. The same facts were observed by Rudbeck, in Sweden, at about the same time, and completely overthrew the notion that all absorbed food must first pass to the liver for assimilation before entering the blood; for here was *apparently* the only path of the absorbed food, and it terminated directly in the great veins on their way to the heart.

At about this date, Bartholin in Denmark, Jolyff in England, and Rudbeck in Sweden, discovered the general lymphatics of the body. They also showed that these lymphatics (*Vasa lymphatica* of Bartholin, *Vasa aquosa* of Rudbeck), or serous vessels either united with the lacteals in the *chylocyst* or joined the thoracic duct, and consequently the lymph and chyle or lacteal fluid unite, and together flow into the great veins. In other words, they showed that the lacteals form only a special part of a great system distributed throughout the entire body.

Not much was added to the knowledge of the lymphatic system for nearly one hundred years after the main facts were established, and naturally, in those early times, with undeveloped methods and superstition both as impediments, knowledge was only general and obtained principally by investigating the lower animals. And yet, in 1628, a criminal was properly fed before execution, and the lacteals demonstrated in the mesentery after death, thus showing conclusively that the absorbed food in man takes the same course as in animals.

Between 1760 and 1787 there was a renewed activity in investigating the lymphatic system. In England the Hunters, Hewson, and Cruikshank, not only investigated the human lymphatics, but pushed their investigations to all forms of vertebrates, and they were found abundantly in all forms. The Monros, in Scotland, were also very active. In Italy the great anatomist, Mascagni, was preparing his magnificent work on the human lymphatics, a work which is still a standard; and reduced copies of his splendid folio plates are still to be found in every extensive account of this system.

As in all departments of human activity, the crowning discoveries in the lymphatic system are due to the work of an almost untold number of men; and yet a few present the principal and salient features so unincumbered with useless, distracting, or foreign details, that they are, for the majority of which the true discoverers. They make the obscure discoverer a part of the knowledge of the past. So in the many historical [illegible] many names have been omitted and undue prominence may have been given to others. Leaving these defects it is hoped that is represented fairly well the progress from vague and erroneous to correct knowledge of this system.

Since the work named above, something noteworthy has appeared almost every decade, but it has been mostly toward the elucidation of special details of function, origin, development, or structure, rather than an investigation of the whole field. The work of Sappey forms an exception to this general statement. His investigations have extended over more than forty years and with a vast care and all the refinement of modern methods, he has not only done much on the general subject both in human and comparative anatomy, but many of the difficult points have been elucidated by him. His atlas is probably, without qualification, the most important monograph that has appeared since Mascagni's.

GENERAL STRUCTURE IN MAN AND ANIMALS.—Considered as a whole, the lymphatic system consists of minute and larger vessels, of distinctly walled capillaries and larger trunks. Lymphoid or adenoid tissue seems also to be an integral part, and in man and the higher forms this adenoid tissue is, in part, aggregated into special masses, the lymphatic glands, situated in the course of the vessels and forming a sort of sponge-work through which the lymph must percolate on its course to join the blood-vessels.

Like the blood-vessels, the lymphatics may be divided into groups according to their position, as (a) subcutaneous, subserous, or superficial, and (b) subintermuscular, submucous, or deep; and as visceral, those belonging to the heart, lungs, urinary and generative organs, and the alimentary canal. Part of these, e.g., those from the small intestine, are called lacteals or chyle-vessels. All of the larger vessels possess more numerous valves than do the veins.

In distribution, the lymphatics follow mostly the course of the blood-vessels, but this does not apply to the subcutaneous lymphatics, as will be seen by comparing Figs. [illegible] and [illegible], with figures showing subcutaneous veins. Furthermore, in many situations lymph-vessels or lymph-canals and spaces extend beyond the blood-vessels and more intimately envelop the tissue elements.

The lymphatic capillary network, although agreeing in general appearance to a blood capillary network, is composed of larger vessels and its mesh is coarser. With the larger vessels the anastomoses are more frequent, but differ in character from the anastomoses of blood-vessels inasmuch as the parallel vessels divide equally or unequally and unite at a very acute angle, making a long narrow meshed network (Fig. 4979), and nowhere is found the great disparity in the size of the vessels as is found with the great arterial and venous trunks. Even the terminal lymphatic trunks are minute as compared with the vessels which they supply. The entire lymphatic system is supposed to have a capacity one half as great as the venous, and perhaps more, but no exact determination can be made on account of the structural peculiarities of the lymphatics, and the immense number of valves. In man and the higher forms, all lymph is supposed to traverse one or more lymphatic glands before joining the common lymphatic trunks.

In the higher mammals the general arrangement and distribution of the lymphatics is as in man. So far as has been investigated, however, the lymphatic vessels are fewer in number; this is markedly the case with the cutaneous and subcutaneous vessels. The lymphatic glands, although abundant in the horse and ox, are less numerous in most forms. Groups of glands in man are often represented by a single one or are wholly absent. Although fewer [illegible] a vessel finally of many joins the great trunk without first traversing one or more glands (Figs. 4975, 4980, and 4981). In the lower mammals there is a strong tendency to symmetry in the lymphatic system, the right and left terminal trunks being more nearly equal in size and in the area from which the vessels come. This tendency is also marked in the horse, and especially so in the rabbit; it is frequently observed in the cat, also occasionally in man. The crossing of considerable trunks from one side to the other is more marked in the lower mammals than in the higher, but even in man considerable trunks not infrequently cross from one side to the other (Figs. 4975 and 4976, 4977), and in all the forms there is the closest possible relation between the two sides through the lymphatic plexuses, that is, networks formed by groups of lymphatic glands and their connecting lymphatic vessels. While it is not uncommon to speak of a network of lymphatic vessels as a plexus, the term is coming to be restricted rather to a lymphatic network in which the glands form the nodal points of the mesh (see Fig. 4974).

Of the animals below the mammalia, the birds possess few lymphatic glands, and those are restricted to the neck, or in a few forms to the neck and axilla. A cutaneous and subcutaneous lymph network has not been demonstrated in the birds. Those that have been shown, it is supposed, correspond with the costal and visceral lymphatics of mammals. The two trunks opening into the veins of the neck are symmetrical, that is, equal right and left trunks. There are also two openings for the lymphatics in the pelvic veins, and lymph hearts are found in this region, but they have muscular walls in only few forms (ostrich, cassowary, stork, and some gulls). Lymph hearts are never present in man and the other mammals, although, in addition to the birds mentioned, they are found in reptiles, amphibia, and some fishes. They are mostly situated in the pelvic region, and possess striated muscle which is paralyzed by curare like the skeletal muscles. In the tailless amphibia (frogs) there is a pair of lymph hearts on the thoracic dorsum as well as in the pelvic region; and with some elongated amphibia, *salamandra maculosa* and *siren lacertina*, eight to twelve lymph hearts exist along the sides of the body and tail, at the junction of the dorsal and ventral body muscles. Finally, in some cheloneans the number of lymph hearts is very great.

Below the birds the lymphatic glands are absent, their place being supplied by lymphoid tissue and by special fine vascular nets or networks into which the vessels break up in their course. Perfect valves like those present in mammals are found in birds, less perfect ones in reptiles and amphibia, and finally in the fish-like forms none at all are found, so that the system may be injected toward the periphery like the arteries.

TOPOGRAPHICAL ANATOMY OF THE LYMPHATICS.—While it would seem more philosophical to treat the various parts of the lymphatic system in their entirety throughout the whole body, viz. the costal, superficial, or subcutaneous; the costal, subaponeurotic or deep; and the visceral lymphatics with the corresponding glands and lymphoid tissue, it is better practically, both for the purposes of demonstration and study, to consider all the lymphatic structures belonging to a given region at one time. This method is also really in accord with nature, because all the lymphatic structures in any reasonably well defined region of the body are, sooner or later, intimately connected and really form one whole for the given region.

Following the plan ordinarily pursued, the lymphatic vessels will be considered as extending in the direction in which their contents flow, as with the veins, and also in the order in which they must be demonstrated by injections. This will require the investigation to commence at the periphery and extend toward the centre. In the descriptions here given, usually only the trunks containing valves will be considered. The origin of the vessels in the tissues and the valveless networks will be considered below, under the origin and relations of the lymphatics. When the term plexus is used in this article it will be restricted to a lymphatic plexus composed of lymphatic glands with their connecting lymphatic vessels, and will not apply to a network of vessels without glands. After the vessels of a region have been described, there will be given a list of the groups of the lymphatic glands and the plexuses belonging to the region, together with the source and destination of the afferent and efferent vessels. This will serve both to give the proper information concerning the number and position of the glands, and also to form a condensed summary of the lymphatic system in the region.

LYMPHATIC VESSELS OF THE HEAD, FACE, AND NECK.—The ectal or subcutaneous lymphatic vessels of the head and face are very abundant and follow, in general, the course of the occipital, temporal, and facial blood-vessels, converging somewhat toward the great vessels of the neck; they traverse one or more of the lymphatic glands which form an irregular zone nearly around the base of the head (Fig. 4974), and finally enter the internal jugular plexus, and terminate in the thoracic duct on the left, or the common lymphatic trunk on the right (Fig. 4990). In addition to the general description just given, the lymphatics of the eyelids, nose, and ear require special mention.

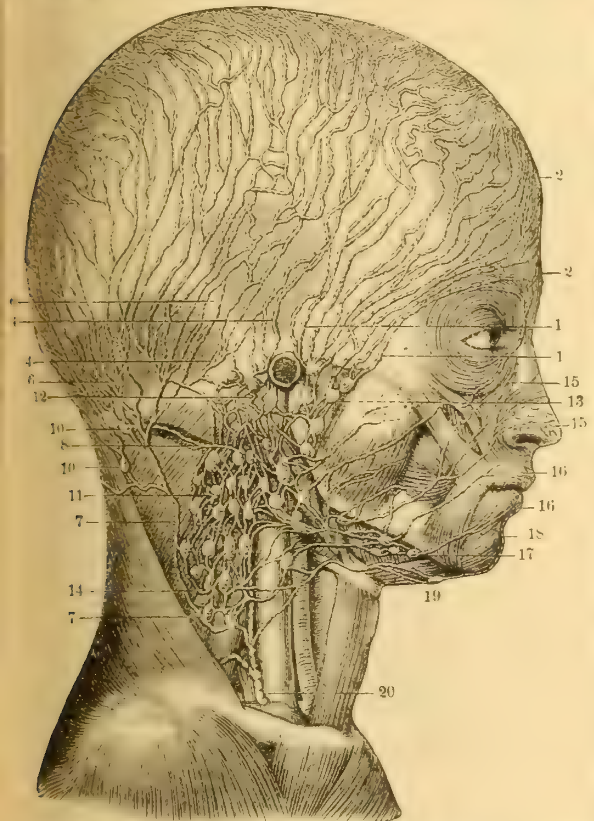

FIG. 4974.—Ectal Lymphatics of the Head and Face, the Ental Lymphatics of the Neck, and the Right Common Lymphatic Trunk. (Sappey.) 1, 1 Lymphatics from the frontal region going to the parotid lymphatic glands; 2, 2, vessels arising near the middle of the forehead, the upper ones going to the parotid, the lower ones to the submaxillary lymphatic glands; 4, 4, vessels from the parietal and temporal region extend to the mastoid lymphatic glands; 6, 6, vessels from the parietal and occipital region joining the occipital plexus; 7, trunk from occipital plexus to the supra-clavicular glands; 8, trunk from the occipital to the cephalic, ental (superior deep) cervical glands; 10, 10, occipital lymphatic glands; 11, cephalic ental (superior deep) cervical glands and plexus; 12, mastoid glands; 13, parotid lymphatic glands; 14, part of supra-clavicular glands; 15, 15, lymph vessels from the nose to the submaxillary glands; 16, 16, lymphatics from the lips to the same glands; 17, submaxillary glands; 18, vessel from the lip to 19, the supra-hyoid gland; 20, right common lymphatic trunk opening into the veins at the angle formed by the junction of the subclavian and internal jugular veins.

The lymphatics of the eyelids and palpebral conjunctiva form a very abundant network, although it is somewhat difficult to demonstrate. Those from the conjunctiva wind round the edges of the lids and mingle with those of the integument, which are especially abundant at the edges of the lids. The branches unite into two great groups at the canthi of the lids, those at the lateral canthus extending to the parotid lymphatic glands, while those at the nasal canthus join those from the middle of the forehead and the nose, and extend to the submaxillary lymphatic glands (Fig. 4974).

The skin of the nose, especially the thicker part around the tip, where the large sebaceous glands are so abundant, is possessed of a very dense network of lymph capillaries and minute trunks. These trunks are joined by the abundant lymphatics from the vestibule, which in turn are continuous with the lymphatics of the nasal mucosa. Finally, the collecting trunks from the vestibule and the nasal integument extend obliquely across the face to the submaxillary lymphatic glands.

The lymphatics of the external ear and meatus form three principal groups: 1. Those of the helix, antihelix, and convex (posterior) surface. Those of the helix and antihelix wind round the free border of the ear to the convex surface, where they join the trunks of that surface, and uniting into several (4 to 5) considerable vessels, they extend to the mastoid lymphatic glands. 2. The lymphatics of the external auditory meatus, also the membrana tympani (see below), the concha and tragus, terminate by two or three trunks in the parotid lymphatic glands. 3. The lymphatics of the lobule unite into seven or eight considerable trunks which extend to the caudal or lower of the mastoid lymphatic glands.

Ental Lymphatics of the Face and Head.—These are exceedingly abundant, and extend mostly to the deep cervical glands, but the relations of the vessels and the terminal glands are so various that a special description is required for each of the principal organs. Nasal cavities and sinuses opening into them: The existence of lymphatic vessels in the nasal mucosa was not demonstrated until 1859, when E. Simon showed by successful puncture injections that they were numerous. He also showed their relation with the network of the naso-pharynx. The existence of these vessels has been verified by Sappey in man and numerous animals. According to Sappey, the demonstration is comparatively easy wherever the mucosa is of considerable thickness. Schwalbe, and later Key and Retzius, showed that the nasal lymphatics could be injected from the subdural space; Key and Retzius[2] further showed that the injection was equally successful from the subarachnoid space of the brain, the subarachnoid and subdural spaces of the myel (spinal cord). They also found that, while in most cases the perineural sheaths of the olfactory nerves were injected at the same time, yet true lymphatic vessels did not communicate with these, but had special passages through the lamina cribrosa, and were often injected when the perineural sheaths were not injected; and sometimes the perineural sheaths were injected without the injection of the lymphatics. They were not successful in injecting the nasal lymphatics of man from the cranial lymph-spaces, although the perineural sheaths of the olfactory nerves were in some cases filled. The freshly sacrificed dog and rabbit furnished the most successful preparations. The lack of success in man was attributed to the inability to obtain sufficiently fresh material; it was also suggested that in man the lymph from the cranial lymph-spaces might have a sufficient number of other outlets.

The lymphatic network covers the entire nasal mucosa, both on the olfactory and the respiratory part, and that lining the septum. In man this network is directly continuous with that of the vestibule of the nose, but the collecting trunks extend toward the pharynx. The network is also continued into the frontal, and presumably the other, sinuses opening into the nasal fossæ. As they approach the pharynx, the collecting trunks of the nasal mucosa are continuous with those of the dorsal surface of the soft palate and of the pharynx, especially the dense network around the Eustachian orifice. From these situations the collecting trunks accompany those of the soft palate and the pharynx sending one trunk through the wall of the pharynx, to the large lymphatic gland instead of its true (or the position of the atlas; see Fig. 3300). This gland, according to Sappey, is the most constant lymphatic gland in the body, and becomes involved in diseases of both the nose and the pharynx. The upper trunk traverses the pharyngeal wall, and extends along [illegible] to the level of the [illegible] muscle [illegible] nerve, where it [illegible] the deep cervical glands covered by the sterno-mastoid muscle at this point. Not rarely, also, several [illegible] join the [illegible] trunks, which, having the posterior pillars of the fauces, end in the deep cervical glands by the thyrohyoid [illegible] (Plate XXVIII., III.). In the dog all the lymphatics from the nasal mucous are known to join and descend in reaching the deep cervical glands (3, 4, of Fig. 3300). Sappey figures and describes the exceedingly abundant lymphatics of the nasal mucosa in the [illegible] and [illegible]. In both these animals, but especially in the horse, the lymphatics of the mucous lining the nasal septum are very abundant, and in both animals, besides the trunks extending toward the pharynx, there are large trunks extending toward the nostrils, where they become subcutaneous, and extend with the facial vessels to the submaxillary lymphatic glands.

Lymphatics of the Eye and the Orbit.—The lymphatics of the conjunctiva extend around the edge of the eyelid, and join those of the integument as described above, and finally reach the parotid and submaxillary lymphatic glands. Sappey denies the presence of lymphatics in the eyeball itself; but most anatomists consider that, while the eye may not be supplied with numerous independently walled lymphatics, nevertheless it is abundantly supplied with lymph-passages, etc., many of which have no endothelial lining. The lymph-channels of the cornea, which are exceedingly abundant, following the nerves as well as the corneal corpuscles and their communicating processes, communicate with the conjunctival vessels, and also with the lymph-clefts of the sclerotic; the aqueous chamber also communicates indirectly with the conjunctival lymphatics through the cornea. In the [illegible] have been described distinct anastomosing lymphatic vessels by Altmann, and their presence has been lately confirmed by one of his pupils.

The retinal blood-vessels are well supplied with perivascular lymph-spaces like those of the central nervous system, and may be injected from the lymph-spaces of the optic nerve. Both chambers of the eye and the perichoroidal, and the space enclosed by the capsule of Tenon, and the lymph-spaces of the optic nerve, all communicate; and as shown above, the corneal spaces and the aqueous chamber through the cornea communicate on the one hand with the conjunctival lymphatics and on the other with the lymph-clefts in the sclerotic. In accordance with this complicated relation of the lymph-passages of the eye, the lymph-streams have been likewise found of equal complexity—passing from the vitreous to the papilla, and along the central canal of the optic nerve, with the blood-vessels, and ultimately reaching the cranial cavity. This has been shown to be the direction in the cat, dog, rabbit, and guinea-pig, and is supposed to be also the case in man. There is also a stream flowing from the subarachnoid and subdural spaces in the cranium, which follows the prolongations of these spaces around the optic nerve; these finally reach the eye and communicate with its various lymph-spaces, and through the perichoroidal space with the lymph-space in the capsule of Tenon, and presumably through this with the lymphatic vessels in the orbit. That is, there is a lymph-stream flowing from the eye to the cranial cavity, and another from the cranial cavity back to the eye through a different channel. If the assumption is correct, that the lymphatics of the eyeball communicate through the capsule of Tenon with the lymphatics of the structures in the orbit, their destination is to the lymphatic glands of the [illegible] group in the [illegible]. Toward the cranial cavity the lymph from the eye mingles with the lymph of the subarachnoid and subdural spaces to one point, with which these spaces communicate.

Lymphatics of the Ear.—The lymphatics of the membrana tympani are like the blood-vessels in three layers, corresponding to the cutis, the mucosa, and the intermediate fibrous framework. They extend to the external auditory meatus and, joining those, finally enter the parotid lymphatic glands, as described above for the external ear. Those of the tympanum or middle ear are numerous, but apparently confined mostly to the submucosa. They are directly continuous with the lymphatics of the Eustachian tube, and extend with them to the abundant network in the pharynx around the Eustachian orifice, and finally extend to the [illegible] cervical lymphatic glands. The lymphatics of the internal ear consist entirely of spaces which are in communication with the subarachnoid and subdural spaces through the perineural spaces of the auditory nerve, thus agreeing with the eye and nose.

Lymphatics of the Mouth, Pharynx, and Larynx.—The intimate relations of the lymphatic network in these regions, their connection with the nose, and through the nose with the cranial lymph-spaces, with the middle ear, [illegible] and trachea, and the varied terminations of the collecting trunks, give the lymphatics of this group an especial anatomical interest. They are not less important pathologically from their involvement in the grave disorders of the mouth, nose, and throat.

The lymphatic network of the buccal mucosa, gums, [illegible], and that of the mouth, palate, and pharynx, may be said to be continuous but the collecting trunks in different regions have quite different destinations. At the lips the network is also continuous with that of the integument, but the course of the lymph-stream is away from the lips. For the gums of the maxilla or upper jaw, the lymphatics extend between the teeth and join those of the mucosa of the cheek; these follow in general the contour of the jaw and penetrate the cheek at various points, extend in part to the parotid lymphatic glands, but mostly to the submaxillary glands. Near the pharynx they join the palatine lymphatics (Fig. 3307).

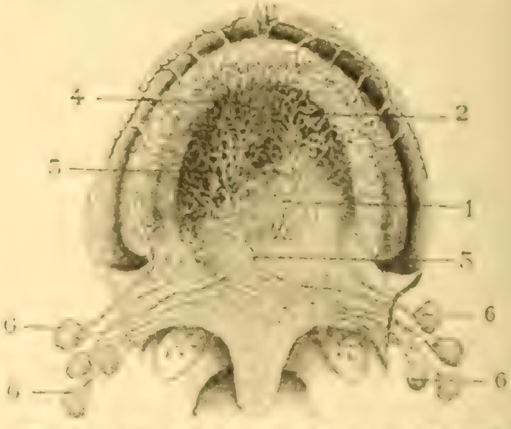

Fig. 3307.—Lymphatics of the Roof of the Mouth and the Gums in a [illegible] (Sappey, [illegible].) [illegible]

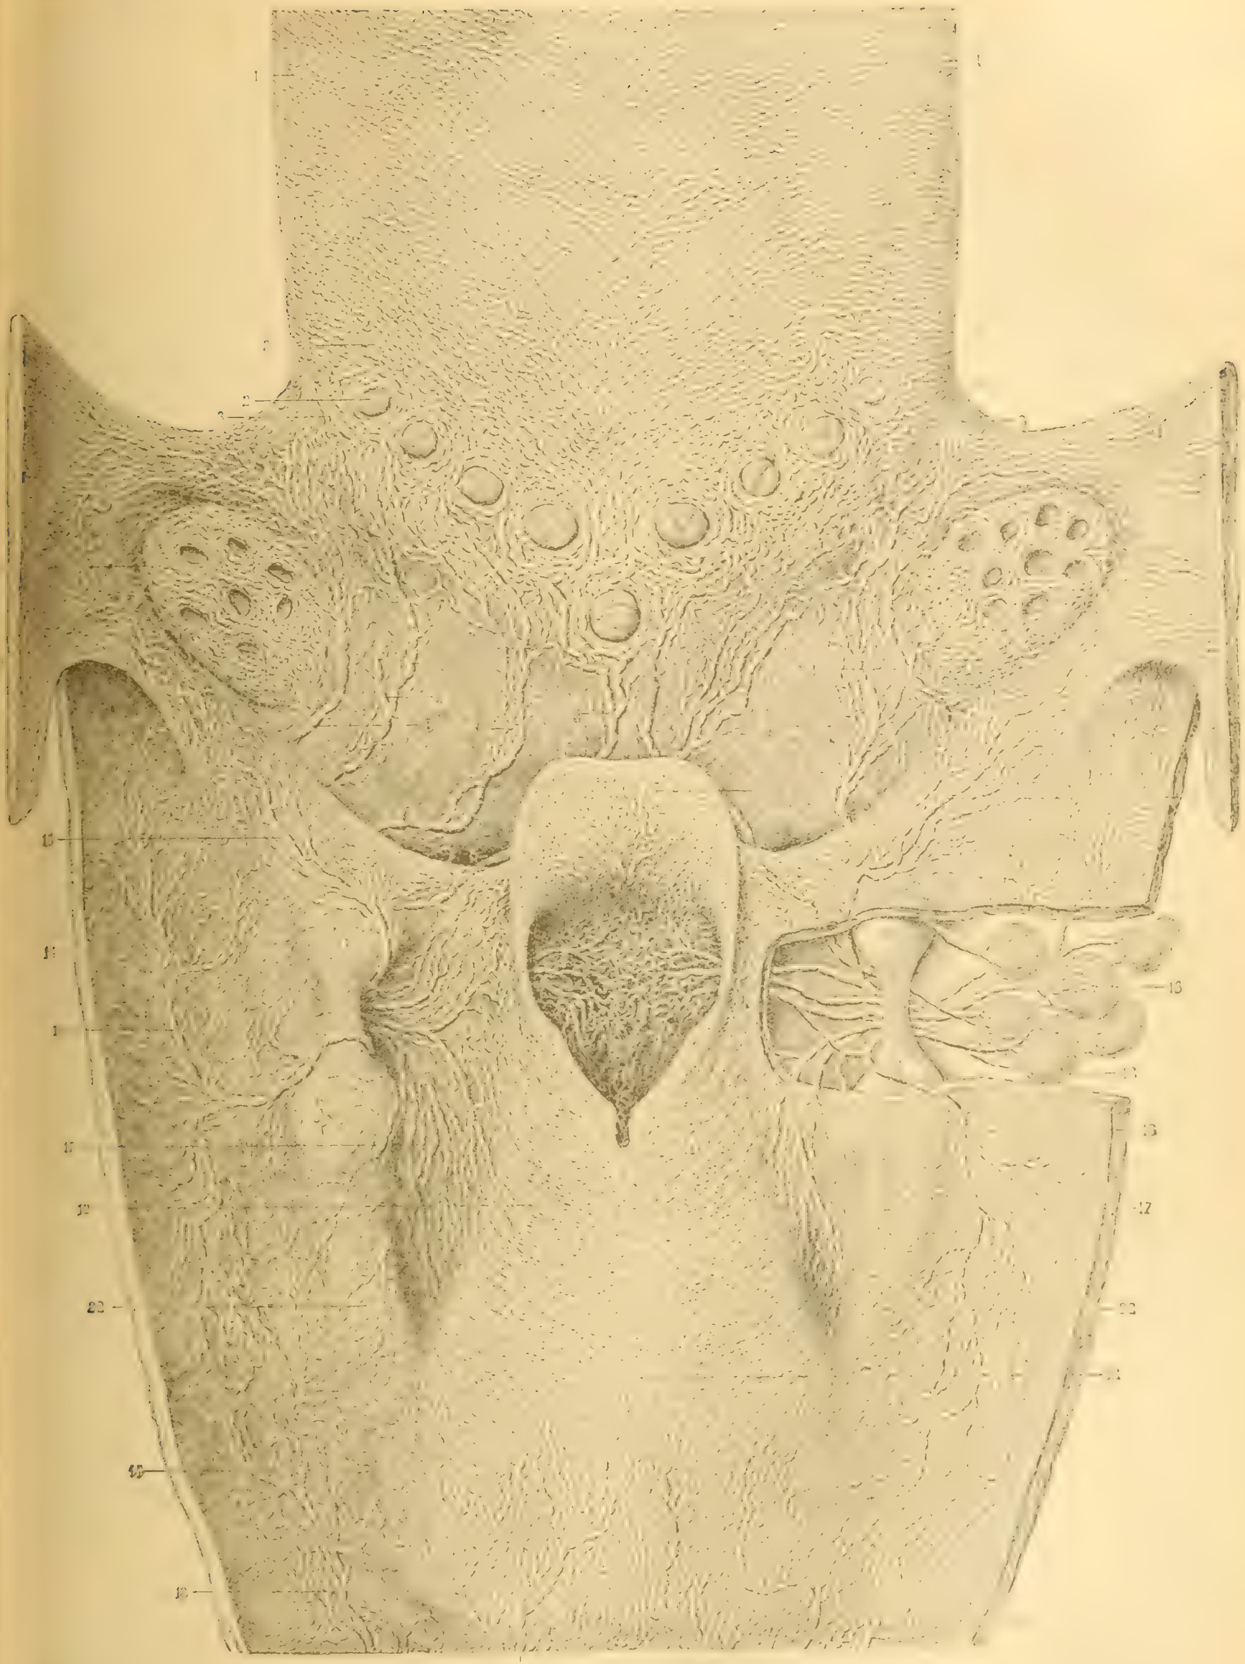
A large number of those from the gums of the mandible or lower jaw join the lymphatics of the cheek and extend to the submaxillary lymphatic glands. A part also join those of the pillars of the fauces.

The lymphatics of the hard and soft palate, while directly continuous with those of the gums, have a direction toward the pharynx, the trunks of the two sides often crossing. They join those of the pillars of the

EXPLANATION OF PLATE XXXIII.

WHICH REPRESENTS THE BASE OF THE TONGUE, THE TONSILS, THE PHARYNX, AND THE OPENING OF THE LARYNX OF MAN. THE PHARYNX WAS DIVIDED ON THE DORSAL SIDE, AND THE WALLS REFLECTED. (Sappey, "Atlas.")

1, 1, Lymphatic network on the dorsum of the tongue, the general direction of the vessels is obliquely toward the fauces (isthmus) and the base of the tongue; 2, 2, circumvallate papillæ in the form of a **V**; 3, 3, 3, 3, vessels surrounding these papillæ and soon converging to form mesal and lateral trunks; 4, 4, lymphatic trunks extending along the meson from the middle circumvallate papilla; 5, 5, continuation of 4, one on each side of the middle glosso-glottic fold; and finally penetrating the lateral fold, they enter the lymphatic glands (13) of the ental cervical plexus near the lateral thyro-hyoid ligament; 6, 6, other trunks farther from the meson, taking the same course; 7, 7, lateral trunks from the base of the tongue, tonsil, etc.; they penetrate the pharyngeal mucosa and terminate in the same group of glands, but cross the dorsal instead of the ventral surface of the great cornu of the hyoid; 8, 8, trunks coming from the anterior pillars of the fauces, skirting the edge of the tonsils, and finally entering the cephalic, ental (superior deep) cervical lymphatic glands; 9, 9, the tonsils covered by a dense network of lymphatics; 10, 10, 10, 10, the reflected sides of the arch of the palate (just below the "10" on each side is the divided uvula); 11, dense lymphatic network covering the epiglottis and extending upon the aryteno-epiglottic folds; 12, 12, a similar very dense and fine network of lymphatics upon the pharyngeal mucosa covering the larynx; 13, 13, several lymphatic glands belonging to the cephalic, ental (superior deep) cervical lymphatic glands, situated at the level of the thyro-hyoid ligament; as is evident from the plate, they receive the trunks from the base of the tongue, part of the palatine arch, the tonsils, the larynx and a great part of the pharynx; 14, lymphatics arising from the ventral and lateral part of the pharynx; 15, 15, lymphatics from the posterior pillars of the fauces, they wind round the ventral edge of the great cornu of the hyoid and enter the deep cervical glands at 13, 13; 16, 16, lymphatics arising from the dorsal and lateral aspect of the pharynx and extending to the cervical glands at 13, 13; 17, 17, lymphatic trunks on each side of the larynx to the ental cervical glands at 13, 13; 18, 18, lymphatics from the dorsal and lateral wall of the pharynx next the œsophagus; they extend toward the thorax and enter the chain of ental cervical glands along the trachea and œsophagus; 19, 19, lymphatics from the ventral part of the pharynx, and extending to the chain of ental cervical glands in company with 18; 20, summit of the great cornu of the hyoid exposed by the removal of the pharyngeal wall; 21, end of the major horn of the thyroid, connected with the hyoid by the thyro-hyoid ligament; 22, 22, dorsal border of the thyroid showing through the pharyngeal wall.



BASE OF THE TONGUE, THE TONSILS, PHARYNX, AND OPENING OF THE LARYNX OF MAN.

(SAPPEY, ATLAS.)

fauces, and go with them to the ental cervical glands near the larynx (Fig. 4975; Plate XXXIII.). Some also extend to the glands near the bifurcation of the common carotid with the trunks from the soft palate (Fig. 4975). The lymphatics of the soft palate on the pharyngeal or superior surface are only moderately developed, and communicate with those from the nose and from the Eustachian tube; the collecting trunks extend in part along the posterior pillar of the fauces to enter the glands along the larynx (Plate XXXIII., 13). But a greater number of collecting trunks pass laterad and penetrate the pharyngeal walls to enter the gland on the ventral aspect of the atlas. The ventral or lower face of the soft palate differs from the dorsal or upper face in having a greater number of lymphatic vessels, and the uvula is so richly supplied that it appears almost like erectile tissue, increasing two or three times in volume when successfully injected. The collecting trunks from the uvula and ventral aspect of the soft palate extend along the two pillars of the fauces, and join the trunks from the base of the tongue; but the greater number pass laterad through the wall of the pharynx and extend to the ental cervical lymphatic glands around the bifurcation of the common carotid.

The lymphatics of the tongue escaped discovery until 1847, when Sappey demonstrated them. They are difficult to demonstrate in the adult on account of the number and calibre of the veins, but in the infant and child the veins cause less trouble, and the lymphatics are easily injected. They form a rich network over the entire free surface to a point slightly beyond the circumvallate papillæ. Around the circumvallate papillæ they reach their greatest development. Up to the present no lymphatics have been demonstrated as arising in the substance of the tongue itself, the vessels traversing the tongue being collecting trunks from the mucosa. Around the edges of the tongue the network of the dorsal and ventral surfaces freely anastomose. But the main course of the collecting truncules is toward the middle, on the dorsal side, and toward the base. A few small trunks penetrate the tongue and after traversing the lingual glands, when those are present, extend to the ental cervical glands near the bifurcation of the common carotid. Most of the trunks, however, continue along the dorsum of the tongue, unite into large trunks beyond the circumvallate papillæ, and extend in a wide curve to the ental cervical lymphatic glands situated near the thyro-hyoid ligament (Plate XXXIII., 13). The lymphatics on the ventral side of the tongue extend mostly through the substance of the organ, traversing the lingual glands when present, and finally extend with those which penetrate from the dorsal side, to the lymphatic glands around the bifurcation of the common carotid.

The tonsils, although composed of lymphoid tissue, were not shown to possess a lymphatic network until Sappey succeeded in demonstrating it, in 1876. This network, which covers the surface and extends into the depths of the tissue, is much more easily injected in the new-born child than in the adult. The network anastomoses with that of all the surrounding structures, and the collecting trunks pass with those from the tongue and pillars of the fauces to the glands next the thyro-hyoid ligament (Plate XXXIII.). The lymphatics of the pharynx also resisted demonstration for a long time. They were found by Sappey to be directly continuous with those of the bordering structures, and while the trunks all communicate at their origin, there are three groups on each side: 1. A dorsal group extending along the dorsal or posterior wall of the pharynx nearly to the postnares, and then turning laterad and penetrating the pharyngeal wall, enters the gland on the ventral side of the atlas. 2. Several lateral trunks which extend along the side of the larynx and enter the lymphatic glands near the thyro-hyoid ligament. 3. Several ventral trunks extending mostly in a caudal (inferior) direction to join the supra-clavicular lymphatic glands along the œsophagus and trachea.

Larynx.—The lymphatics of the larynx form one of the densest networks known in the body. Commencing with the epiglottis and the entire opening, the number is almost infinite, the appearance being as if all the soft structures were composed of nothing but lymphatics. With the infant the abundance of lymphatics is continued without interruption along the trachea; but as age advances, the network in the larynx quite suddenly diminishes, so that, commencing with the vocal cords, the network in the larynx and trachea is comparatively slight. From the epiglottis, vestibule of the larynx, the sinus or ventricle, and the vocal cords, collecting trunks extend through the lateral wall of the vestibule, perforate the thyro-hyoid membrane, and terminate in the ental cervical glands beside the larynx (Pl. XXXIII., 13).

Lymphatics of the Central Nervous System.—The spaces and membranes of the brain and the myel are so directly continuous that a discussion of the lymphatics of both seems desirable. Sappey denies lymphatics to the entire nervous system, both central and peripheral, but this is not in accordance with most observers who have made special investigations upon the subject. It is true that independent vessels with definite walls are not found to exist in the nervous substance proper; but from the investigations of Kölliker, Virchow, Robin,[5] and Key and Retzius, it has been shown that, in the nervous substance of the brain and myel, the blood-vessels ramifying in it are possessed of a loose adventitia which is continued from the pia, the so-called pial funnels; and in the meshes of this adventitia are long spaces, like those around the blood-vessels of reptiles. It is supposed that these communicating spaces form the lymph-passages of the nervous substance. They may be injected for a considerable distance into the nervous substance from the subarachnoid space, and injections by the puncture method into the nervous matter not infrequently fill these passages, and extend into the subarachnoid space. After reviewing carefully all the evidence, Key and Retzius[2] consider the perivascular space of His—that is, a space entirely outside all the walls of the blood-vessel—as an artefact, as is also the presence of a subpial lymph-space into which it opens. From the stand-point of Key and Retzius, then, the nervous matter of the central nervous system is drained of its lymph through the adventitial lymph-spaces of its blood-vessels, and these spaces open into the subarachnoid space.

The lymphatics of the meninges are still in some doubt. In the dura there are wide-meshed, often ampulliform, vessels with endothelial walls that are supposed by some to be true lymphatics. Although their form is so strikingly like lymph-vessels, Key and Retzius found, on making the crucial test, that they communicate with the blood-vessels and do not extend to lymphatic glands. There are, however, in the dura a great number of elongated clefts which are probably lymph-clefts or channels. In the pia a very distinct and undoubted network of lymph-vessels has been described and figured. It is probably largely through these that the lymph of the subdural and subarachnoid spaces is drained away.

The subarachnoid space communicates directly with the neurocœle through the foramen of Magendie, and both the subarachnoid and subdural spaces of the optic, auditory, and olfactory nerves, and, in fact, all the nerves arising from the brain and myel, except that in the ordinary nerves the arachnoid as a special membrane soon disappears, and the subdural and subarachnoid spaces become one.

The ento-cranial lymphatics converge to form larger and larger trunks. Those from the vascular plexuses or telas accompany the *vena magna Galeni* to the base of the brain, where they are joined by the lymphatic trunks from the surface of the brain. The combined trunks follow the great blood-vessels out of the cranial cavity mostly through the jugular foramen, and enter the ental cervical lymphatic glands. Small trunks are described as traversing the spinous and oval foramina with the middle meningeal vessels, finally to enter the ental cervical glands in the spheno-maxillary fossa; but the existence of these lymphatic trunks is disputed.

As stated, the subarachnoid and subdural spaces of the brain are directly continuous with the corresponding sponse of the larynx and has been projected and with the … most completely with the optic, auditory, and olfactory, and in this way communication is gained with the lymphatics of the structures to which the nerves are distributed.

The exact relations of the intraspinal lymphatics do not seem to have been well worked out, but they are described as following the blood-vessels, and terminating in the glands in course of the blood-vessels which they follow. The lymphatics of the central nervous system are related to all great groups of glands in the neck and trunk.

Lymphatics of the Neck.—These are ectal and ental, and include the lymphatics of the structures of the neck proper and that of the lymphs from the head and face. The vessels from the integument extend mostly to the ectal cervical glands, but part of them reach the supraclavicular glands directly (see 10 of Fig. 4997).

LYMPHATIC GLANDS OF THE HEAD AND NECK.—These are very numerous and important. They are all continued

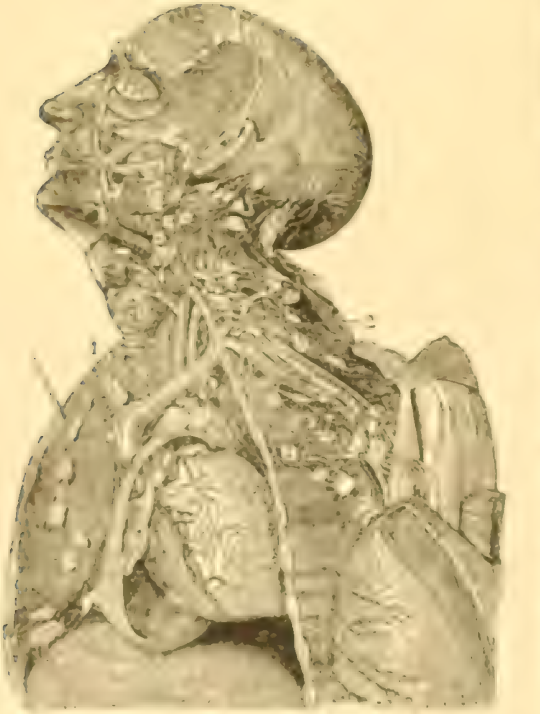


FIG. [illegible] [illegible]

to the sides of the face, around the base of the head, some having been found within the skull, and along the great cervical blood-vessels. They have been divided into two great paired groups or plexuses, the ectal or external, and the ental or internal jugular lymphatic plexuses, the ectal jugular plexus including all the ectal glands and finally emptying its lymph into the ental plexus, which includes all the ental cervical glands. This, while intercommunicating with the glands in the thorax and axilla, sends a main efferent trunk, forming commonly, to join the thoracic duct on the left, the common lymphatic trunk on the right; or it may reach the jugular veins, quite partly or wholly independently to the veins (8 and 9 of Fig. 4995). These plexuses form a kind of double and closely connected chain along the course of the great cervical vessels, and yet, for convenience of description and reference, they have been described as several groups; but here, as in other parts of the body of man, the groups merge so insensibly into each other that the same gland might be placed in one group by one anatomist and in the adjoining group by another. Furthermore, it should not be lost sight of that from a limited region lymphatics may go to quite widely separated groups of glands, and also that the number and size of the glands in a group are subject to considerable individual variation.

The ectal glands of the head and neck, i.e., the glands of the ectal or external jugular lymphatic plexus, are divided into the five following groups:

1. The occipital lymphatic glands (*glandulæ lymphaticæ occipitales s. suboccipitales*), one or two, usually small glands on the complexus muscle between the cranial attachment of the trapezius and the sternomastoideus. The afferent vessels are from the occipital, partly also from the temporal and parietal regions; the efferent vessels extend partly to the ectal cervical, and partly to the supraclavicular glands (Figs. 4994 and 4995).

2. Parotid lymphatic glands (*glandulæ lymphaticæ parotideæ s. auriculares anteriores s. faciales superficiales s. superficiales*). There are usually 10–12 of these on the surface and in the substance of the parotid salivary gland. The afferent vessels are from the temporal and frontal regions, the sides of the face, lateral part of the eyelids and conjunctiva, concha, tragus, [illegible] and external auditory meatus of the ear; from part of the mucosa of the cheeks and the gums of the maxilla or upper jaw. The efferent vessels pass to the submaxillary and ectal cervical lymphatic glands.

3. Mastoid lymphatic glands (*glandulæ lymphaticæ mastoideæ s. retroauriculares s. auriculares posteriores*). Several small glands on the cranial attachment of the sternomastoid muscle, near the mastoid process and base of the ear. The afferent vessels are from the parietal, temporal, and occipital regions in part, from the helix, antihelix, convex surface, and lobule of the ear. The efferent vessels extend to the ectal and ental cervical glands.

4. Submaxillary lymphatic glands (*glandulæ submaxillares*). There are several of these extending along almost the entire extent of the body of the mandible. In this group is included the glands on the buccinator muscle, sometimes described as a separate group (*glandulæ buccales s. buccinatorii*) and sometimes classed with the ectal glands. The submaxillary glands extending near the chin are also sometimes called submental, and a single one near the mesal has been named suprahyoid by Sappey. The afferent vessels of this group are from the middle of the forehead, the nasal portion of the eye, the integument of the nose and vestibule, and in the horse and ox also partly from the nasal fossæ; from the cheeks and lips, the gums of the mandible in part, and the floor of the mouth; part of the efferent vessels from the parotid lymphatic glands; the efferent vessels pass to the ental and ectal cervical glands.

5. Ectal cervical lymphatic glands (*glandulæ lymphaticæ cervicales ectales s. superficiales, s. jugulares externæ*). Several small glands along the ectal jugular vein, but extending on both sides of it. They are between the platysma and the sternomastoid muscle. The afferent vessels are from the ectal structures of the neck, part of the efferent vessels from the occipital, parotid, mastoid, and submaxillary groups; efferent vessels extend to the supraclavicular glands.

The ectal or external jugular lymphatic plexus in the larger herbivora—horse and ox—is approximately like that of man; but in the rabbit it is represented only by the submaxillary lymphatic glands and two small glands near the ear (3 and 4 of Fig. 4997). In the dog only the submaxillary lymphatic glands seem to belong to this plexus (3 of Figs. 4996 and 4998). In the cat the mastoid glands are large and may be injected from the inner or concave aspect of the external ear. It is possible that the small gland on the trunk following the external jugular vein, shown in Fig. 4998, may also belong to the ectal plexus. One cannot help being struck with the fewness of the glands in the dog, cat, and rabbit.

The ental glands of the head and neck, or the glands of the ental jugular plexus are situated on the course of the great vascular trunks and extend from the atlas to the thorax. The lymphatics of the entire head and neck ultimately traverse this plexus.

The glands of this plexus have been quite commonly divided into three great groups, with some minor groups —the deep facial, the superior and inferior deep cervical; but in actual descriptions of the lymphatics of the various organs the anatomists of the present day, although they recognize three groups, and some of them minor groups, actually divide all the glands of the ental jugular plexus into two groups, viz., those extending from the level of the base of the cranium, along the deep vessels, to the bifurcation of the common carotid, and those from the bifurcation of the carotid to the junction of the jugular and subclavian veins. This division was adopted in the previous description, and has been called (1) ental cervical, and (2) supraclavicular. (1) Ental cervical lymphatic glands (*glandulæ lymphaticæ cervicales entales, s. profundæ, s. glandulæ lymphaticæ jugulares cephalicæ*). The ental cervical, or jugular group of glands, includes all the ental glands around the deep structures from the bifurcation of the common carotid artery nearly to the base of the skull, and includes the glands on the internal maxillary vessels in the sphenomaxillary fossa, which are usually given a separate group under the name of deep facial or internal parotid, etc. It also includes the glands generally grouped as the superior jugular or superior deep cervical.

The glands in this group are numerous and quite widely separated from one another, extending from the ventral face of the atlas to the side of the larynx, being about as variously arranged as the organs of this region. The one between the atlas and pharynx is said to be the most cephalic of all the lymphatic glands of the body.

The afferent vessels of this group are from the orbit, nasal cavity, the cheeks, roof and floor of the mouth, in part from the tongue, pharynx, tonsils, tympanum, and Eustachian tube, the larynx, the thyroid, and the brain and its membranes. The efferent vessels pass to the supraclavicular glands.

(2) The supraclavicular glands (*glandulæ lymphaticæ supraclaviculares, s. cervicales profundæ inferiores, s. jugulares inferiores*). These glands are arranged along the carotid artery and internal jugular vein from the bifurcation of the common carotid to the junction of the subclavian and internal jugular veins. All the efferent trunks from the ectal jugular plexus and from the ental cervical glands enter this group, also many of the lymphatics of the pharynx, œsophagus, trachea, the lymphatics accompanying the vertebral artery and vein, also some of the ectal and ental lymphatics of the neck and the clavicular region. They also communicate with the anterior mediastinal and with the axillary glands. The efferent vessels form a single or multiple trunk (*truncus lymphaticus jugularis*) and terminate on the left in the thoracic duct, or on the right in the right common lymphatic trunk, or sometimes partly or wholly by an independent opening into the great veins (Figs. 4974 and 4994).

In the horse and ox the glands of the neck are approximately like those of man; but in the cat, dog, and rabbit there is but a single ental cervical lymphatic gland, and the jugular trunk is usually large and long, and not infrequently opens partly or wholly into the vein independently (Figs. 4993, 4994, 4996, and 4998).

Lymphatic Vessels of the Thoracic Limb (*Arm and Shoulder*).—The lymphatics of the arm and shoulder form an ectal and ental set, as in most parts of the body. The lymphatics of the hand arise by a complex net-work on the dorsal and palmar surface of the fingers, and extend toward each side of the finger, where they unite into two or three anastomosing trunks which follow the direction of the collateral arteries to the hand when they reach the dorsal surface. From the palm many vessels wind round both edges to the dorsal side also; but many next the wrist extend directly upon the ventral or flexor aspect of the arm and extend to the axillary region. The trunks on the dorsum of the hand and the extensor side of the entire arm gradually wind round to the flexor surface in their course to the axilla. Most of the vessels enter directly the axillary glands, but a few of those from the fourth and fifth fingers and the ulnar side of the anti-brachium traverse one or two glands (ectal brachial or supra-epitrochlear glands in the flexure of the elbow, Fig. 4978) before proceeding to the axillary glands. Frequently, if not constantly, one or more trunks follow the cephalic vein and go to the subclavian glands instead of going to the axilla, and not infrequently there is a gland in the course of these near the insertion of the deltoid, or even farther along (13 of Fig. 4978; see also Fig. 4980). The ectal lymphatics of the shoulder either join the trunk following the cephalic vein or extend round to the axilla. The ental lymphatics of the arm arise in the deep structures and follow the principal blood-vessels much more closely than do the ectal lymphatics. In the antibrachium there are, therefore, three groups following the radial, ulnar, and interosseous blood-vessels. There are occasionally a few small lymphatic glands in the antibrachium (antibrachial glands) through which a part of the vessels pass; but usually none are reached until in the flexure of the elbow, where, extending along the brachial vessels, there are regularly met three or four glands (ental or deep brachial glands), which most of the vessels traverse. Before reaching the axillary glands, according to most authors, there is a free anastomosis between the ectal and ental lymphatics at the wrist and elbow, but Sappey denies any such anastomosis.

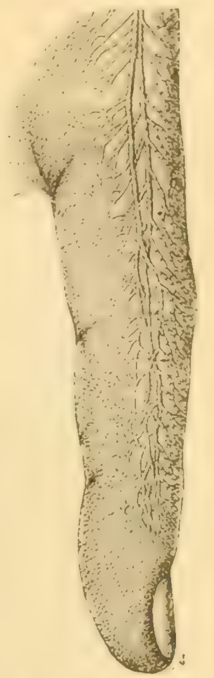

FIG. 4977.—Ectal Lymphatics of a Finger. (Sappey.) To show the extreme abundance of the lymphatics and the fineness of the net work on the end and the palmar aspect, also that the vessels from both the dorsal and ventral surfaces extend to the side where two or three considerable trunks, parallel with the collateral artery, convey the lymph toward the hand. By comparing Fig. 4978, it will be seen that these trunks always extend upon the dorsum of the hand.

According to the description of most veterinarians, the lymphatics of the arm and shoulder of the horse and ox are quite comparable with those of man both as to glands and vessels, except that there is a large lymphatic gland in the fold between the scapula and the neck—the prescapular gland. In the dog and cat the arrangement is exceedingly simple. All of the vessels, except a few cutaneous ones whose course is somewhat irregular, which can be injected from the pads of the manus (forepaw), finally extend upon the dorsum of the foot, and extend from there by two or more frequently anastomosing trunks along the radial nerve to the elbow, and then follow the cephalic vein to the prescapular gland, no axillary glands being present (Figs. 4992 and 4995). Occasionally, in the cat, one or more branches turn in the bend of the elbow to follow the brachial vessels to the axilla, and finally enter the nearest pectoral gland.

In the rabbit, vessels likewise follow the radial nerve to the elbow, then extend obliquely around the radial side of the brachium to the axillary glands. Other trunks follow the large blood-vessels, and enter the axillary glands. The lymphatic vessels of the arm, whatever their course, traverse but a single gland in the dog and cat, sometimes two glands in the rabbit.

LYMPHATIC GLANDS OF THE ARM AND SHOULDER. —Ectal brachial glands (*Glandulæ brachiales ectales, s. su-*

ulnarium, s. cubitales superficiales, s. supratrochleares; two glands often found in the course of part of the trunks from the fourth and fifth finger and the ulnar side of the arm. The gland in the course of the trunk following the cephalic vein has not been found.

The volar glands. There are sometimes a few in the antibrachium (*Glandulae lymphaticae antibrachiales*), through which traverse the volar antibrachial lymphatics on their way to the cubital brachial glands (*Glandulae lymphaticae brachiales cubitales s. profundae, s. cubitales profundae s.* [illegible]). These are just proximal of the elbow joint on the brachial vessels. Through these pass part of the volar lymphatics.

The axillary lymphatic glands (*Glandulae lymphaticae axillares*, Fig. 4980) are situated in the axillary region around the great vessels and nerves, are covered by the pectoral muscles and extending from the edge of the great pectoral into the subclavian fossa, where they are in communication with the supraclavicular glands. All the lymphatic vessels of the arm and most of those of the shoulder enter these glands; also many from the supra-umbilical part of the abdomen, side, and back; also the lymphatics of the mammary gland and the other structures of the breast, including the efferent vessels of the pectoral lymphatic glands. The efferent trunk (*truncus subclavius*) is one of the important tributaries of the common lymphatic trunks.

In the dog and cat no axillary glands are present, all the trunks going to the prescapular gland (*glandula praescapularis*) (Figs. 4992, 4996). In the rabbit all go to axillary glands [illegible] (Fig. 4997 and 4998).

Lymphatic Vessels of the Pelvic Limb.—The volar lymphatics of the foot, leg, and thigh are almost precisely like those of the hand and arm. The vessels of the toes and sole extend mostly to the dorsum of the foot and then wind round the leg to the inguinal region and enter the subcutaneous inguinal lymphatic glands (Figs. 4979 and 4980). A limited number of vessels from the heel and fibular side of the foot accompany the short saphenous vein to the popliteal space where they enter the popliteal glands and join the volar lymphatics.

The subaponeurotic or volar lymphatics also resemble those of the arm, following the main vascular trunks; hence in the crus there are three groups: one on the ex-

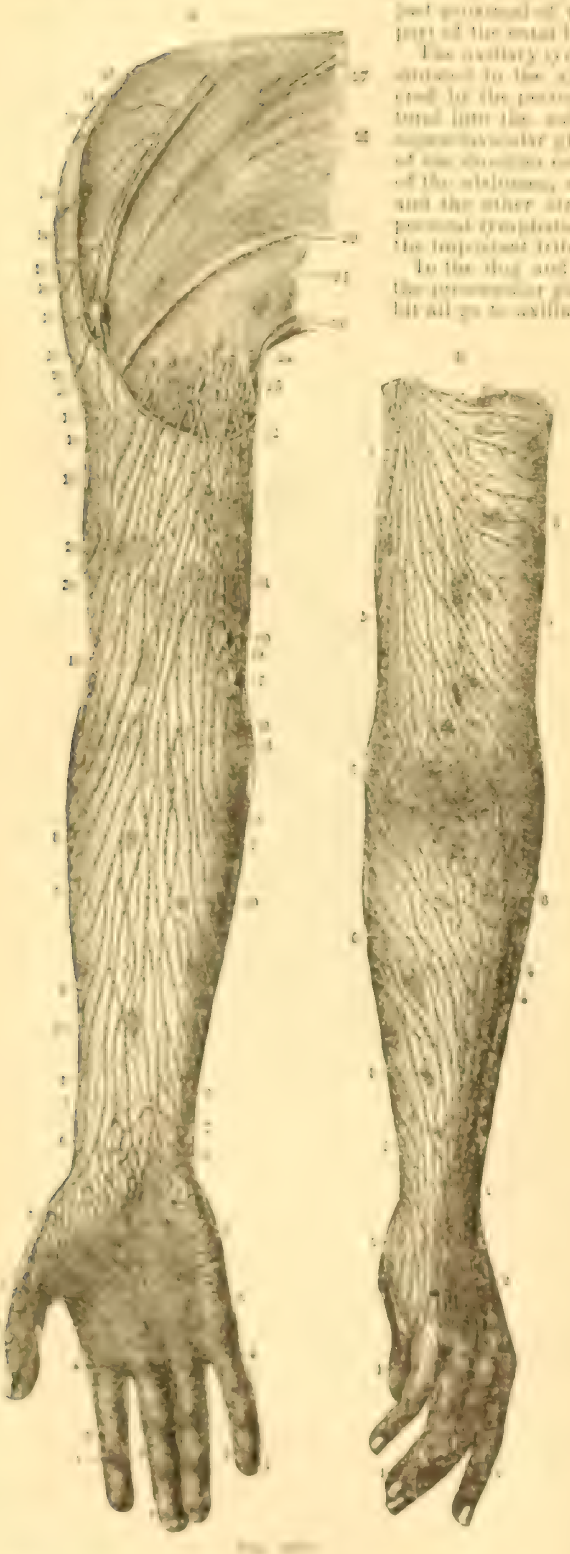

Fig. 4978.

FIG. 4978.—Volar Lymphatics of the Hand and Arm. [illegible]

tensor side of the crus following the anterior tibial vessels, and sometimes traversing one or two anterior tibial glands at about the middle of the crus. The lymphatics penetrate the interosseous ligament near the knee to enter the popliteal glands. The other two groups follow the peroneal and posterior tibial blood-vessels to the popliteal glands. After traversing the popliteal glands the lymphatics follow the femoral vessels to the inguinal region, where they enter the ental inguinal glands and after traversing these accompany the femoral vein and artery into the abdomen to the iliac glands. Besides these there are lymphatic trunks accompanying the sciatic and gluteal vessels, which traverse one or more small glands, gluteal and ischiadic glands, at the sacro-sciatic foramen and then enter the hypogastric glands. The trunk following the obturator artery constantly traverses, according to Cruveilhier, a considerable gland (*glandula foraminis obturatorii*) before entering the hypogastric glands.

In the dog, cat, and rabbit there is the same simplicity of the lymphatic trunks as pointed out for the arm. Injections into the pad of the pes (hind paw) demonstrate vessels on the dorsum and great-toe side of the foot. Part of these trunks follow the course of the long saphenous vein, others, usually larger trunks, wind round the calf, with the short saphenous vein, to the popliteal space and enter a popliteal gland (Figs. 4992, 22). In the rabbit, branches extend to the popliteal space from both sides of the crus (Fig. 4997). From the popliteal gland the main efferent vessels in all pass between the peroneal and tibial nerves, and accompany the femoral artery and vein, freely anastomosing with the trunk along the saphenous artery. No inguinal glands are present, and the vessels extend directly to the lumbar glands (Fig. 4980, 22 and 24).

LYMPHATIC GLANDS IN THE LEG.—The most distal gland is the tibialis anterior, situated on the interosseous ligament near the middle of the crus. Through it pass the ental trunks, following the anterior tibial vessels on their way to the popliteal glands. This gland is frequently absent. The popliteal glands (*Glandulæ popliteæ*, Fig. 4979) are in the fat in the popliteal space. Two are near the surface and receive the lymphatics accompanying the short saphenous vein. Their efferent trunks pass to the two more deeply situated glands around the popliteal blood-vessels ;

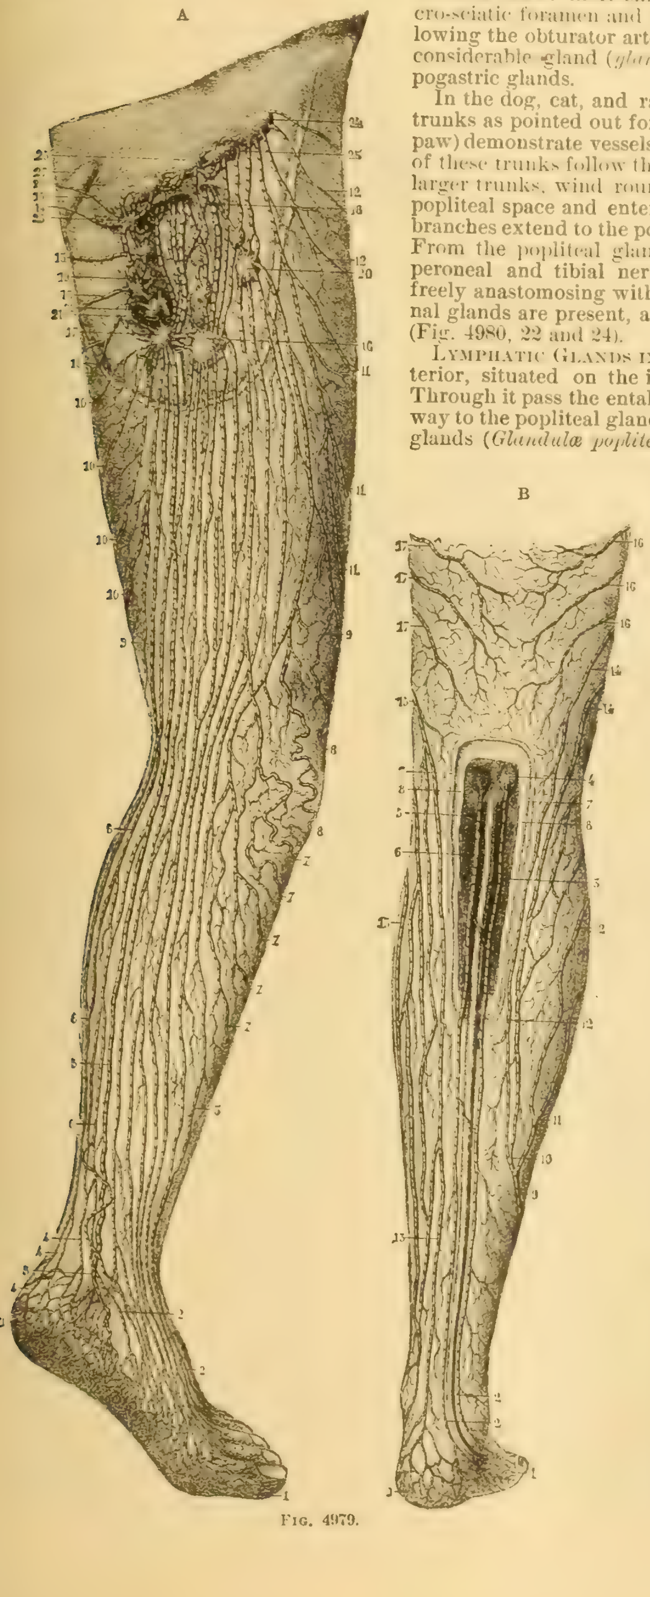

FIG. 4979.

FIG. 4979.—Ectal Lymphatics of the Foot and Leg, to show the Origin, Number, and Course of the Lymphatic Trunks, and the Popliteal and Inguinal Lymphatic Glands. The skin is represented as transparent, except where removed in the popliteal space and in the inguinal region. (Sappey, Atlas. A. The tibial side of the foot and entire leg. 1, 1, Truncules arising from the sole, great toe, and side of the foot ; 2, 2, trunks arising at the toes and extending across the dorsum of the foot to reach the tibial side of the leg ; 3, great trunk arising from the plantar aspect near the instep, and skirting the tibial or internal malleolus on its way to the inguinal region ; 4,4,4, trunks coming from the heel and extending along the ankle and leg ; 5, 5, and 6, 6, trunks extending along the crus parallel with the calf ; 7, 7, 7, 7, trunks winding round the edge of the tibia to reach the tibial or inside of the leg ; 8, 8, lymphatic trunks winding round the knee to reach the inside of the leg. They are very tortuous when the knee is extended, more nearly straight when it is flexed ; 9, 9, trunks curving round from the extensor side of the meros, or thigh, to reach the inguinal glands ; 10, 10, 10, 10, numerous trunks winding round from the flexor side of the thigh to the inguinal glands ; 11, 11, 11, trunks curving round from the extensor side of the thigh to the inguinal glands ; 12, 12, trunks from the gluteal region ; 13, 13, trunks from the perineal and anal region to the inguinal glands ; 14, trunks from the scrotum (cf. Fig. 4980) ; 15, trunk from the penis ; 16, the large distal ganglion of the ectal inguinal group, into which enter so many of the trunks of the leg ; 17, another large gland at the same level ; 18, large efferent trunk from 16 ; it follows the course of the femoral artery ; 19, lymphatic trunks following the course of the femoral vein ; 20, large gland receiving many of the trunks from the extensor sides of the thigh ; 21, gland receiving many of the trunks from the flexor side of the thigh ; 22, 22, cut end of the vena saphena magna ; 23, ganglion in the groin to which extend many of the lymphatics from the penis (cf. Fig. 4980) ; 24, large corner ganglion receiving most of the trunks winding round the ilium from the lumbar and gluteal region ; 25, 25, proximal row of glands in the fold of the groin to which extend many of the trunks from the ventral wall of the abdomen ; 27, inguinal ring with the contained spermatic cord.

B. Flexor Aspect of the Distal Half of the Leg. 1, 1. Trunks from the heel and fibular side of the foot ; 2, 2, two lymphatic trunks following the course of the vena saphena to the popliteal glands ; 3 and 5, the two lymphatic trunks, 3 on the fibular, 5 on the tibial side of the vein ; 6, vena saphena parva ; 7 and 8, cut edge of the skin, and aponeurosis removed to bring the popliteal glands into view ; 9, great trunk on the fibular side of the crus ; it follows the contour of the calf, and by its branches furnishes nearly all the trunks on the fibular or outside of the crus ; 10, 12, bifurcations and branches of 9 ; 13, 13, trunks on the tibial side of the crus. They curve round to the inner side of the leg, and extend to the inguinal glands ; 14 and 16, trunks on the fibular side of the thigh, which wind round to the extensor aspect, and then to the inguinal glands (cf. 11 in A) ; 15, large trunks on the tibial or inside of the knee, on its way from the heel, crus, and thigh, to the inguinal glands ; 16 and 17, trunks winding round the thigh in opposite directions to reach the inguinal glands.

through the deeper ones pass all the [illegible] and [illegible] part of those from the knee. The efferent vessels pass with the femoral blood-vessels to the inguinal glands.

Inguinal glands (Glandulæ lymphaticæ inguinales, Figs. 4979 and 4980).—There are two groups of these, the deep or subinguinal, and the superficial or inguinal.

The superficial inguinal glands, forming an irregular four-sided figure with the border along Poupart's ligament. The afferent vessels are the cutaneous lymphatics of the [illegible] limb, [illegible] part of the body and the external genitalia. The efferent vessels traverse the cribriform [illegible] and enter the deep or subinguinal glands; frequently a few trunks pass into the body cavity and join the iliac glands.

The subinguinal glands are situated along the femoral artery and vein in the [illegible]; they are usually three or four, although in number there may be six or seven. They are covered by the femoral fascia and are in intimate contact with the femoral vessels; one of them is found almost constantly in the [illegible] of the femoral or crural ring, which according to [illegible] it assists in closing. The afferent vessels of this group are derived from the deep lymphatics of the foot, leg and thigh (in part), the efferent trunks from the popliteal and most of those from the subinguinal glands.

A part of the efferent vessels traverse the abdominal wall with the femoral artery, but most of them accompany the femoral vein through the crural canal. They join the iliac glands, sending a few branches, however, to the hypogastric glands.

In the larger domestic animals (horse and ox) the glands of the leg are almost as numerous as in man, but with the cat, dog and rabbit they are represented only by the popliteal gland, the inguinal glands being absent, unless the gland on the external epigastric vessels may represent the subinguinal glands. As the iliac glands are also absent, vessels may pass from the foot (i.e., those accompanying the saphenous artery) directly to the lumbar glands (Figs. 4992, 4995, and 4997).

LYMPHATICS OF THE ABDOMEN AND EXTERNAL GENITALIA.—The cutaneous lymphatics of the abdomen have three quite sharply defined areas of origin, and from these the vessels extend in opposite directions. The areas are the [illegible], the ventral, and a somewhat irregular zone surrounding the body at the level of the umbilicus (Fig. 4980). The vessels cross these boundaries and intercommunicate in a complex manner; frequently a puncture made in the boundary will give rise to an injection in both directions, although injections made at either side would inject only the corresponding side. In the lower [illegible] especially

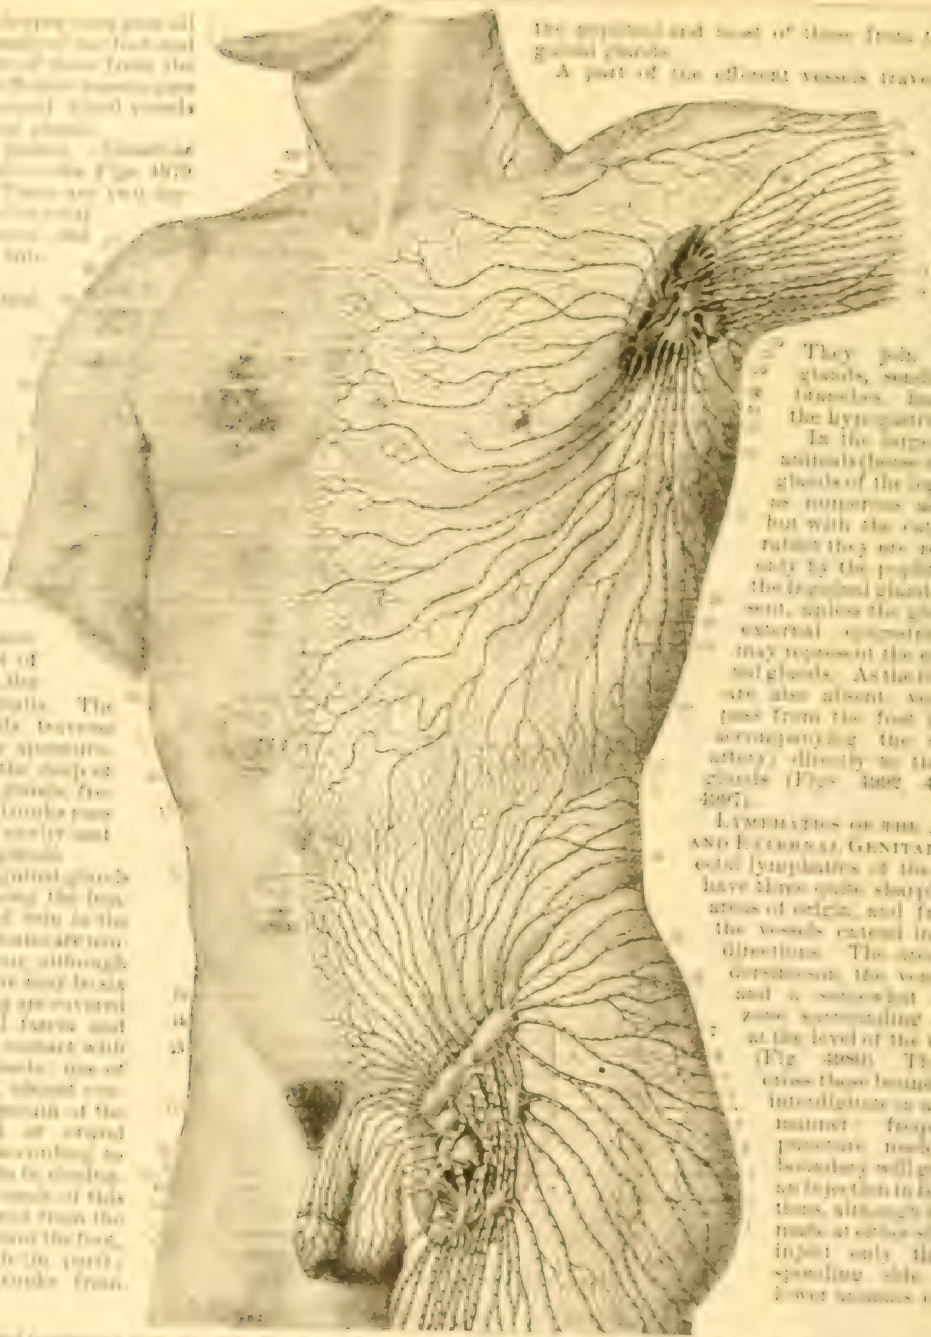

FIG. [illegible].—[illegible]

investigated for this—cat and opossum—the communication from side to side is more intimate, an injection of one side often filling that of the other. This is especially marked opposite the pubis of the opossum, where there is constantly a large transverse lymphatic, recalling the transverse vessels between the jugular veins.

As seen in Fig. 4980, the lymphatics of the subumbilical region of the body extend in the most direct manner on the abdomen to the inguinal or the axillary glands. Those from the lumbar and gluteal regions extend around in great curves, often following the crest of the ilium, to the lateral inguinal glands. Others from the gluteal region curve round the nates to the perineal and anal regions, finally to join the perineal and anal vessels and extend with them to the median glands of the ectal inguinal group.

The lymphatic net-work around the anal opening is very dense and is continuous with the lymphatics of the rectum. Those of the perineum are less dense. From both these regions the vessels wind round the thigh to the median or inner of the ectal inguinal glands. In the female the number of the trunks from the perineum is reduced apparently in direct proportion to the reduction in area of the region. The lymphatics of the external genitalia of the male are naturally divisible into those of the scrotum and the penis. The vessels of the scrotum are very numerous, perhaps more so than in any other equal area of integument in the body. As in the trunk, the meson—here indicated by the raphe—forms a natural dividing line for the two sides. The vessels extend in great curves, partly to the pubis and partly on the thigh, to enter the median row of ectal inguinal lymphatic glands; those on the thigh communicating with the vessels from the perineum, and those of the pubis with the cutaneous vessels of the penis. The vessels of the integument of the penis, commencing on both surfaces of the prepuce and from the line of the urethra, wind round the two sides to the so-called dorsum of the organ when they extend toward the pubis, and curve laterally toward the two sides to enter the large gland forming the corner of the ectal group (Fig. 4981). The lymphatics of the glans penis are exceedingly numerous, and in several superimposed layers of net-works. The collecting trunks converge toward the frænum preputii, where they are joined by the trunks from the urethra.

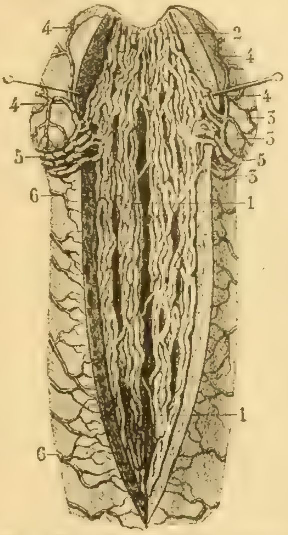

FIG. 4981.—Human Penis, opened Longitudinally to show the Urethral Lymphatics. (Sappey, Atlas.) 1, 1, The very abundant longitudinal net-work of vessels in the urethral mucosa; 2, continuity of the urethral lymphatics with those of the glans at the meatus urinarius; 3, 3, 3, trunks traversing the urethral wall opposite the frænum and joining those of the glans; 4, 4, 4, 4, trunks from the periphery of the glans joining those from the urethra; 5, 5, large trunks formed by the union of the urethral lymphatics and those from the glans, they penetrate the substance of the penis and follow the deep blood-vessels to the pubis, whence, according to Sappey, they extend to the inguinal, but, according to many authors, to the hypogastric lymphatic glands; 6, 6, lymphatics of the integument of the penis.

The urethral lymphatics begin at the prostate, anastomose with the prostatic lymphatics, with the net-work of the ejaculatory canals, and through them with the *vesiculæ seminales*. They extend to the *meatus urinarius*, forming a hollow cylindrical net-work of large, densely packed lymphatics (Fig. 4981), which reaches its greatest development opposite the fossa navicularis. Opposite the frænum two or three trunks penetrate the urethral wall and join the trunks from the glans, then penetrate the substance of the penis and reach the dorsal aspect of the *corpus spongiosum*, where the trunks of the two sides usually unite into one, which follows the course of the deep blood-vessels to the pubis, when it again divides, sending a branch to each side, finally to terminate in the large median gland of the ectal inguinal group (Fig. 4980). According to most authors the urethral and glandular lymphatics of the penis follow the internal pudic blood-vessels into the abdomen and enter the hypogastric glands. But Sappey is very definite, both in his atlas and anatomy, in stating that they enter the large gland, forming the corner of the ectal group.[1]

The external genitalia of the female very closely resemble those of the male in their arrangement and termination. The collecting trunks from the clitoris and the surrounding parts extend nearly directly to the pubis, where they curve to the right and left, and terminate in the large median gland, forming the corner of the ectal inguinal group, and, according to Krause,[6] they also communicate with the lymphatics of the round ligament of the uterus. The lymphatics of the female urethra are less abundant than in the male. The trunks from the urethra, meatus urinarius, labia, and the external or inferior fourth of the vagina extend laterally to reach the vulvo-crural fold, in which they wind around the thigh, with a few small trunks from the perineum to the median of the ectal inguinal glands, only a few reaching the large corner gland to which so many from the male genitalia extend.

The ental lymphatics of the abdominal wall and the lumbar part of the trunk follow the deep blood-vessels; part, therefore, extend to the sternal and axillary glands; part, with the deep epigastric vessels, to the iliac glands; part, with the lumbar and ileo-lumbar vessels, to the lumbar glands. Still others follow the circumflex iliac vessels, often traversing one or more glands along the crest of the ileum before finally entering the iliac glands.

With the dog, cat, and rabbit, the lymphatics of the abdominal wall, and the external genitalia are as in man, except that the tendency to form anastomoses across the meson is more marked, and that there is constantly present along the external epigastric vessels, about opposite the brim of the pelvis, a considerable gland. To this gland pass the ectal abdominal lymphatics, also part of those from the elongated mammary glands and from the external genitalia. There is another gland along the external epigastric blood-vessels about opposite the umbilicus, in the cat at least. After traversing these glands the efferent vessels either join or accompany the femoral lymphatics to the lumbar glands. In the cat they penetrate the abdominal wall with the epigastric artery, and extend, in part, to the hypogastric, and in part to the iliac glands (Fig. 4992, 22, 24). These glands may represent the ectal inguinal glands of man. In the rabbit there is also constantly present a gland on the ilio-lumbar vessels, next the abdominal wall, and along the edge of the sartorius muscle; the efferent vessels pass to the lumbar glands (see 22 of Fig. 4997).

LYMPHATICS OF THE PELVIC AND ABDOMINAL VISCERA.—*Internal genitals of the male—testicle, spermiduct, vesiculæ seminales*, and *prostate*.—Probably no organ in the masculine body is more richly supplied with lymphatics than the testicle. Those of the albuginea are sometimes described as the ectal lymphatics of the testis.

They are only moderately numerous, and extend upon the spermiduct to join those from the testicle proper. Those of the testicle proper follow the seminal tubules to the epididymis, and joining those of the epididymis extend with the spermatic cord through the inguinal canal. After reaching the body cavity they follow the blood-vessels, and finally terminate in the lumbar glands near the end of the spermatic vein.

The lymphatics of the testis of a mature animal are exceedingly easy to inject by the puncture method, and the collecting trunks accompanying the spermatic vein are so prominent, straight, and well supplied with valves that they are among the most striking of the lymphatic trunks in the body.

The lymphatics of the spermiduct are abundant at the

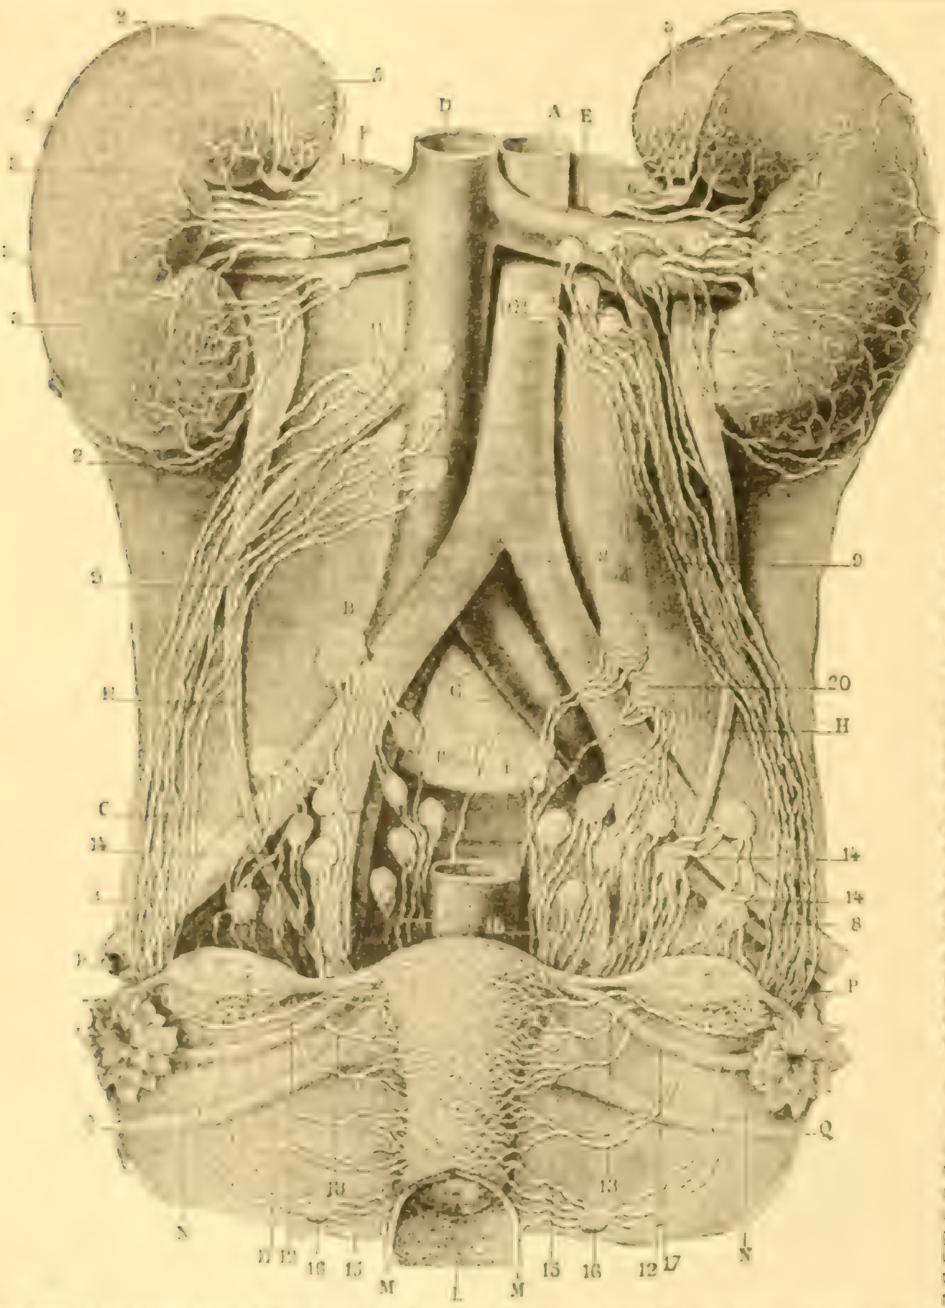

FIG. [illegible].—Lymphatics of the Kidneys, Adrenals, and Internal Genitalia [illegible]

[illegible]

ends, but very few along the middle part. Those from the one half follow the lymphatics of the testis, while those from the other half join the lymphatics of the vesiculæ seminales. The lymphatics of vesiculæ seminales form a plexus which was first described by Henle; they unite into two principal trunks. These meet the spermiduct with the lymphatics of the latter, and together they enter one of the iliac glands. The other trunk passes between the prostate and vesiculæ seminales, so as to join an iliac gland. The lymphatics of the prostate were discovered and described by Sappey in 1854 who found them abundant, and with two collecting trunks on each side. One of the trunks passes quite directly to one of the hypogastric glands, while the other extends upon the walls of the urocyst or urinary bladder, and then curves to the side to enter a hypogastric gland. The trunks extending upon the urocyst were mistaken by Mascagni and Cruikshank for the lymphatics from the bladder itself.

Internal Female Genitalia.—Vagina, Uterus, Fallopian Tubes, and Ovaries.—As described above, the external or inferior fourth of the vagina sends its lymphatics to the [illegible] inguinal glands; from the remaining three-fourths the collecting trunks extend toward the uterus, penetrate the wall of the vagina, and traverse the utero-vaginal lymphatic gland on the way to the hypogastric glands. Up to the present no lymphatics have been demonstrated in the muscular wall of the vagina in the human being, but their presence has been shown in that of the large domestic animals.

The uterine lymphatics are naturally divided into those of the mucosa and those of the muscularis. Those of the mucosa are difficult or impossible to demonstrate in a gravid uterus, and often so in a non-gravid adult uterus, and Sappey states that he never succeeded in demonstrating them in the uterine mucosa of any of the lower animals. It is only in girls before puberty that these lymphatics are demonstrable by the ordinary methods. No doubt they exist in the adult woman, and also in the uterine mucosa of the lower animals, but they have not been satisfactorily demonstrated. When demonstrated in a child they showed a delicate net-work whose collecting trunks traverse the walls of the neck of the uterus and enter the utero-vaginal lymphatic glands (15 and 16, of Fig. 4982). At the os uteri they are continuous with those on the vaginal part of the uterus and the vaginal mucosa.

The lymphatics of the uterine walls are numerous and easily demonstrated in most animals. The collecting trunks extend laterally in the broad ligament on each side to three different groups of glands; those from the summit follow the Fallopian tubes out to the ovary, where they join the ovarian net-work, and accompany the collecting trunks of the ovary to the lumbar glands around the termination of the ovarian veins (Fig. 4982). Those from the body of the organ extend across the broad ligament, curve round the Fallopian tubes, and enter the iliac glands; while those from the cervical region extend with those from the utero-vaginal glands to the hypogastric plexus.

Lymphatics have been demonstrated only on the uterine and ovarian ends of the Fallopian tubes. But it is probable that they are present throughout the whole extent. The collecting trunks accompany the ovarian lymphatics.

The lymphatics of the ovary, like those of the testis, are in prodigious numbers, and are very easily injected. The collecting trunks are very long and straight, and accompany the ovarian vein, and consequently those on the left are opposite the hilus of the kidney (Fig. 4982).

In the lower animals, so far as has been investigated, the lymphatics of the internal genitalia agree in all essential particulars with those of the human being. In the dog, cat, and rabbit, while the ovarian and testicular lymphatics follow the same general course, they almost always enter the lumbar glands, and therefore do not follow the spermatic or ovarian veins to their termination (Fig. 4992). Occasionally one or more branches extend nearly opposite the renal blood-vessels and appear to enter the chylocyst without having traversed any gland. In nearly every case, however, a gland, often exceedingly minute, can be detected in the course of the vessel before its entrance into the chylocyst.

Urinary Organs and Adrenal.—Up to the present time all efforts to demonstrate lymphatics in the mucosa of the urocyst or urinary bladder have failed both with men and with animals, but the muscular coat has been shown to be plentifully supplied. The vessels form a wide-meshed net-work at the summit and on the body. This net-work unites into one or more trunks on each side, and the trunks extend nearly or quite to the neck when they turn aside and enter the hypogastric lymphatic glands. The trunks described by Cruikshank and Mascagni as urocystic lymphatics were really from the prostate. Sappey succeeded only once in injecting them in man, but almost constantly in the dog and rabbit.

The muscularis of the ureters has been shown to possess lymphatics in the horse, but all attempts to demonstrate them in the mucosa has failed. Although not demonstrated in man they are presumably present.

The lymphatics of the kidney form an ectal net-work over the surface and an ental net-work in the substance of the organ. The trunks were first seen in 1532 by Massa, but first described carefully by Nuck in 1590. Those of the surface form a wide-meshed net-work, the collecting-trunks of which extend in part directly toward the hilus of the kidney and join the ental lymphatics, and part extend toward the convex border and then wind round the ends to the hilus. Next the adrenal the lymphatics of the two organs are closely connected. The ental lymphatics follow the blood-vessels and terminate in a group of the lumbar glands situated on the renal vessels.

Although the blood-vessels of the adrenal have been long known the lymphatics were not so early discovered. It is now known that the lymphatics are as abundant as the blood-vessels, extending throughout the substance as well as upon the surface. The collecting trunks, many of them join those of the kidney, and all extend to a gland near the junction of the adrenal and mesal or hilic aspect of the kidney (5, 6, of Fig. 4982).

Lymphatics of the Intestine and Stomach.—Throughout the entire alimentary canal, it has been shown that where a distinct muscular coat exists the lymphatics form two layers or sets, one in the mucosa, including the submucosa, and one in the muscularis. In those parts supported by duplicatures of serosa (mesenteries) the finer net-work of the mucosa proper extends to a coarse and characteristic net-work in the submucosa (Fig. 5009), and finally the collecting trunks penetrate the wall at the attached edge and join the lymphatics of the muscularis. The lymphatics of the muscularis are throughout its entire thickness, but soon become subserous and wind round to the attached edge, and with those from the mucosa extend between the layers of the supporting membrane mostly in company with blood-vessels to lymphatic glands, which are also situated between the serosal walls (Fig. 4983, 19, 22, 24).

The intestinal lymphatics at the anus are directly continuous with those of the skin. The trunks from the muscularis and mucosa of the rectum extend between the folds of the mesorectum, often traversing minute glands in their course, and then enter the sacral lymphatic glands and ultimately go to the lumbar glands on their way to the chylocyst. The lymphatics of the main part of the *colon descendens* pass to the lumbar lymphatic plexus. Those of the *cæcum, colon ascendens et transversum*, also part of the *colon descendens* pass through one or more of the numerous mesocolic glands and then enter the mesenteric glands and mingle with the lacteals from the small intestine, and with these go through the *truncus intestinalis* to the chylocyst.

Lacteals.—The lymphatics of the small intestine are usually called lacteals or chyle vessels, from the fact that during digestion they have a cloudy or milky appearance owing to the contained chyle.

As the small intestine has two planes of lymphatics like the rest of the alimentary canal, it is really only those of the mucosa which absorb and convey the chyle, and which, therefore, should properly be denominated lacteals, as those from the muscularis always convey lymph only. A further and finer distinction still has been made by Sappey,[1] who holds that the vessels of the intestinal villi are the only ones which absorb the chyle, and they do nothing else, so that they alone are the true lacteals, and that the other lymph-vessels of the mucosa and submucosa, including those from the Peyerian patches and other lymphoid tissue, should be considered simply as lymphatics, as they take no part in the absorption of the chyle. The submucosal net-work simply receives the chyle poured into it by the lacteals of the villi. As stated above, this is not the common view. It is ordinarily believed that the lacteals contain lymph like other lymphatics, except during digestion. It is also common to call all the vessels from the small intestine lacteal vessels, without regard to their origin from the muscularis or the mucosa. Whatever the origin, all the vessels unite at the attached border and extend to the nearest gland, where their contents are mixed, so that usually all the collecting trunks in the mesentery appear milky and are called lacteals or chyle-vessels, although some of them might really have come from the large intestine. In man there are usually several tiers of mesenteric glands through which the chyle passes before finally emptying into the large trunk along the superior mesenteric artery. This trunk, which also receives the efferent vessels of the cœliac and mesocolic glands (*truncus lymphaticus intestinalis*), is either single or multiple, and found one of the most important constituents of the [illegible] (Fig. [illegible]).

Stomach.—The lymphatics of the stomach are continuous with those of the œsophagus and duodenum. Those of the mucosa form a most beautiful net-work throughout the entire thickness of the coat; the collecting trunks penetrate the tunics and become subserous, and form an intermediate stratum, with trunks extending to the [illegible] of the chain of lymphatic glands, extending almost around both curvatures; those in the lesser curvature being known as the *glandulæ lymphaticæ gastro-epiploicæ superiores*, and those around the great curvature as the *glandulæ lymphaticæ gastro-epiploicæ inferiores* (Plate XXXIX.). The lymphatics of the gastric mucosa form a remarkable net-work throughout the entire thickness of the coat, being very fine in the mucosa propria and coarser in the submucosa. The collecting vessels penetrate the muscularis along the curvatures, like those of the muscularis, extend to the same glands, and finally to the intestinal lymphatic trunk.

Pancreas.—The lymphatics of this organ are difficult to demonstrate, but when well injected are found to form a fine net-work around the acini (alveoli), and the collecting trunks emerge quite directly to the surface, and form upon the surface a round-meshed, rather coarse net-work, around the lobules. From this net-work trunks extend in three directions—part of them go to the tail or splenic end of the pancreas to join the glands at the hilus of the spleen, part to the [illegible] edge of the pancreas to enter some of the numerous glands along the course of the splenic vessels, and still others extend toward the duodenum to enter a large gland which also receives part of the lymphatics of the duodenum. The lymph finally reaches the intestinal trunk after traversing one or more of the cœliac glands. No lymphatics have yet been demonstrated in the pancreatic ducts.

Spleen.—The lymphatics of the spleen are in enormous numbers. Their origin seems to be from the lymph-follicles so abundant throughout the organ. According to Sappey, the usual division of the lymphatics into a superficial and deep set does not hold good here, where the vessels on the surface quickly enter the substance of the organ and accompany the ental blood-vessels. With the horse, ox, and pig, however, there is a true outer net-work extending over the entire surface. The collecting trunks pass to the hilum of the organ and terminate in the numerous glands there situated. The efferent trunks from these glands pass to the cœliac glands and the intestinal lymphatic trunk, or some may enter the cisterna chyli directly.

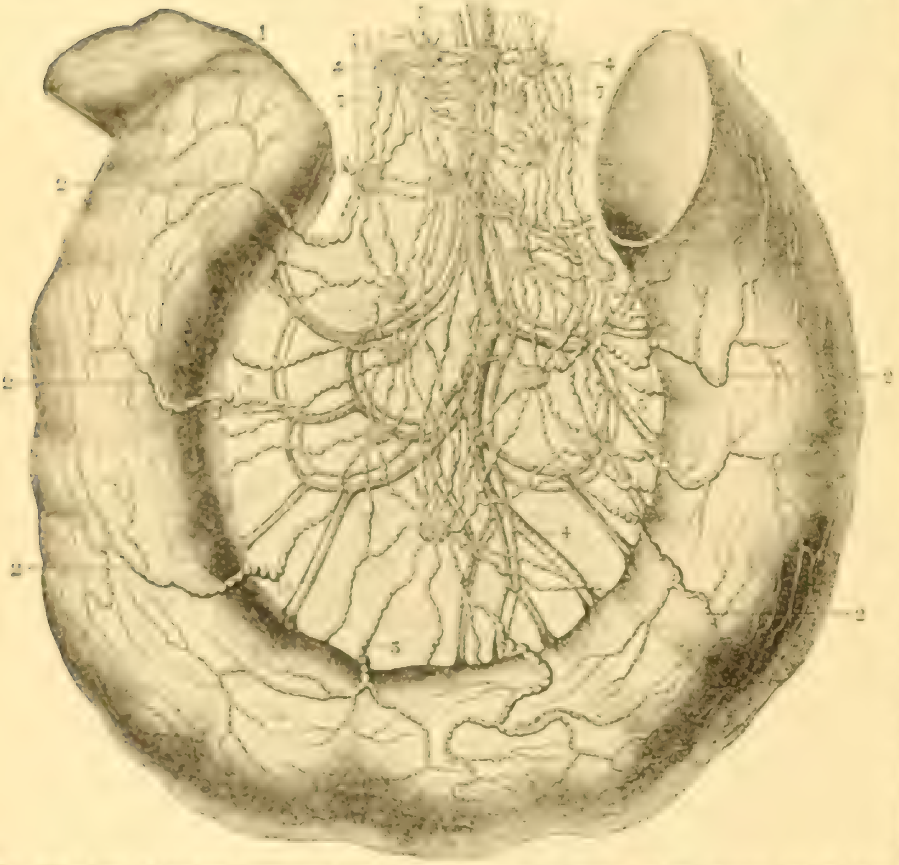

FIG. 4985.—Loop of the Small Intestine of Man, to show the Mesenteric Glands and Blood-vessels and the Lymphatics. [illegible] 1, 1, Two ends of the loop of intestine; 2, 2, 2, 2, 2, lymphatic vessels [illegible]; 3, [illegible]; 4, 4, 4, mesenteric glands [illegible]; [illegible]

Liver.—The lymphatics of the liver were very early seen, and the efferent trunks from the hilus were, for a long time, supposed to be the continuation of the lacteals to the liver. It has been found that the lymphatic system of the liver is quite as remarkable as the blood-supply. In general there are both ectal and ental lymphatic vessels, and the ducts and gall-bladder possess a rich supply. The collecting trunks form three great groups and take three main courses, following the portal vessels to the hilus, the hepatic vessels to the postcava, and the suspensory ligament to the diaphragm.

The ectal or superficial lymphatics of the convex surface extend in four directions according to their position. Most of those near the caudal or inferior border, penetrate the surface and join the ental lymphatics. In the right cephalic (superior) part, they wind round the border and join the glands at the head of the pancreas, or extend to the glands around the postcava as it enters the thorax. On both sides of the suspensory ligament the trunks collect in great numbers, and extend between the folds of the suspensory ligament to the diaphragm, which they penetrate, and enter two or three glands whose efferents join the sternal plexus (14 of Fig. 4986 and 10 of Fig. 4987). Still further to the left, a group pass round to the postcava as it enters the thorax; on the right, still others penetrate the triangular ligament and enter the glands around the œsophagus. Many of the apparently superficial lymphatics of this lobe penetrate the substance of the liver and join the ental lymphatics as with the right lobe. In fact, in most animals this is the normal condition, and a true ectal set of lymphatics is not present.

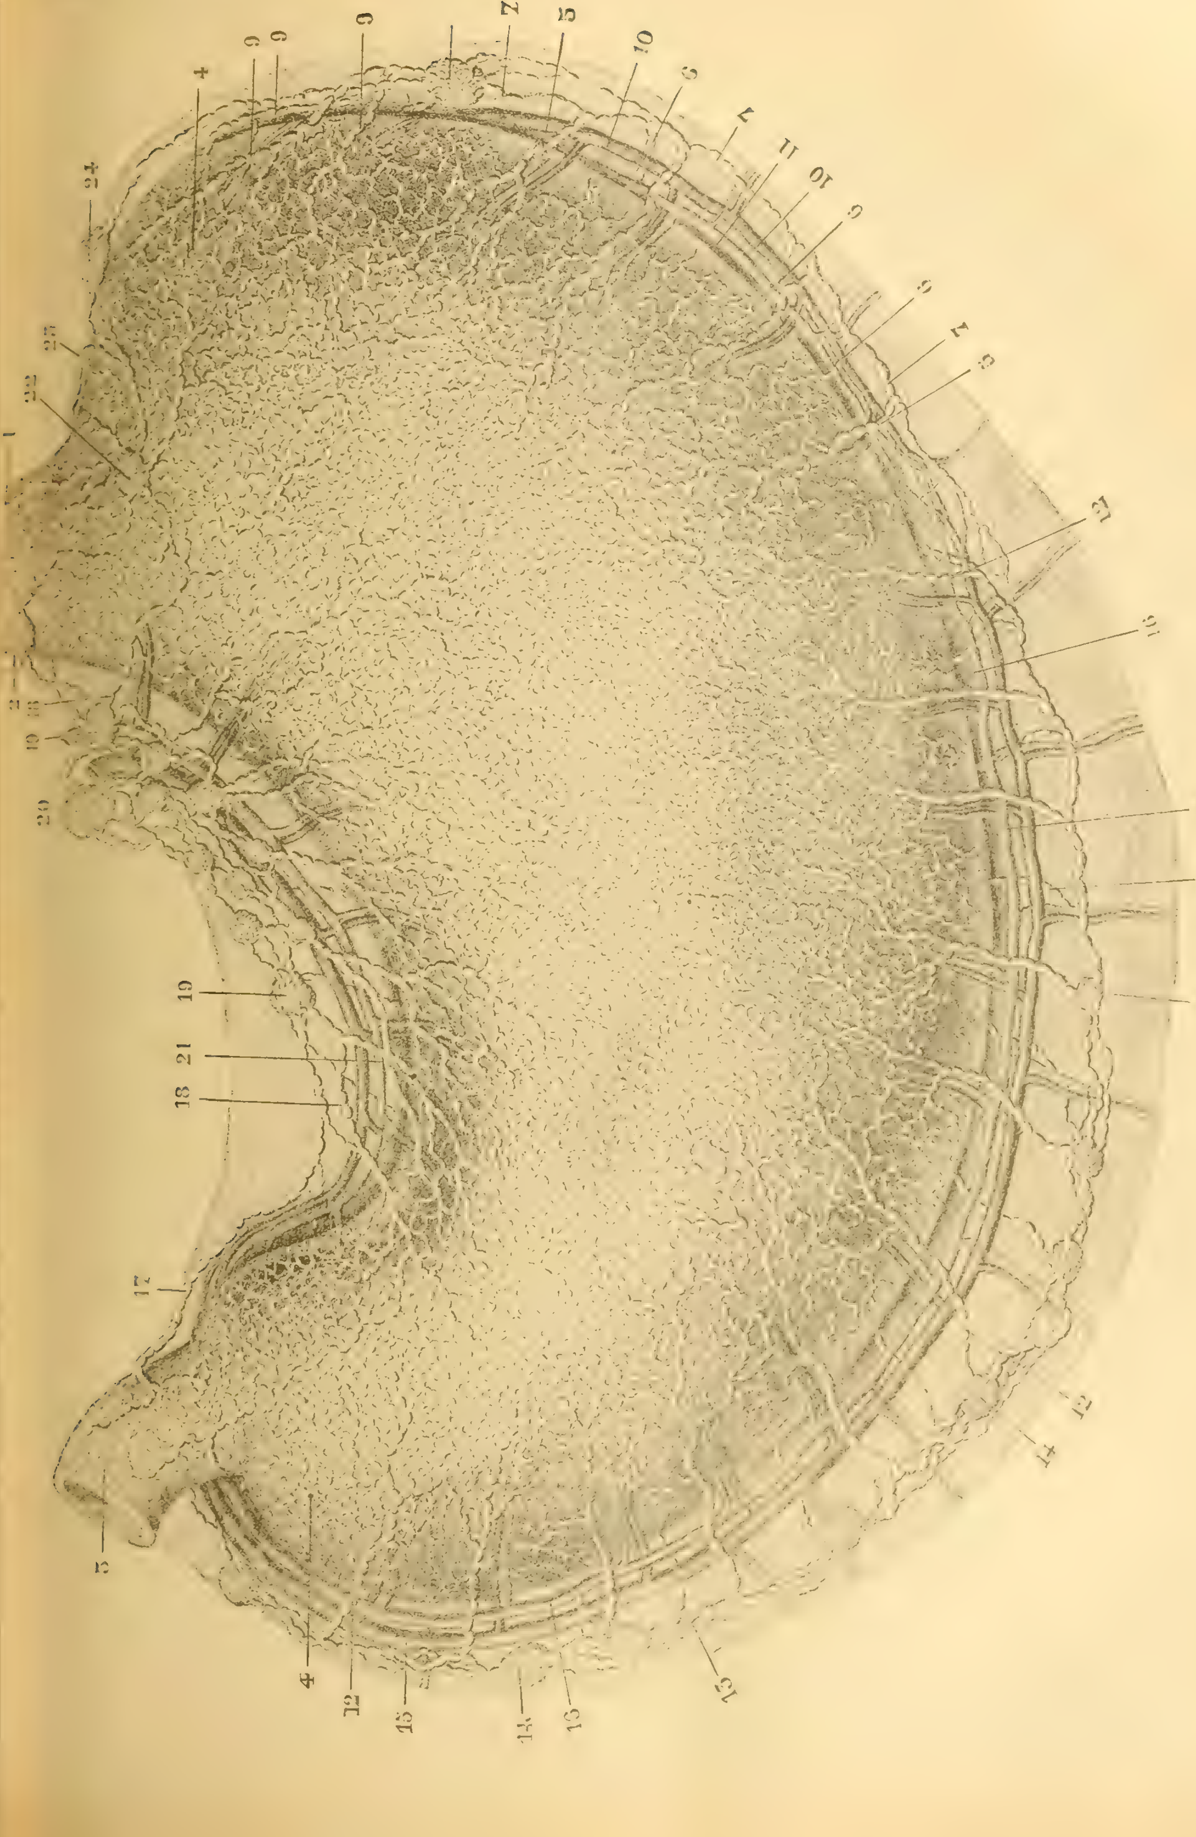
On the concave surface of the liver, many of the surface lymphatics penetrate the liver substance and join the ental lymphatics, but the greater number join the glands in the hilus and then mingle with the ental lymphatics (Fig. 4988). The ental or deep lymphatics, according

EXPLANATION OF PLATE XXXIV.

WHICH REPRESENTS THE LYMPHATICS OF THE HUMAN STOMACH. (SAPPEY, ATLAS.)

1, Gastric end of the oesophagus; 2, lymphatic gland receiving part of the oesophageal lymphatics; its efferent vessels extend to the glands around the coronary blood vessels and there join those from the stomach; 4, 4, fine net-work of vessels in the muscularis of the stomach; 3, the beginning of the duodenum; 4, 4, fine net-work of lymphatic vessels in the muscularis; from this fine net-work arise all the collecting trunks of the muscular coat; 5, 5, 5, lymphatic trunks on the left part of the great curvature; 5.5, 6.6, lymphatic vessels from the dorsal and ventral surfaces of the left third of the great curvature; 7, 7, 7, the principal trunk encircling the left half of the great curvature of the stomach; it receives the branches from the stomach and extends toward the left to enter a large gland (8) situated near the tail of the pancreas and the hilus of the spleen; 8, gland at the left of the stomach near the hilus of the spleen; it receives trunks from both directions, also some from the spleen; 9, trunks from the extreme left of the stomach to the gland marked 8; 10, vena gastro-epiploica sinistra; 11, arteria gastro-epiploica sinistra; 12 and 13, trunks from the dorsal and ventral aspect of the pyloric region; 14, 14, 14, the chain of glands on the right along the great curvature; through these pass all the lymphatics from the half next the greater curvature. The efferent trunks from these glands finally extend to the glands at the head of the pancreas; all the glands in the chain around the great curvature are sometimes designated as the *glandulæ lymphaticæ gastro-epiploicæ inferiores*. They lie in the great omentum and form part of the cœliac lymphatic plexus; 15, 16, vasa gastro-epiploica dextra; 17, trunk from the duodenum and the pylorus to the glands along the lesser curvature; 18, 18, trunks extending to the lesser curvature; 19, 19, the lymphatic glands along the gastric coronary vessels in the lesser curvature (*glandulæ lymphaticæ gastro-epiploicæ superiores*); they receive all the so-called ascending trunks from the stomach and some of the trunks from the oesophagus; they form part of the cœliac lymphatic plexus; 20, the large cœliac gland to which the efferent vessels from 19 extend; 21, vasa coronaria gastrica; 22, gland, often double, on the ventral aspect of the cardia; 23, large trunk winding round the cardia and joining the trunk to 22 and 24; 24, gland, sometimes visible, at the extreme left of the great curvature.

PLATE XXXIV.



LYMPHATICS OF THE HUMAN STOMACH.

SAPPEY ATLAS

to Sappey, are divided into two distinct, although anastomosing sets, one set following the portal vessels and bile-ducts, the other the hepatic vessels. Those following the hepatic vessels enter the thorax, traversing some glands on the postcava, and mingling with the ectal lymphatics, follow the pillars of the diaphragm to join the thoracic duct. The lymphatics following the portal veins reach the hilus of the liver, and traverse one or more of the glands there situated (Fig. 4984). From these glands in the hilus, branches extend to the glands in the lesser curvature of the stomach, and to those on the splenic vessels; but finally all pass to the cœliac glands, and then some branches may enter the chylocyst independently, but most of them join the intestinal trunk.

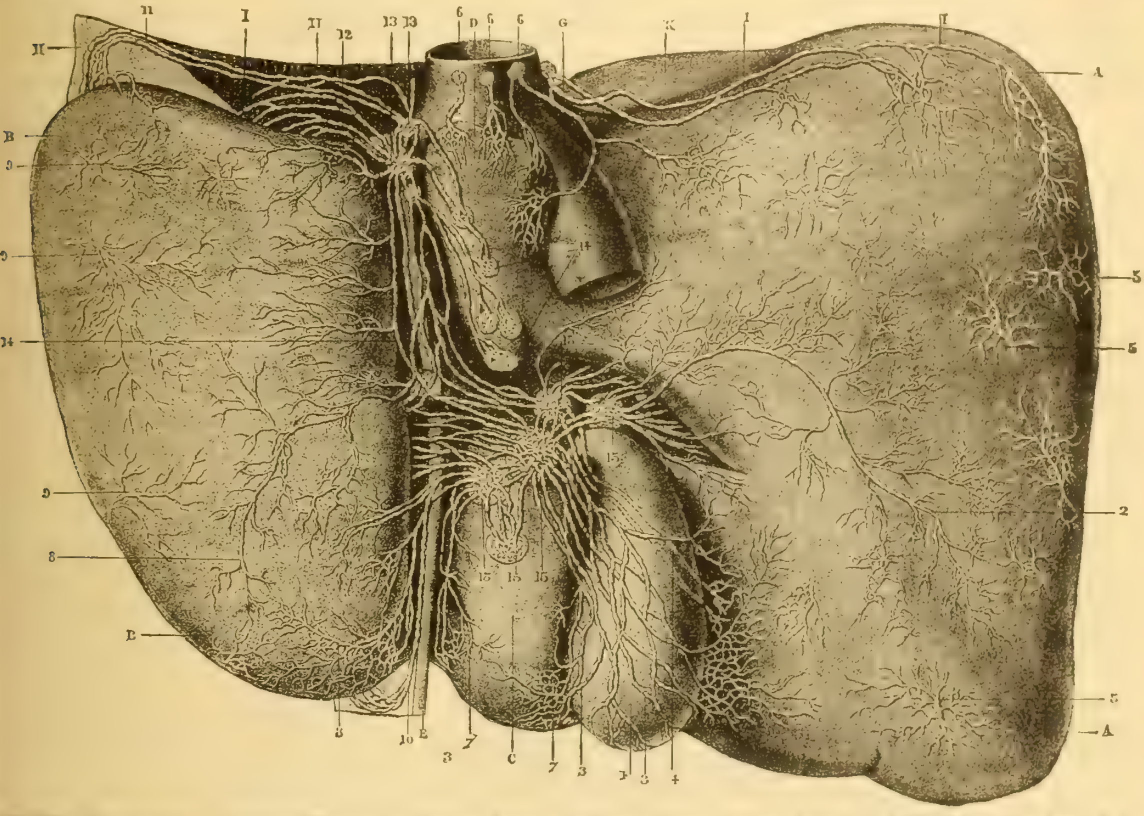


Fig. 4984.—Lymphatics and Lymphatic Glands on the Concave Aspect of the Liver of Man. (Sappey, Atlas.) A, A, Right lobe of the liver; B, B, left lobe; C, quadrate lobe; D, Spigelian lobe; E, round ligament or remnant of umbilical vein; F, cholecyst or gall bladder; G, postcava receiving the hepatic veins just as it traverses the diaphragm; H, left triangular ligament of the liver; I, diaphragm; K, the most projecting part of the convex surface of the liver.

1, 1, Two trunks near the cephalic edge of the right lobe extending to the glands on the postcava just within the thorax; 2, single trunk from the middle of the right lobe to the lymphatic glands in the hilus of the liver by the neck of the cholecyst; 3, 3, trunks upon and at the border of the cholecyst to the glands in the hilus; 4, two vessels having the same origin and termination, but covered by the cholecyst: their course is indicated by the dotted lines; 5, 5, trunks arising on the surface of the right lobe, but penetrating the substance of the liver to accompany the ental vessels; all the vessels from the surface take this course in most animals; 6, 6, 6, trunks from the Spigelian lobe, and the glands around the postcava receiving them; 7, 7, vessels belonging to the quadrate lobe; 8, 8, principal trunks of the left lobe; 9, 9, vessels arising on the surface, but soon entering the liver to join the deep lymphatics like 5 of the right lobe; 10, trunks from the convex surface of the liver following the round ligament and finally entering the glands at the hilus; 11, 11, 12, several trunks from the convex surface of the left lobe, winding over to the concave surface and entering glands in the fissure of the ductus venosus; 13, 13, lymphatic glands in the fissure of the ductus venosus, their efferent vessels extend to the glands in the hilus; 14, glands corresponding to the terminal end of the œsophagus; 15, 15, lymphatic glands receiving the lymphatics from most of the concave surface of the liver and the ental lymphatics following the portal vein.

Lymphatic Glands, Plexuses, and Trunks of the Abdominal and Pelvic Cavities.—The glands in the abdominal and pelvic cavities form a continuous net-work from the inguinal glands to those in the œsophageal opening; they also extend out on the great vessels of the viscera. Although there are no sharply defined limits and limited grouping of the 200 to 400 glands in this part of the body, groups have been made as in the neck for convenience. Following Krause, the following groups may be recognized, commencing with the iliac region: (1) Iliac; (2) hypogastric; (3) sacral; (4) lumbar; (5) mesenteric, including those of the meso-colon; (6) cœliac. Each of these groups of glands with the connecting vessels is also called a plexus. As the efferent vessels of all these groups unite to form the *chylocyst* and thoracic duct by three main trunks, these also have received names: (1) The two lumbar trunks (a *truncus lymphaticus lumbalis* of each side) from the iliac, hypogastric, sacral, and lumbar plexuses, and (2) a single trunk (*truncus lymphaticus intestinalis*) from the mesenteric and cœliac lymphatic plexuses. As was remarked in discussing the cervical glands, different authors may assign a collecting trunk from an organ to different groups of glands, although the same gland is meant. As the division into groups is artificial, and the glands vary considerably in position and in different individuals, even in number, this confusion is probably inevitable.

The iliac lymphatic glands and plexus (*glandulæ iliacæ, s. iliacæ externæ, s. anteriores; plexus lymphaticus iliacus, s. iliacus externus, s. anterior*) form a chain along the external and common iliac blood-vessels. At the crural ring this plexus is continuous with the inguinal plexus. The afferent vessels are from the inguinal plexus, those accompanying the internal epigastric and circumflex iliac blood-vessels, those from the vesiculæ seminales and the body of the uterus (those from the last two sources are often said to extend to the hypogastric plexus). This plexus is connected with the hypogastric and sacral by several communicating branches, but the main efferent trunks pass to the lumbar plexus.

Hypogastric Glands and Plexus (*glandulæ lymphaticæ hypogastricæ s. iliacæ internæ s. pelvinæ; plexus hypogastricus s. iliacus internus s. pelvinus*). These are on the sides of the pelvis around the hypogastric and internal iliac blood-vessels. The afferent lymphatics are from the gluteal, sciatic, and obturator vessels, part of the perineum, the prostate, urethra, most of the vagina, the [illegible], and neck of the uterus. According to most authors the ental lymphatics of the external genitalia in both sexes pass to these glands. Sometimes also part of the inguinal efferents pass to this group. This plexus is closely connected with the iliac and sacral, but its principal efferent trunks pass to the lumbar plexus.

Sacral Glands and Plexus (*glandulæ lymphaticæ sacrales; plexus lymphaticus sacralis*). This group of glands is between the folds of the mesorectum next the sacrum. The afferent vessels come from a part of the pelvic wall and the vertebral canal, also from the rectum. Like the other pelvic plexuses it is connected with all the others, but its efferent trunks pass to the lumbar plexus.

The Lumbar Glands and Plexus (*glandulæ lymphaticæ lumbales s. lumbares; plexus lymphaticus lumbalis*). The lumbar glands form three irregular rows, one mesal and two lateral, extending along the great blood-vessels from the bifurcation of the aorta nearly to the origin of the superior mesenteric artery. Its afferent vessels are the efferent trunks from the iliac, hypogastric, and sacral plexuses, lymphatics accompanying the ilio-lumbar and part of the lumbar blood-vessels, those from the testis, spermatic cord or parovarium, ovary, summit of uterus, Fallopian tubes, kidney, adrenal, and some of the colon descendens. It is also connected by a greater or less number of communicating branches with the cœliac plexus. Its efferent vessels unite to form two principal trunks, a right and left lumbar lymphatic trunk (*truncus lymphaticus lumbalis*), which with the intestinal trunk form the *chylocyst*, the enlarged beginning of the thoracic duct.

Cœliac Glands and Plexus (*glandulæ lymphaticæ cœliacæ; plexus lymphaticus cœliacus*). The cœliac plexus is situated along the cœliac vessels, the portal vein and the beginning of the superior mesenteric artery on the dorsal side of the pancreas, duodenum, and pylorus. This group was formerly described as part of the lumbar plexus. The afferent lymphatics come from the stomach, part of the œsophagus and duodenum, part of the liver, the pancreas and spleen. The efferent vessels join the intestinal trunk, or sometimes one or more branches pass directly to the chylocyst.

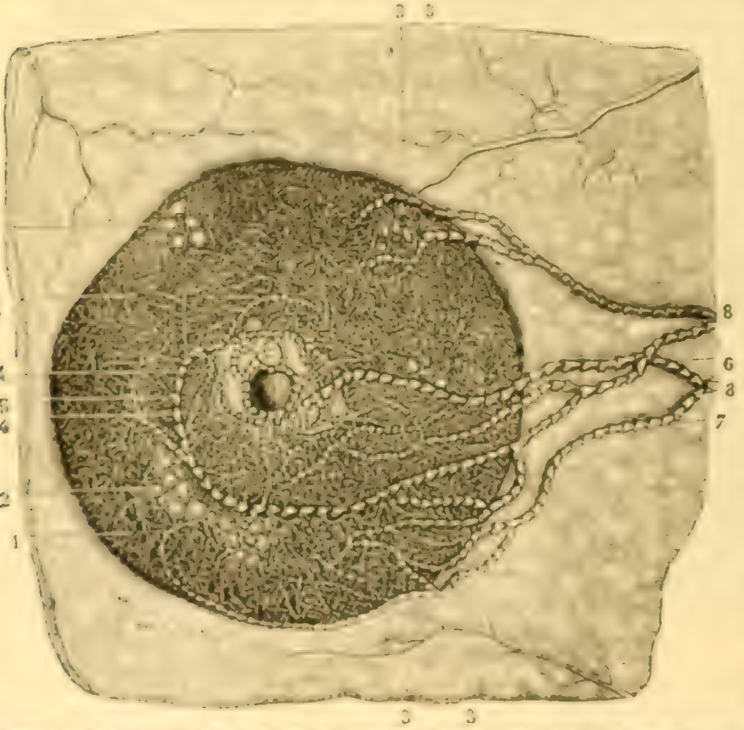

FIG. [illegible].—Left Mammary Gland of a Woman during Lactation. The skin and adipose tissue have been removed to bring the lymphatic plexus into view. At three of the corners of the figure blood-vessels are represented. (Sappey: [illegible].) 1, 1, Network of lymphatics [illegible]; 2, 2, [illegible]; 3, 3, large trunks at the corners of the gland; 4, 4, [illegible] of large vessels around the nipple; they originate in the depth of the [illegible]; 5, 5, great trunk arising at the mesial side of the nipple, and extending across the [illegible] to the axillary lymphatic glands; 6, large trunk from the [illegible] of the nipple extending directly toward the axilla; 7, large trunk from the [illegible] of the mamma, and uniting with the preceding on its way to the axilla; 8, 8, the two great trunks from the mammary gland going to terminate in the axillary lymphatic glands.

Mesenteric Glands and Plexus (*glandulæ mesentericæ s. mesaraicæ; plexus lymphaticus mesentericus s. mesaraicus*). The mesenteric glands and plexus (100 to 200) lie along the blood-vessels between the folds of the mesentery and the mesocolon. They are usually in three irregular tiers, one tier being near the intestine, one near the middle, and one near the root of the mesentery. The afferent vessels are from the small intestine except part of the duodenum, and the large intestine to the sigmoid flexure. The efferent vessels receive the efferent trunks from the cœliac plexus and then terminate in the chylocyst as the intestinal trunk (*truncus lymphaticus intestinalis*).

As will be seen by a glance at Figs. 4992, 4995, and 4997, the lymphatics and the glands in the abdominal cavity of the dog, cat, and rabbit, are essentially as in man, but there is a greater concentration of the glands, so that the groups are well defined. No sacral glands were certainly found in any of them.*

LYMPHATICS OF THE THORAX.—The thoracic lymphatics are divisible into three fairly distinct, although communicating, groups: (1) Those of the skin and other surface structures; (2) the ental lymphatics of the thoracic walls, including the diaphragm; (3) the lymphatics of the thoracic viscera—heart, lungs, trachea, and œsophagus.

The ectal lymphatics, like those of the abdomen, are quite sharply divided into those of the right and those of the left side, although on both the dorsi- and ventri-meson the vessels intercommunicate.

The beginning of many of the subcutaneous trunks of the thorax is likewise from an oblique zone surrounding the body at about the level of the umbilicus (Fig. 4986), and there is a somewhat similar, although less clearly defined, limiting zone between the neck and thorax. The collecting trunks extend in the most direct manner to the axillary lymphatic glands (Fig. 4989). Part of those, however, in the subclavicular and adjoining pectoral regions pass to the supraclavicular glands. This is supposed to explain the involvement of these glands in some cases of cancer of the breast.

---

* Sappey describes and figures in his Atlas (Plate XXVIII., Fig. [illegible]) the lumbar trunks [illegible] [illegible]. Such a condition was never observed by the writer in any of the white rabbits dissected.

Belonging to this ectal group are the lymphatics of the mammary gland. In the male they are but little more developed than the surrounding integument; but in the female, especially in preparation for and during lactation, they are present in enormous numbers, and their size is also greatly increased. Those of the mammary integument are especially numerous in the areola, but it is in the glandular substance itself that they reach their highest development. From the substance of the gland they reach the surface in four places, and extend as four principal trunks toward the axilla, but most often unite to form two large trunks before entering the axillary glands. Most authors assign part of the lymphatics of the breast to the internal mammary or sternal plexus, but Sappey states that the course is as described above.

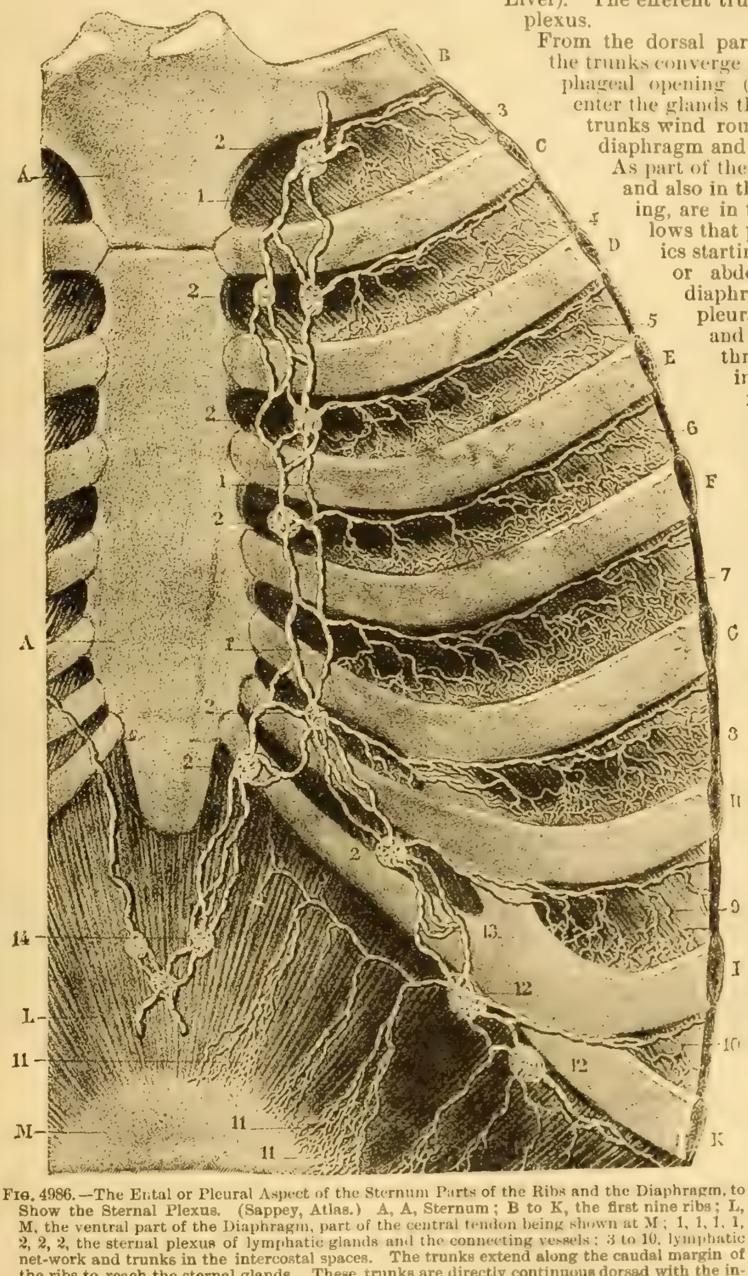

Fig. 4986.—The Ental or Pleural Aspect of the Sternum Parts of the Ribs and the Diaphragm, to Show the Sternal Plexus. (Sappey, Atlas.) A, A, Sternum; B to K, the first nine ribs; L, M, the ventral part of the Diaphragm, part of the central tendon being shown at M; 1, 1, 1, 1, 2, 2, 2, the sternal plexus of lymphatic glands and the connecting vessels; 3 to 10, lymphatic net-work and trunks in the intercostal spaces. The trunks extend along the caudal margin of the ribs to reach the sternal glands. These trunks are directly continuous dorsad with the intercostal plexus (cf. Fig. 4991); 11, 11, vessels on the pleural surface of the diaphragm, finally extending to the sternal glands; 12, 12, 13, sternal glands opposite the eighth and ninth ribs and their efferent trunks; 14, glands receiving the lymphatics from the suspensory ligament of the liver.

Besides the lymphatics from the mammary glands, many of those from the ectal muscles pass to the axillary glands. These trunks pass along the great pectoral muscles and the vasa thoracica longa, and usually traverse a few small glands (pectoral glands) in their course.

The lymphatics of the diaphragm were discovered by Rudbeck, and fully described by Nuck. They are among the most easily demonstrated of any in the body, and from the thinness of the diaphragm and the clearness with which the lymphatics may be followed, this organ is a favorite object for study. The lymphatics extend from the peritoneal to the pleural surface, hence it is upon the thoracic face that the great trunks are found (Fig. 4987). These are arranged into three paired and one azygos group. The lymphatic trunks of the diaphragm practically surround the whole organ and the openings through it. From the ventral group, occupying somewhat more than the ventral half, the trunks extend toward the sternum, traverse a gland about opposite the seventh rib, and then extend to the sternal plexus, those of the right going to the right lymphatic trunk, and those of the left going to the thoracic duct (Fig. 4987). The azygos group appears opposite the xiphisternum, and is represented by three glands (supra-xiphoid of Sappey, anterior mediastinal of authors), and their efferent trunks. These are not properly diaphragmatic lymphatics, for they come from the surface of the liver and suspensory ligament (see Liver). The efferent trunks join the sternal plexus.

From the dorsal part of the diaphragm the trunks converge to the aortic or œsophageal opening (dorsal group), and enter the glands there situated. Other trunks wind round the pillars of the diaphragm and enter the abdomen. As part of the glands in the aortic, and also in the œsophageal opening, are in the abdomen, it follows that part of the lymphatics starting on the peritoneal or abdominal side of the diaphragm extend to the pleural or thoracic side, and then turn back through these trunks into the abdomen before finally terminating in the thoracic duct. Everything seems to be complex in anatomy.

The deep structures of the thoracic walls are drained by lymphatics following the intercostal spaces. As will be seen by consulting Figs. 4986 and 4991, the collecting trunks form a half-circle, the vessels extending both toward the sternal and toward the intercostal plexus. In their course along the intercostal spaces they usually traverse one or more glands. Near the spinal column is a row of glands whose efferent trunks may extend directly to the thoracic duct, but usually two or three of them unite to form a common trunk, which opens into the thoracic duct. It is a remarkable fact, that those from the last three intercostal spaces unite to form trunks on each side, which extend through the diaphragm into the abdomen to join the chylocyst, instead of entering the thoracic duct in the thorax (cf. Fig. 4993, where vessels pass from the abdomen to the thorax).

From the first few intercostal spaces the collecting trunks on the right side pass to the right lymphatic trunk; and from the sternal half of all of the spaces the collecting trunks join the sternal plexus, those on the right extending therefrom to the right lymphatic trunk, and those on the left to the thoracic duct. This offers a very striking illustration of the close connection between the right and left lymphatic trunks in man, a condition much more fully realized in many of the lower animals, as marsupials, birds, reptiles, amphibians, and fishes. The lymphatics of the spinal canal and the muscles of the back follow their blood-vessels and enter the intercostal plexus, the greater number finally reaching the thoracic duct.

Œsophagus.—The lymphatics of the œsophagus form two sets, like the rest of the alimentary canal, viz., those of the muscularis and those of the mucosa; they penetrate the muscular wall and enter the small glands scattered along its course. The lymphatics are directly continuous with those of the pharynx at one end and with those of the stomach at the other. At the gastric end the collecting trunks, after reaching the surface, extend toward the stomach, and part of them traverse the œsophageal open-

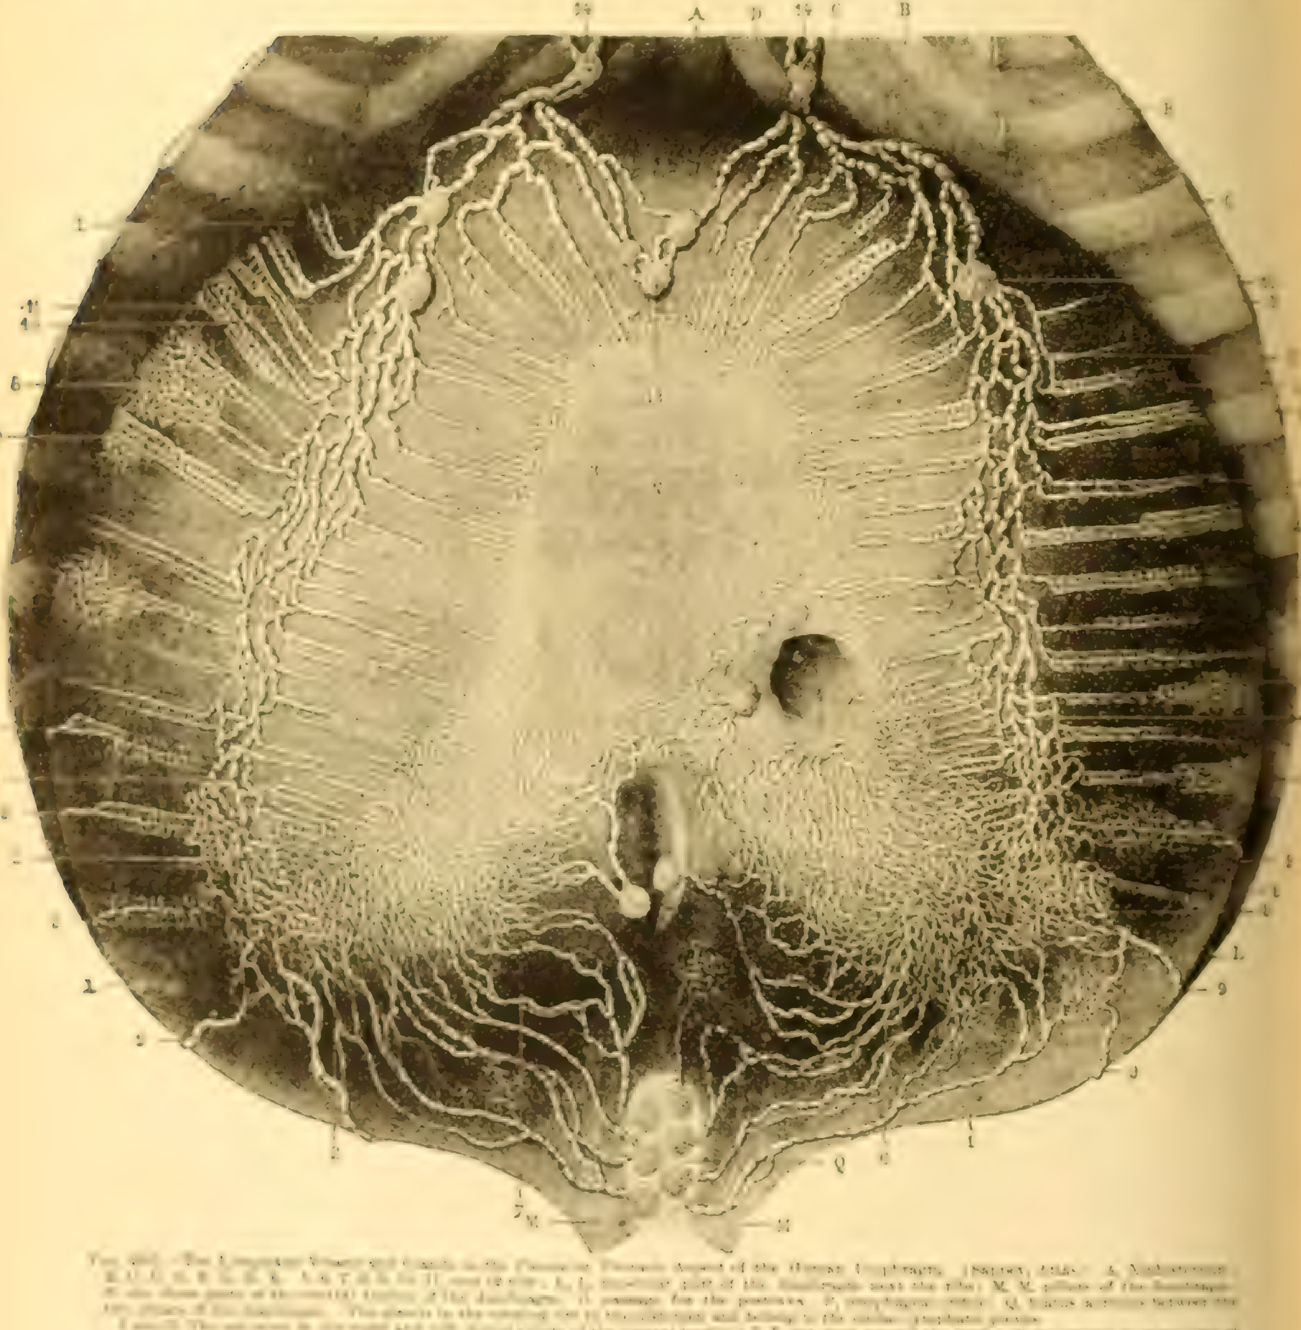

FIG. [illegible].—The Lymphatic Vessels and Glands in the [illegible] Aspect of the Human Diaphragm. (Sappey, [illegible].) [illegible] M, M, pillars of the diaphragm; [illegible] Q, hiatus [illegible] between the two pillars of the diaphragm. [illegible] Fig. [illegible].

ing and enter the glands around the cardia of the stomach (Plate XXXIV.). Those of the middle region enter the dorsal (posterior) mediastinal glands, while those in the neck join the internal jugular plexus. Up to the present time the lymphatics of the muscularis have been actually demonstrated only in the larger domestic animals (horse and ox), but the probability that they exist in the human œsophageal muscularis is very strong.

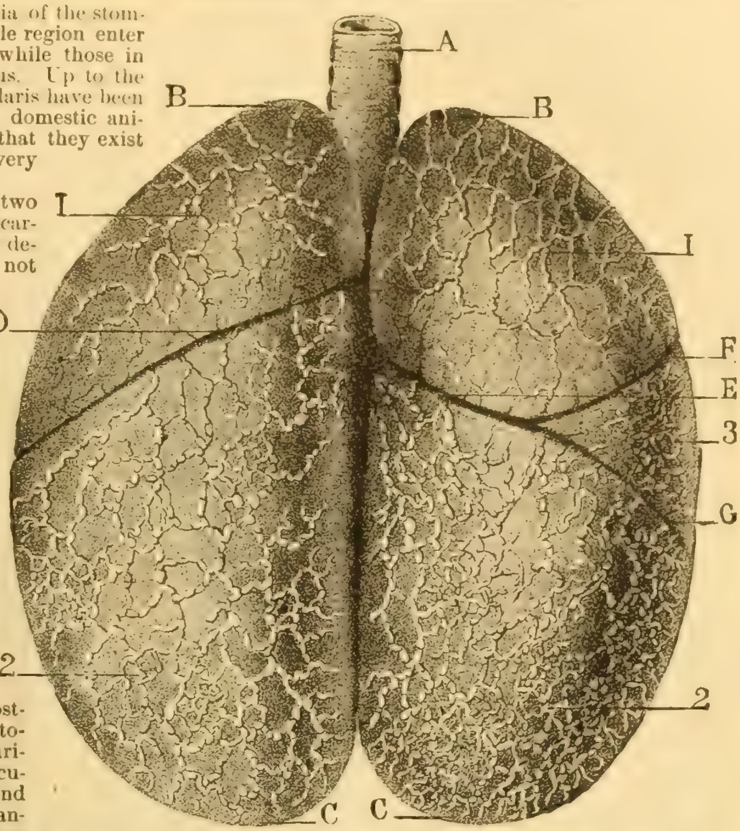

Fig. 4989.—Ectal or Subserous Lymphatics of the Dorsal Surface of the Lungs of a Child at Birth. (Sappey, Atlas.) A, trachea—the line points to the membranous portion; B, B, summit or cephalic lobes of the two lungs; D, the fissure dividing the left lung into two lobes; E, F, G, fissures dividing the right lung into three lobes.
1, Lymphatic net-work on the cephalic lobe; 2, 2, net-work on the caudal lobe; net-work on the middle lobe of the right lung. The fine net-work surrounding and covering the pulmonary lobules is not shown in this figure.

Heart.—The cardiac lymphatics are in two groups—a sub-pericardial and a sub-endocardial net-work—but in both cases they are derived from the muscular substance, and not from the serosa. The ectal or sub-pericardial net-work commences with the apex of the heart and extends over the whole surface, but the larger trunks occupy the dorsal and ventral grooves or depressions containing the large cardiac blood-vessels. The ental or subendocardial vessels unite into collecting trunks which penetrate the myocardium near the apex and near the auriculo-ventricular groove, and anastomose with the ectal lymphatics, and all together extend to the groove between the auricles and ventricles, and form an anastomosing circle around the base of the ventricles. The rather few lymphatics of the auricles mostly extend toward the auriculo-ventricular groove and join the anastomosing ring, but some extend directly to the main trunks along the two sides of the pulmonary artery. From the anastomosing ring in the auriculo-ventricular groove two trunks arise, the one representing the left heart extends along the left side of the pulmonary artery, and between it and the left auricle to the left bronchial glands, and therefore finally to the thoracic duct. The trunk representing the right heart follows the right side of the pulmonary artery, and passes between this vessel and the arch of the aorta to reach the right bronchial glands, ultimately to terminate in the right common lymphatic trunk.

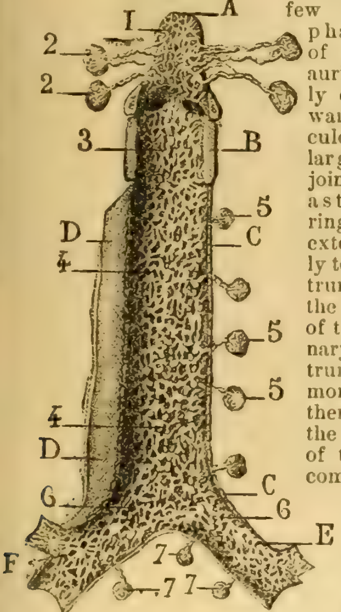

Fig. 4988.—Trachea and Bronchi Opened on the Dorsal Side to Show the Abundant Lymphatic Net-work of the Mucosa: from a Child at Birth. (Sappey, Atlas.) A, Epiglottis; B, section of the cricoid cartilage to expose the interior of the larynx; C, C, trachea; D, D, the membranous portion of the trachea drawn to the left, exposing the interior; E and F, the two bronchi.
1, The lymphatic net-work of the epiglottis: 2, 2, ental cervical lymphatic glands (cf. Plate XXXIII., 13); subglottic net-work in the larynx: this is very sparing in the adult: 4, 4, net-work of the tracheal mucosa; 5, 5, ental cervical glands along the trachea into which the collecting trunks enter; 6, 6, the lymphatic net-work in the bronchi; it will be seen from this figure that the lymphatic net-work from the epiglottis into the bronchi is uninterruptedly dense; in the adult there are comparatively few lymphatics in the larynx proper and in the trachea; 7, 7, bronchial lymphatic glands.

Lungs.—The lymphatics of the lungs are exceedingly numerous. They arise in the lung substance between the alveoli, and in the bronchial mucosa. Those near the surface extend toward the periphery and become subserous, and then extend to the root of the lung to enter the bronchial glands (Figs. 4988 and 4989). The ental lymphatics follow the bronchi and finally, after traversing a few small glands on the bronchi (the so-called pulmonary lymphatic glands), they enter the bronchial glands. From these glands extend trunks to the left to enter the thoracic duct, and to the right to enter the right common lymphatic trunk.

Trachea and Bronchi.—As seen above, the epiglottis and entire laryngeal opening possess an almost infinite number of lymphatics (Pl. XXXIII.). In the infant this wealth of vessels continues throughout the entire larynx, and trachea and its branches; but as age advances the lymphatics of the larynx, commencing at the level of the vocal cords, and the trachea become less and less, until in the adult they are comparatively few; but in the smaller bronchi the abundant lymphatic net-work persists. The vessels arise in the mucosa and the intercartilaginous tissue, penetrate the tracheal wall, and are distributed to the glands so abundantly supplied to the neck along the trachea and bronchi (Fig. 4988).

THORACIC LYMPHATIC GLANDS.—The lymphatic glands of the thorax are only second in importance and number to those in the abdomen. Within the thorax they form a continuous net-work, and are closely connected with those of the abdomen on the one hand, and with those of the neck on the other. Those without the cavity are continuous with the axillary glands.

The pectoral glands (*glandulæ lymphaticæ pectorales, s. thoracicæ superficiales*) are situated along the caudal (inferior) border of the great pectoral muscle, and some more deeply along the vasa thoracica longa. Through them pass many of the trunks following the long thoracic blood-vessels, and many of those from the thoracic region on their way to the axillary lymphatic glands.

Within the thorax there are several named groups with corresponding plexuses. The sternal glands and plexus (*glandulæ lymphaticæ sternales s. substernales, s. thoracicæ profundæ s. internæ s. parasternales; plexus lymphaticus sternalis s. mammarius internus*) commence opposite the xiphisternum and extend along the thorax on each side of the sternum in company with the sternal blood-vessels (Fig. 4999). The afferent vessels of this plexus come from the deep abdominal muscles in the supra-umbilical region of the abdomen, the ventral two-thirds of the diaphragm, part of the convex surface of the liver through the supra-xiphoid glands, the structures in the intercostal spaces in the ventral part of the body. The efferent vessels usually join the ventral (anterior) mediastinal glands, and with their trunks pass to the two great common lymph-trunks. Sometimes one or more, or all, of the trunks pass directly to the great lymph-trunks without traversing the mediastinal glands.

The intercostal glands and plexus (*glandulæ lymphaticæ intercostales; plexus lymphaticus intercostalis*) are found on each side of the thorax in the intercostal spaces and along the vertebral column. The afferent vessels are from the intercostal structures, the spinal canal, and the deep muscles of the back. The efferent trunks pass mostly to the thoracic duct, but part of those on the right pass to the right lymphatic trunk.

The dorsal or posterior mediastinal glands and plexus (*glandulæ lymphaticæ mediastinales dorsales, s. posteriores; plexus lymphaticus mediastinalis dorsalis s. posterior*) are situated along the thoracic aorta and the œsophagus in the dorsal or posterior mediastinal folds. The afferent vessels are from the œsophagus, the dorsal third of the diaphragm, and some from the liver. The efferent vessels enter the thoracic duct directly or join the bronchial glands.

The ventral (anterior) mediastinal glands and plexus (*glandulæ lymphaticæ mediastinales ventrales s. anteriores, s. gl. l. cardiacæ; plexus lymphaticus mediastinalis ventralis s. anterior*) are in the ventral mediastinal fold, and are principally concentrated around the arch of the aorta and the roots of the great blood vessels. The glands called supra-xiphoid by Sappey (14 of Fig. 4986) are frequently assigned to this group. The afferent vessels are from the sternal plexus, and through this many vessels from the convex surface of the liver; the lymphatics of the thymus, and, according to some authors, the lymphatics of the heart. The efferent vessels either go to the bronchial glands or join the vessels from these, and extend from the right half to the right lymphatic trunk, and from the left half to the thoracic duct.

The bronchial glands and plexus (*glandulæ lymphaticæ bronchiales; plexus lymphaticus bronchialis*) are situated in the bifurcation of the trachea, and extend upon the trachea (where they are called tracheal lymphatic glands) to the internal jugular plexus, and others extend out along the bronchi into the lungs (pulmonary lymphatic glands). In childhood and youth they are pink, but with advancing age they become dark and even black, if the individual has inhaled a plentiful supply of coal-dust or other carbonaceous matter. These glands are very large and important. The afferent vessels are from the lungs, and, according to some authors, the heart, the bronchi, the efferent vessels of the dorsal mediastinal glands, and sometimes the ventral mediastinal glands also. The efferent vessels extend from the left side to the thoracic duct, and from the right to the right lymphatic trunk. Frequently the efferent vessels of the sternal, ventral mediastinal, and bronchial glands unite to form a large single or multiple trunk (*truncus lymphaticus broncho-mediastinalis, s. lymph-mediastinus, s. broncho-mediastinus*), which extends to the common lymphatic trunk of the right or left. Such a trunk is more common on the right. On the left the efferent trunks are usually smaller and less concentrated.

COMMON LYMPHATIC TRUNKS.—In man and the mammals there are but two common lymphatic trunks, one on the right and one on the left side; and these trunks terminate at two points in the great veins of the neck, usually at the junction of the jugular and subclavian veins—that is, just before the formation of the brachio-cephalic venous trunks, or in animals like the rabbit (Fig. 4998) with a right and left precava, just before the formation of these. In man and the higher animals these trunks are of different length and size, and receive the lymphatics of very unequal portions of the body, that on the left side being naturally much the more extensive. In the lowest mammals the tendency is very strong to equalize these trunks and also the area drained by them; and in the animals below mammals, the two are approximately equal.

Thoracic Duct (*ductus thoracicus s. truncus s. canalis lymphaticus communis sinister, s. major, s. ductus chyliferus s. Eustachianus*; named after Bartolommeo [Eustachius, 1564]).—The common lymphatic duct, canal, or trunk of the left side collects and empties into the venous system, the lymph of the pelvic limbs, the reproductive and urinary organs, the alimentary canal, pancreas, spleen, much of that of the liver, of the left half of the body cephalad of (above) the umbilicus with the addition of a part from the right half of the thoracic wall (Figs. 4989 and 4990 to 4998).

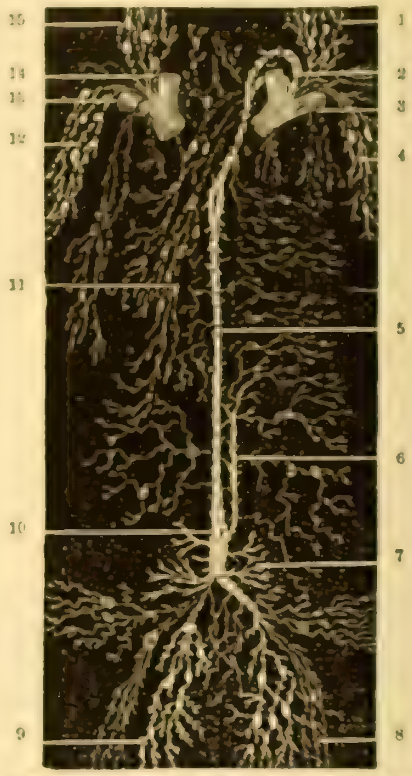

FIG. 4990.—Diagram of the Thoracic Duct, the Right Lymphatic Trunk, and the Lymphatic Plexuses of the Human Body. (After Quain.) 1, left jugular plexus; 2, arch of the thoracic duct near its entrance into the angle between the subclavian and internal jugular veins; 3, left subclavian vein; 4, left axillary lymphatic plexus; 5, the thoracic duct in the thorax; 6, trunk from the intercostal plexus to the duct, where it joins the [illegible]; there should be a similar trunk on the left (cf. Fig. 4991); 7, cisterna; 8 and 9, inguinal and iliac plexuses of the left and right; 10, [illegible]; 11, the sternal, bronchial, and mediastinal plexuses; 12, axillary plexus of the right; 13 and 14, right subclavian and internal jugular veins; the right lymphatic trunk enters the vein at the angle between the subclavian and internal jugular as does the thoracic duct on the left; 15, right jugular lymphatic plexus.

In man the thoracic duct is formed in the abdomen opposite the first, second, or third lumbar vertebra by the union of the trunks of the lumbar and mesenteric lymphatic plexuses. The most caudal end is the result of the union of the right and left lumbar trunk (*truncus lymphaticus lumbalis dexter et sinister*). The large trunk thus formed is then increased by the addition of the unpaired or azygous trunk (*truncus intestinalis*) from the stomach and intestines, part of the liver, the spleen and pancreas, and the right and left trunk from the intercostal plexuses (Fig. 4990). At the beginning of the duct where all these confluents unite there is usually a marked dilatation, the chylocyst, chyle receptacle or cistern of Pecquet (*chylocystis, s. receptaculum chyli, s. cisterna chyli*). This is sometimes absent in man as the confluents form a kind of net-work instead of one large trunk. In this case the thoracic duct is formed by the union of the net-work without there being present a special enlargement or chylocyst. This condition is said by Owen to be normal in the marsupials examined by him, but in the dog, cat, rabbit, and most of the higher animals there is usually a very well-marked chylocyst. From the chylocyst the thoracic duct traverses the diaphragm with the aorta, usually on the right side, and extends along the thorax mostly on the right and dorsal side of the aorta until opposite the sixth to the third thoracic vertebra it gradually inclines to the left, passes dorsad of the arch of the aorta, reaches the left side of the œsophagus which it follows for a short distance, passing on with it along the dorsal side of the great blood-vessels until opposite the seventh cervical vertebra when it forms an arch something like the arch of the aorta, curving ventrad and to the left between the vertebral blood-vessels and the jugular vein to terminate at the junction of the left internal jugular and the subclavian vein. The opening is guarded by a double valve, so that reversal of the direction of the stream is avoided.

The thoracic duct differs in length with the length of the trunk. The average in an adult is about 40 ctm., and its diameter is about 2 to 3 mm., it being greater near its origin than near its termination. It in many cases divides into two or more parallel and anastomosing vessels, which finally unite to enter the vein together. The chylocyst is from 40 to 50 mm. long and 6 to 8 mm. thick, and in the arch near the termination there is sometimes, if not regularly, found a dilatation something like that shown in the dog and the rabbit (Figs. 4996 and 4998). The thoracic duct receives confluent branches throughout its entire course, and near the termination enter the important trunks from the arm, lungs, and head and neck (the jugular, subclavian, and broncho mediastinal trunks). The entrance of each of these vessels is usually guarded by a paired valve.

Varieties.—There are sometimes two ducts—one opening into the right, and one into the left veins of the neck. Sometimes a single duct divides, sending one branch to the right and one to the left, as shown in the figure of the cat and rabbit (Figs. 4993 and 4998). Rarely there is a transposition, the left thoracic duct opening on the right. "In two instances the thoracic duct has been seen to terminate in the vena azygos." Multiple openings into the veins are not uncommon (cf. Fig. 4994).

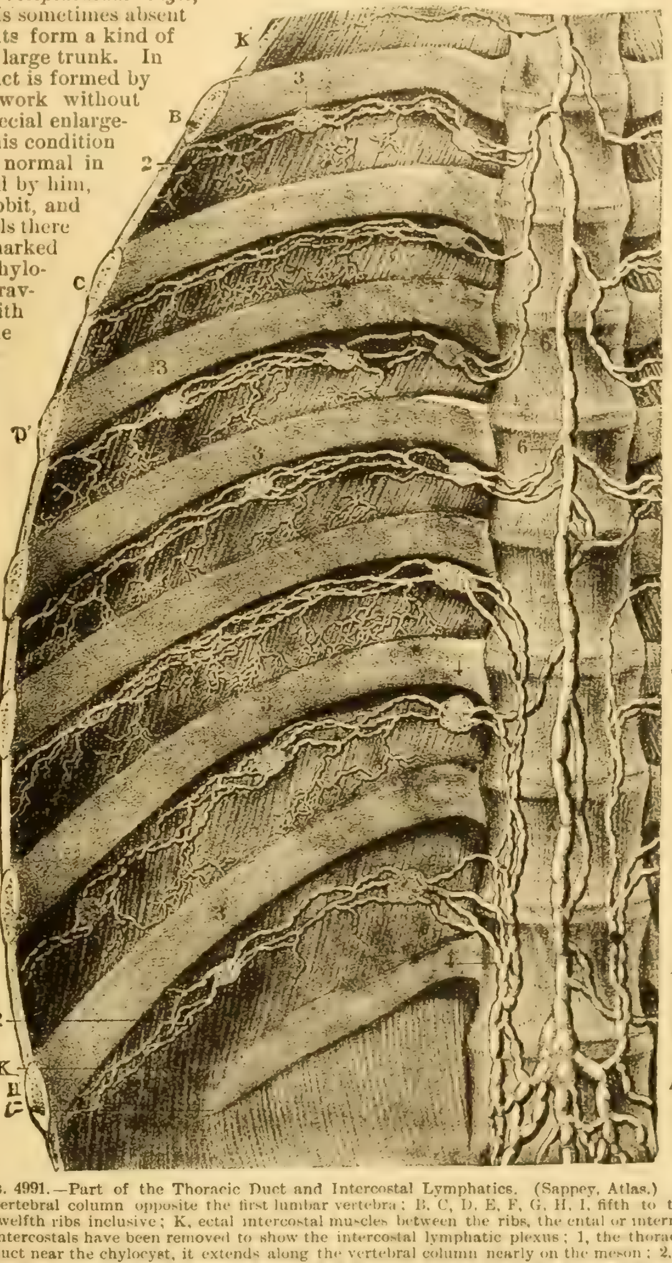

Fig. 4991.—Part of the Thoracic Duct and Intercostal Lymphatics. (Sappey, Atlas.) A, vertebral column opposite the first lumbar vertebra; B, C, D, E, F, G, H, I, fifth to the twelfth ribs inclusive; K, ectal intercostal muscles between the ribs, the ental or internal intercostals have been removed to show the intercostal lymphatic plexus; 1, the thoracic duct near the chylocyst, it extends along the vertebral column nearly on the meson; 2, 2, trunks arising in the intercostal spaces; 3, 3, 3, lymphatic glands in the course of the vessels; 4, 4, large trunk conveying the lymph from the three or four intercostal spaces into the abdomen and then pouring it into the chylocyst; 5, 5, similar trunk on the left side; 6, 6, and 7, trunks on the right and left, from the intercostal spaces to the thoracic duct.

Right common lymphatic trunk (*truncus lymphaticus communis dexter, s. minor; vena lymphatica dextra*).—The right common lymphatic trunk is only about 14 mm. long, but is nearly as great in diameter as the thoracic duct. It is formed by the confluence of the lymphatics from the right side of the head (*truncus lymphaticus jugularis dexter*), those from the right arm, shoulder, and breast (*truncus lymphaticus subclavius*), the efferent trunks from the right half of the sternal, and ventral mediastinal and bronchial plexuses (*truncus broncho-mediastinalis dexter*). This common trunk, therefore, collects the lymph and pours it into the veins from the right half of the body, cephalad of (above) the umbilicus—part of the liver, the right lung, right side of the heart, right half of the head, face, neck, back, and part of the right intercostal region drains its lymphatics into the thoracic duct. As on the left side there is a tendency for the trunk to terminate by a multiple instead of a single opening. Not infrequently, there is no true common trunk formed, but the great trunks from the different regions open separately.

The great lymphatic trunks in the higher mammals conform quite closely to those of man, but the termination varies somewhat. When the internal jugular is small it is generally near the junction of the subclavian and external jugular (Figs. 4993, 4996, and 4998). In the horse this duct terminates in the precava, and in the ox usually at the junction of the left jugular and the precava. In the ox also it usually traverses a special opening in the diaphragm. In the horse the duct is ampullated at its termination, as it is also in the dog and rabbit (Figs. 4996 and 4998). In all the animals both trunks tend to open by two or more mouths (Fig. 4994), and in all the thoracic duct shows a strong tendency to conform to the lymphatics in general and break up into a kind of network instead of remaining of considerable size. Sometimes this network encloses the aorta, but more frequently it assumes the condition shown in Fig. 4994. In the rabbit almost constantly, and very frequently in the cat, there is a branch of the thoracic duct extending to the right (Figs. 4993 and 4998).

The chylocyst is large in the dog, cat, and rabbit, and in many other animals, and there is a strong tendency for its component trunks (intestinal and lumbar) to divide before entering it, so that it is formed by the union of a coarse network rather than by a few simple vessels (Figs. 4993, 4994, 4996, and 4998).

In the non-mammalia, birds, reptiles, amphibia, and fishes, the great trunks are symmetrical, that is, nearly equal on the two sides. They open into the great veins near the heart. There are also a pair of vessels opening into the ischiadic or other pelvic veins, and in the frog and toad there is a lymph heart on each great trunk near the opening. In the non-amphibian forms, where lymph hearts are present, they are confined to the pelvic region.

ORIGIN AND STRUCTURE OF THE LYMPHATIC VESSELS.—There are three distinct views as to the ultimate origin of the lymphatic vessels: 1. That they are in direct communication with the blood-vessels by means of connecting radicles so small that in normal conditions only the blood plasma can traverse them, and that under pathological conditions these connecting radicles may increase sufficiently in size to admit the passage of blood corpuscles. This was one of the earliest views, and it is supported by the fact of the ready appearance of water or even colored gelatin in the lymphatics soon after the blood-vessels is

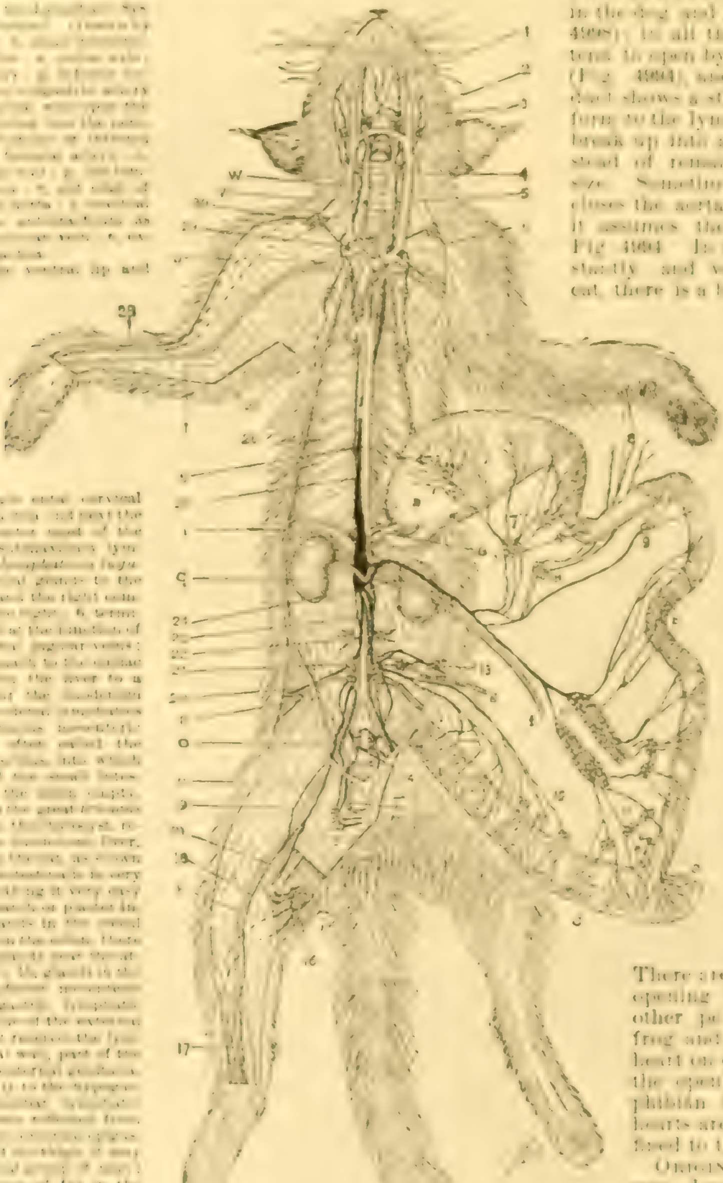

Fig. [illegible]

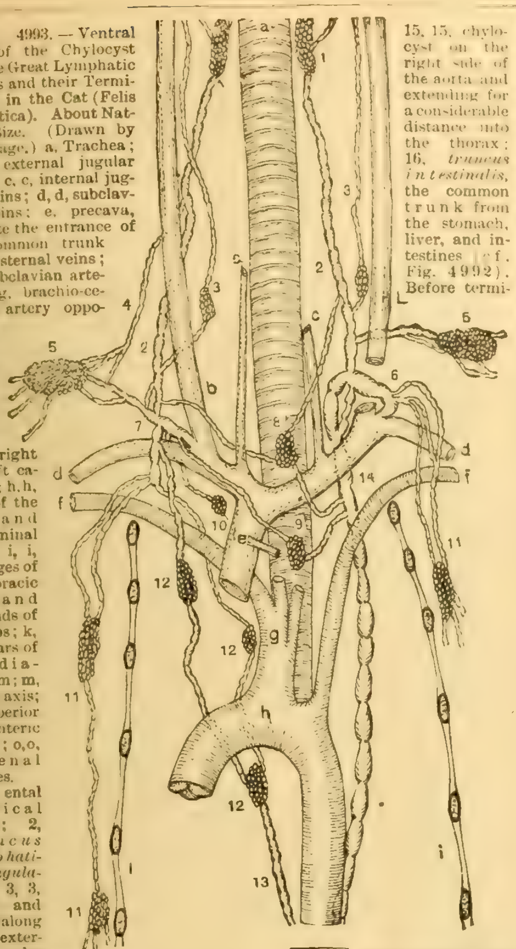

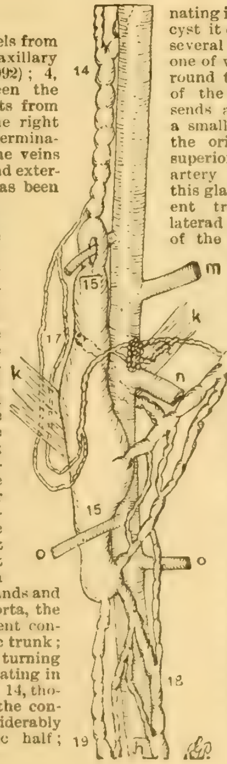

FIG. 4993.—Ventral View of the Chylocyst and the Great Lymphatic Trunks and their Termination in the Cat (Felis Domestica). About Natural Size. (Drawn by Mrs. Gage.) a, Trachea; b, b, external jugular veins; c, c, internal jugular veins; d, d, subclavian veins; e, precava, opposite the entrance of the common trunk of the sternal veins; f, f subclavian arteries; g, brachio-cephalic artery opposite its division into the right subclavian, the right and left carotids; h, h, arch of the aorta and abdominal aorta; i, i, cut edges of the thoracic walls and the ends of the ribs; k, k, pillars of the diaphragm; m, cœliac axis; n, superior mesenteric artery; o, o, the renal arteries.

1, ental cervical gland; 2, *truncus lymphaticus jugularis;* 3, 3, trunk and gland along the external jugular vein, the trunk is one of the efferent vessels from the lateral of the two submaxillary lymphatic glands (cf. Fig. 4992); 4, anastomosing branches between the jugular trunk and the efferents from the prescapular gland; 5, 5, the right and left prescapular gland; 6, termination of the thoracic duct in the veins at the angle of the subclavia and external jugular, a short segment has been removed from the external jugular to show more clearly the arch of the terminal part of the thoracic duct; 7, the right common lymphatic trunk at its termination; 8, lymphatic gland on the trachea, its efferent vessels extend both to the right and to the left; 9, large gland in the ventral mediastinum around the sternal vessels, its efferent vessels extend both to the right and to the left; 10, small gland about opposite the head of the first rib, there is one also on the left but it has been omitted; 11, 11, pectoral glands and lymphatic vessels, they follow the axillary blood-vessels after reaching the axilla and terminate directly in the arch of the thoracic duct on the left, but join other trunks on the right before entering the common trunk; 12, 12, 12, lymphatic glands and trunks near the arch of the aorta, the efferent vessels form prominent constituents of the right lymphatic trunk; 13, branch of the thoracic duct turning to the right and finally terminating in the right lymphatic trunk; 14, 14, thoracic duct. As indicated by the constrictions the valves are considerably farther apart in the cephalic half; 15, 15, chylocyst on the right side of the aorta and extending for a considerable distance into the thorax; 16, *truncus intestinalis*, the common trunk from the stomach, liver, and intestines (cf. Fig. 4992). Before terminating in the chylocyst it divides into several branches, one of which winds round the left side of the aorta, one sends a branch to a small gland near the origin of the superior mesenteric artery and from this gland the efferent trunk passes laterad of the pillar of the diaphragm, enters the thorax with the splanchnic nerves and terminates in the thoracic duct just beyond the chylocyst, still another branch anastomoses with the lumbar trunks; the lymphatics form a perfect maze in this region, so that it is no wonder Eustachius was bewildered in his first investigation of them; 17, lymphatic vessels from the abdomen to enter the thoracic duct in the thorax; this seems like an exact reversal of the condition in man where some of the lymphatics of the thorax (intercostal plexus) enter the abdomen to assist in forming the chylocyst (cf. Fig. 4991); 18, left and 19, right anastomosing trunks from the lumbar glands.

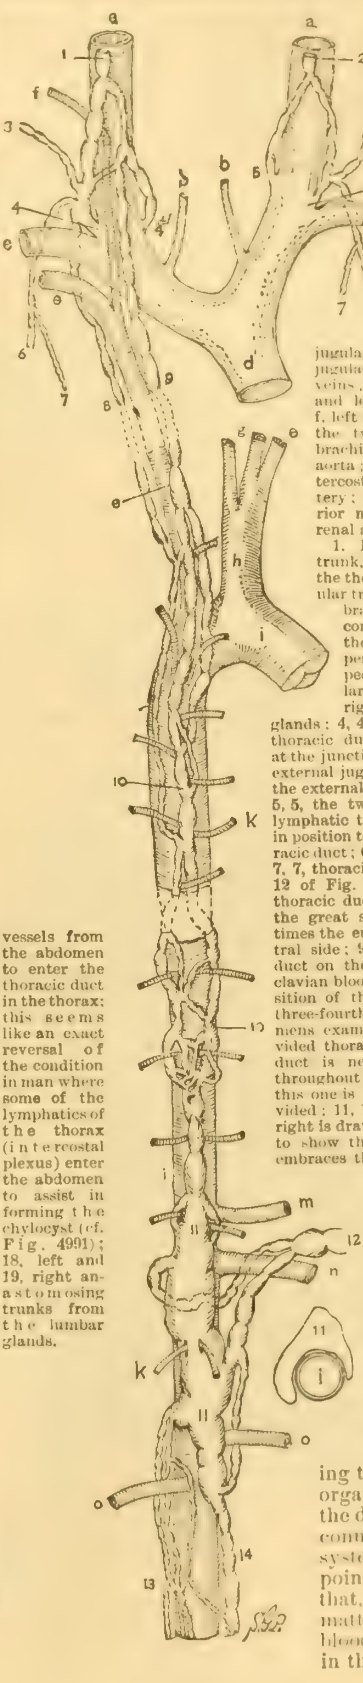

FIG. 4994.—Dorsal View of the Chylocyst and the Great Lymphatic Trunks in their Relation to the Blood-vessels of the Cat (Felis Domestica). Slightly more than Natural Size. The blanks and dotted lines indicate the omission of a part of the length. (Drawn by Mrs. Gage.) a, a, External jugular veins; b, b, internal jugular veins; c, c, subclavian veins, d, precava; e, the right and left subclavian arteries; f, left thyroid axis; g, between the two carotid arteries; h, brachio cephalic artery; i, i, i, aorta; k, k, upper one an intercostal, lower a lumbar artery; m, cœliac axis; n, superior mesenteric artery; o, o, renal arteries.

1. Left jugular lymphatic trunk, bifurcating and joining the thoracic duct; 2, right jugular trunk, bifurcating and one branch joining the right common lymphatic trunk, the other terminating independently in the mesal aspect of the external jugular; 3, 3, trunks from the right and left prescapular glands; 4, 4, the two openings of the thoracic duct, the lateral one being at the junction of the subclavian and external jugular, the mesal one into the external jugular about opposite; 5, 5, the two openings of the right lymphatic trunks—they are similar in position to the openings of the thoracic duct; 6, 6, pectoral lymphatics; 7, 7, thoracic lymphatics (cf. 11 and 12 of Fig. 4993); 8, branch of the thoracic duct on the ventral side of the great subclavian vessels, sometimes the entire duct is on the ventral side; 9, branch of the thoracic duct on the dorsal side of the subclavian blood-vessels—this is the position of the entire duct in about three-fourths of the numerous specimens examined; 10, 10, greatly divided thoracic duct. The thoracic duct is never simple in the cat throughout its whole course, but this one is more than commonly divided; 11, 11, 11, chylocyst. On the right is drawn a section at this point to show that the chylocyst nearly embraces the aorta; 12, intestinal lymphatic trunk sending a large branch on both sides of the aorta to enter the chylocyst; 13, left lumbar trunk greatly divided; 14, right lumbar lymphatic trunk anastomosing with the left and with a branch from the intestinal trunk.

were injected. This was, and still is, a favorite method of demonstrating the lymphatics of an organ. In objection to the doctrine of the direct connection of the two systems of vessels, it was pointed out by Hunter that, when the coarser matters injected into the blood-vessels appeared in the lymphatics, it was due to a leakage somewhere in the wall of the blood-vessel; and further, that the filling of the lymphatics by injecting water or gelatin into the blood-vessels was but natural, as it is one of the properties of the blood-vessels to allow the contents to diffuse through their walls and the lymphatics, from their office as a drainage system, take up the exuded liquid. This does not, however, show how the exuded liquid gets into the lymphatics. The pressure which forces the plasma through the walls of the blood-vessels would seem rather to collapse the lymphatics, as the pressure is in on the outside. In a word, there has been no conclusive proof given that there is or is not a direct connection between blood-vessels and lymphatics.

2. That there is a net-work of minute spaces in the tissues between and around the individual structural elements, through which the diffused plasma slowly moves, bathing all the cells and fibres, giving to them oxygen and the other nutritive elements, and taking in return carbon dioxide and the other products of waste. Part of this waste, especially the carbon dioxide, diffuses

Fig. 4995.—General View of the Lymphatic System of the Dog (Scotch Terrier). (Drawn by Mrs. Gage.) a, Stomach ; b, b, small intestine ; c, cæcum ; d, large intestine ; e, cœliac axis ; f, superior mesenteric artery ; **g, inferior mesenteric artery ; h, epigastric artery displaced from** the abdominal wall to the muscles of the thigh ; i, sciatic nerve and **other popliteal structures brought into view by removing a segment of** the thigh muscles ; k, saphenous or internal cutaneous artery ; m, n, the femoral artery ; o, cut edge of the abdominal wall ; p, ilio lumbar artery ; q, right kidney ; r, cut edge of the diaphragm ; s, aorta ; t, brachial artery and its continuation as the radial artery in the antibrachium ; u, subclavian vein ; v, external jugular vein ; w, trachea. 1, Lymphatic trunks from the ventral lip to the mesal of the two submaxillary lymphatic glands ; 2, lymphatic trunks from the face and **nose, and dorsal lip, injected from the snout ; 3, the two submaxillary** lymphatic glands with the facial vein between them—the mesal glands of the two sides are connected by several transverse vessels ; 4, ental cervical gland ; 5, jugular lymphatic trunk finally joining the thoracic duct on the left, the right lymphatic trunk on the right ; 6, termination of the thoracic duct at the junction of the subclavian and external jugular veins ; 7, cœliac glands receiving the lymphatics of the stomach, **and sending efferent trunks to the intestinal trunk ; 8, lymphatic** or lacteal trunks from the small intestine ; 9, two large mesenteric **glands (so-called glands of Asellius or pancreas Aselli ; from these orig**inates the intestinal lymphatic trunk, which is quite short in the dog **and much more difficult to inject than in the cat ; 10, gland receiving trunks from the duodenum, ileum, and large intestine near the cæcum ; 11, glands receiving the lymphatics from the cæcum,** and part of the large intestine ; **12, glands in the meso-colon along** the inferior mes**enteric artery ; they receive vessels from the large intestine, and the** efferent vessels go to the chylocyst and to the lumbar glands ; 13, gland on the abdomen beside the external epigastric artery ; 14, popliteal **gland ; 15, lymphatics from the foot, following the external or short** saphenous vein around the calf of the leg into the popliteal gland ; the parts of the vessels that would be hidden in this view are indicated by **broken lines ; 16, lymphatic trunk following the saphenous artery. The saphenous trunk freely anastomoses with the trunk following the femoral artery, and with it passes to the lumbar glands ; 18, lumbar** lymphatic glands ; 19, lymphatic trunk, accompanying the ilio-lumbar **artery, and terminating in the lumbar glands ; 20, lumbar lymphatic trunks ; 21, chylocyst ; 22, thoracic duct, double for a considerable** distance ; 23, pectoral lymphatic gland and vessels ; 24, lymphatic **trunks following the cephalic vein, and terminating in the prescapular gland. The course along the brachium is indicated by broken lines, as the vessels would not appear in this view ; 25, termination of the right lymphatic trunk ; 26, prescapular lymphatic gland of the right side.**

Fig. 4996.—Ventral View of the Chylocyst and the Great Lymphatic Trunks in their Relation to the Principal Blood-vessels of the Dog (Scotch Terrier). The blanks with dotted lines in the cervical region, and the blank in the thorax, indicate that part of the length has been omitted. About Natural Size. (Drawn by Mrs. Gage.) a, Larynx ; b, trachea ; c, c, the right and left external jugular veins, with segments removed ; d, d, the two internal jugular veins ; e, e, subclavian veins ; f, precava ; g, g, right and left subclavian arteries ; h, brachiocephalic artery, near its division into the subclavian and the two carotids ; k, k, aorta ; m, m, pillars of the diaphragm ; n, n, cœliac axis ; o, superior mesenteric artery ; p, p, renal arteries.

1, 1, Right and left lateral submaxillary lymphatic glands, receiving trunks from the face, nose, and dorsal lip ; 2, 2, mesal submaxillary **lymphatic glands, receiving trunks from the ventral lip ; these two** glands are connected by numerous anastomosing and crossing trunks ; 3, 3, ental cervical glands, receiving the efferents from 1 and 2 ; 4, 5, **4, 5, jugular trunks from the ental cervical glands to the thoracic duct and right common lymphatic trunk ; 6, 6, trunks from the prescapular** glands, only the right gland being shown ; **7, termination of the thoracic duct on the mesal surface of the external jugular, near its junction** with the internal jugular vein. **The arch in the duct is on the dorsal side of the great subclavian vessels, and it arches toward the meson instead of laterad as with the cat, and before terminating, enlarges considerably. Into the enlargement terminate the jugular trunks and the** one from the prescapular gland ; the enlargement narrows markedly **before entering the vein ; 8, enlargement and termination of the right lymphatic trunk ; 9, 9, pectoral glands and trunks ; the one on the left terminates independently in the lateral aspect of the external jugular, near its junction with the subclavian ; 10, 10, thoracic duct ; it is considerably divided just within the thorax, and then again just before enlarging near its termination ; 11, 11, chylocyst on the ventral, and** right side of the aorta, and extending for a short distance into the thorax ; 12, 12, intestinal lymphatic trunks, one branch winds round the left side of the aorta, and terminates finally on the right side of **the chylocyst ; 13, left lumbar lymphatic trunk ; 14, right lumbar lymphatic trunk.**

Fig. 4997.—General View of the Lymphatic System of a White Rabbit. (Drawn by Mrs. Gage.) *a*, Stomach ; *b*, *b*, small intestine ; *c*, *c*, cæcum ; ***d*, the so-called vermiform appendix ; *e*, large intestine ; *f*, cœliac axis ; *g*, superior mesenteric, and *h*, inferior mesenteric artery ; *i*, external** epigastric artery displaced from the abdominal wall to the muscles of **the thigh ; *k*, sciatic nerve and other popliteal structures exposed by** removal of a segment of the thigh muscles ; *m*, saphenous or internal cutaneous artery ; *n*, *o*, femoral artery ; *p*, cut edge of the abdominal **wall ; *q*, ilio-lumbar artery ; *r*, right kidney, the left has been omitted, although the beginning of the renal artery is shown ; *s*, cut edge of the diaphragm ; *t*, aorta ; *u*, brachial and ulnar artery ; *v*, subclavian** vein ; *w*, external jugular vein ; *x*, trachea.

1, Trunks from the ventral lip and sides of the mouth ; 2, trunks from the snout ; 3, the two submaxillary lymphatic glands on either side of the facial vessels ; 4, lymphatic glands near the base of the ear ; 5, ental cervical lymphatic gland ; 6, left jugular lymphatic trunk on its way to join the thoracic duct ; 7, thoracic duct near its termination in the vein ; 8, cœliac glands, receiving the lymphatics of the stomach ; 9, 9, lacteals from the small intestine to 10, the great mesenteric gland (gland or pancreas of Asellius) ; it gives rise to two intestinal trunks, which are short, small, and difficult to inject with a coarse mass ; 11, large mesenteric gland receiving the vessels from the mass of lymphoid follicles at the termination of the ileum ; 12, lymphoid tissue, *sacculus rotundus*, at the termination of the ileum ; 13, gland receiving the lymphatic trunks from the vermiform appendix ; 14, glands in the meso-colon along the inferior mesenteric vessels ; the efferent vessels pass to the lumbar trunks ; 15, hypogastric or sacral lymphatic gland ; 16, gland on the abdomen by the external epigastric vessels—it has been **displaced with the artery to the thigh muscles ; 17, popliteal glands** receiving vessels from both sides of the crus, sending efferent branches between the peroneal and tibial nerves to follow the femoral artery, and another to accompany the ischiadic artery ; 18, lymphatic trunks from the dorsum of the foot, winding round the tibial or outer side of the calf to join the popliteal gland ; 19, lymphatic following the saphenous artery ; it usually divides near the knee, sending one branch to the pop**liteal gland ; 20, lymphatic trunk extending along with the femoral ar**tery ; it is formed by the intimate anastomosis of those accompanying the saphenous and deep femoral arteries ; 21, lumbar lymphatic glands ; **22, subcutaneous lymphatic gland near the ilio-lumbar blood-vessels,** just at the lateral margin of the sartorius muscle ; the efferent lymphatics follow the ilio-lumbar vessels and enter the lumbar glands ; 23, lumbar lymphatic trunks, the right one is much more divided than the **left ; 24, chylocyst ; 25, thoracic duct ; this is almost invariably more or** less divided and sends out a considerable branch to the right lymphatic trunk ; 26, pectoral lymphatic glands ; 27, anastomosing trunks fol**lowing the radial and brachial artery to the axillary glands ; 28, trunk following the radial nerve, winding round the brachium to terminate in the axillary glands also ; the broken line indicates that** the trunk would be out of sight in this view ; 29, axillary lymphatic **glands ; these are not very closely connected with the axillary vessels ; 30, termination of the right lymphatic trunk.**

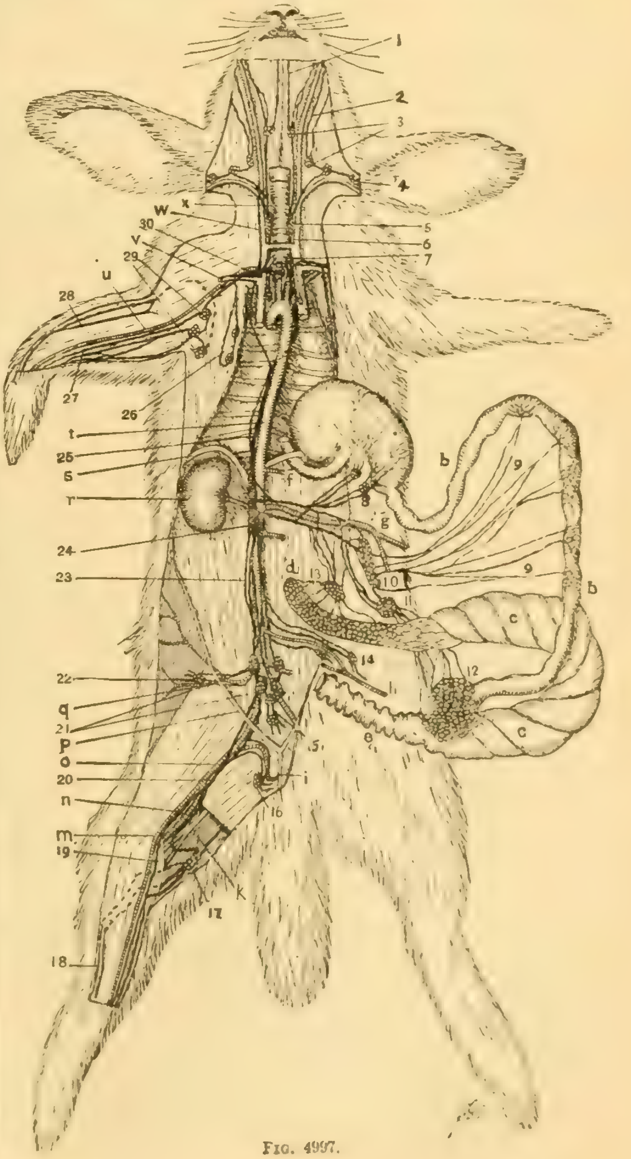

Fig. 4997.

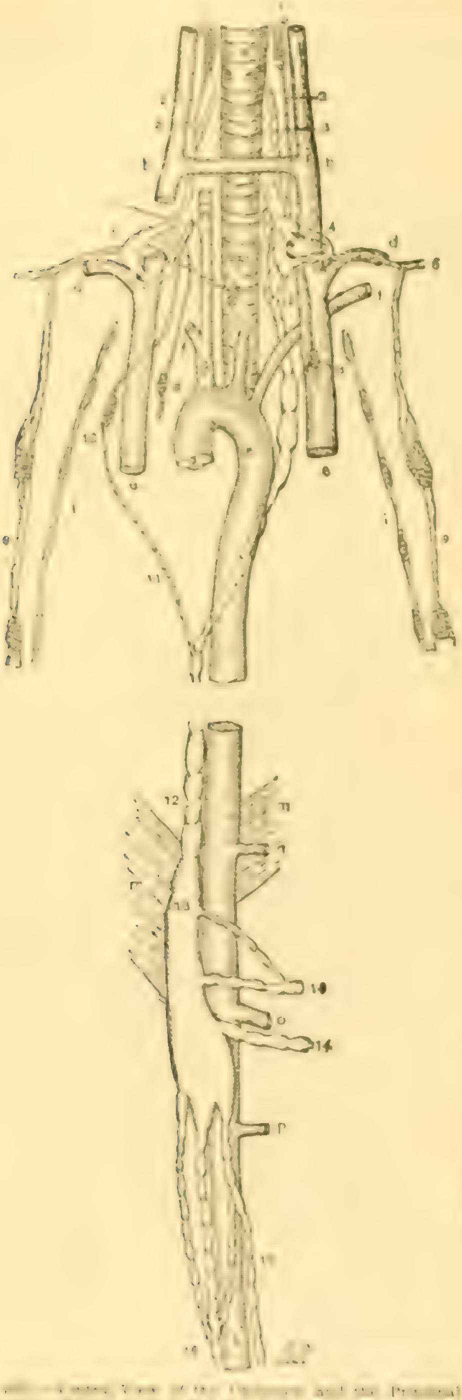
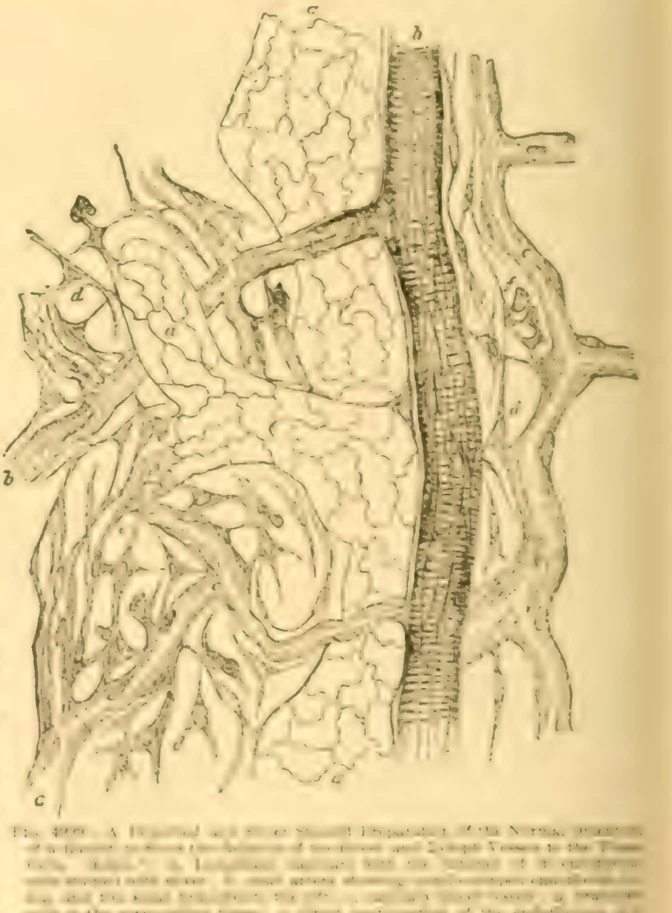


[illegible]

back into the blood capillaries. This system has been called *juice spaces and canals* by Recklinghausen,[6] and the *lymph canalicular system* by Klein.[7] These minute channels and spaces are all interconnected and continuous with the blood vascular system through the intercellular cement and spaces, and with the lymphatic vessels in the same way, and further, these spaces frequently, if not constantly, contain branched cells, the cell body filling the larger spaces and the processes the connecting channels. These cell processes are often projected between the endothelial lining of the capillaries,



[illegible]

[illegible]

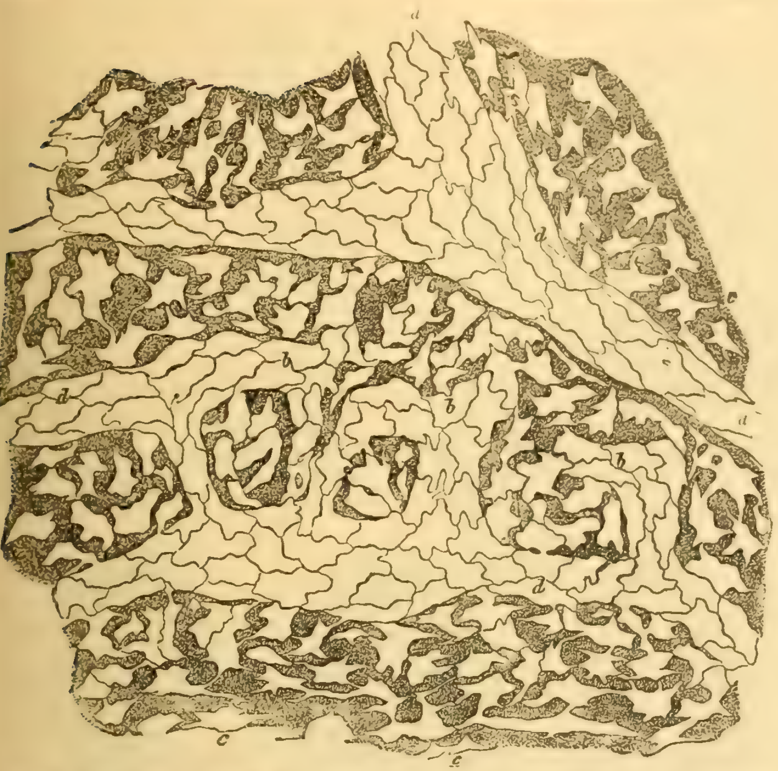


FIG. 5000.—Pencilled and Silver-stained Preparation of the Pleural Aspect of the Central Tendon of a Rabbit's Diaphragm, to show Lymphatic Capillaries and their Relation with the Cell Spaces. (Recklinghausen.[8]) Magnified 300 diameters. *b*, Beginning of the lymph capillaries by a continuity with the cell spaces; *c, c, c*, cell spaces surrounded by the dark ground substance. These spaces contain cells, lymph-canalicular cells, and the cell processes partly fill the white lines connecting the cell spaces (*cf.* Fig. 4999). *d, d, d, d*, Lymphatic capillaries with the serrated endothelial cells.

thus forming the so-called pseudostomata, and therefore bring the lymphatics and blood-vessels really into continuity by the intervening cells and the spaces surrounding them. This is well shown at *e*, in Fig. 4999.

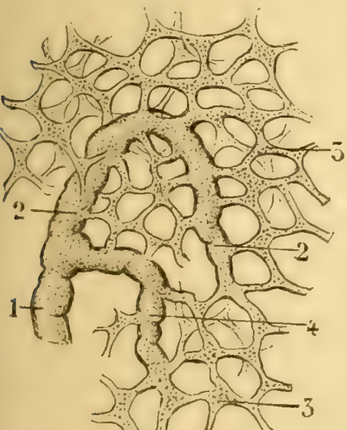

FIG. 5001.—Formation of a Lymphatic Capillary in the Skin of the External Ear. (Sappey, Atlas). 1, Lymphatic capillary; 2 and 4, two minute branches uniting to form the larger capillary; 3, 3, 3, lacunes or dilatations formed by the union of the minutest lymphatic vessels, the capillicules. The union of a multitude of these lacunes forms a lymphatic capillary. This is shown best at the lower part of the figure.

3. The third view is that of Sappey, who has represented with marvellous clearness the entire lymphatic system from origin to termination. He believes, and thinks he has proved by new and special means of research, that the lymphatic system at its origin is invariably composed of minute vessels (capillicules) from 1 μ to 4 μ in diameter, with structureless walls, which extend around and between all the structural elements. These capillicules are closed at the free end, but join, in nearly the same way as do the canaliculi of bone, to form somewhat larger spaces, the lacunes, which vary from 2 μ to 8 μ in diameter, and like the capillicules have structureless walls. By the union of many lacunes the true lymphatic capillaries are formed, and in them first appears the endothelial lining. Further, although the capillicules around and between the structural elements have blind terminations, those connected with the blood-vessels extend into the lumen between the endothelial cells, and have open mouths into which the plasma of the blood can freely enter, and in some pathological conditions they may become so large that the blood-corpuscles may pass through the capillicules to the lymphatic vessels. This view is in part a return to the original doctrine, and it also differs from the doctrine of the lymph canalicular origin in excluding the cells from the spaces or lacunes, and in giving distinct but structureless walls to the capillicules and lacunes.

The second view seems to the writer to be more in accordance with the teachings of modern biology and histology, by which the body is shown to be composed of a continuous net-work of interconnected structural elements, independent only in the form of blood-corpuscles, lymph-, and wandering-cells, but all the other elements being united either by cell cement or by delicate protoplasmic processes, and any spaces left between the structural elements being filled by the product of cell activity, which is known as ground or intercelluar substance. This is very abundant in some tissues, as cartilage, very slight in amount in others, as epithelia. All of these structural elements are constantly bathed with lymph, and it is more in accord with what is at present known of absorption and excretion (see article Nutrition, Vol. V.) to suppose that the lymph depends for its movement in certain definite directions upon the action of the living cells rather than on merely physical conditions. If this is the correct physiological view, then the anatomical structure of the lymph canalicular system and lymph canalicular cells of Klein seems most in harmony with the work to be done.

The readily demonstrated or apparent origin of the lymphatic vessels is in a plexiform network of valveless capillaries of varying sizes (Plates XXXIII. and XXXIV., and Figs. 5009 and 5010). From this capillary net-

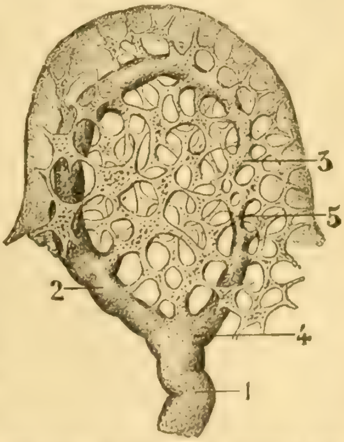

FIG. 5002.—Formation of a Lymphatic Capillary in the Papilla of the Skin of the Ear of Man. (Sappey, Atlas.) 1, Lymphatic capillary at the base of the papilla; 2 and 4, the two trunks of the capillary of origin uniting to form the large capillary; 3 and 5, the point of origin and connection of the two divisions of the capillary trunk. Between and around the originating capillary are the innumerable lymphatic lacunes which unite to form the capillaries, and also to enter them after their formation.

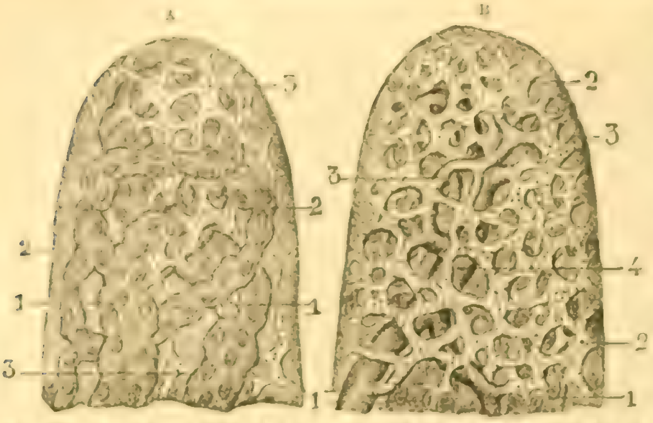

FIG. 5003.—Two Papillæ of the Lip to show the Relation of the Lymphatics and Blood-vessels. (Sappey, Atlas.) A, the blood capillaries, very few lymphatic capillaries and lacunæ being injected: 1, 2, anastomosing capillary loop; 3, lymphatic lacunæ. B, a similar papilla in which the lymphatic net-work is completely injected: 1, 1, blood capillaries with evident nuclei; 2, 2, net-work of lacunæ; 3, 3, lymphatic capillary uniting to form a considerable trunklet, 4.

work extend collecting trunks with abundant valves (Fig. 4978). The serous cavities are likewise directly connected with the lymphatic vessels through the stomata or pseudo-stomata (Figs. 5006, 5008). But according to Balfour and Hertwig the pleuro-peritoneal cavities are not primarily connected with the lymphatic system, but come to be so connected later. Budge has shown lately, however, that in the chick the connection with the body cavity is actually prior to the connection with the blood vascular system.

A distinct plexus of origin has been satisfactorily demonstrated in all the tissues and organs except the following, and in some of these, as the cornea, the lymph is known to circulate, although not in an independent net-work of vessels.

1. The central and peripheral nervous system and retina. The lymph in these situations is either in perivascular spaces or in perineurial spaces. In the optic nerve, however, Key and Retzius figure a well-defined lymphatic net-work.

2. A lymphatic net-work has not been satisfactorily made out for bone or cartilage, and Sappey denies their presence.

3. All forms of epithelia, including hair, nails, and teeth. But Klein figures and describes processes of branched cells projecting between epithelial cells and serving as lymph channels, but no distinct capillaries with endothelial walls are present.

4. Cornea and, according to Sappey, all forms of fibrous tissue, tendons, aponeuroses, fascia, and all serous membranes. Where a plexus of origin appears to be in these it belongs to the underlying tissue. According to many authors the connective tissue is a favorite place for the origin of the capillary lymphatic net-works. There is no doubt of the presence of the net-works, the only question is whether it belongs to the connective tissue or to the surrounding tissues.

The ducts of some glands (as the pancreas) have never yet been shown to contain lymphatics, although in the

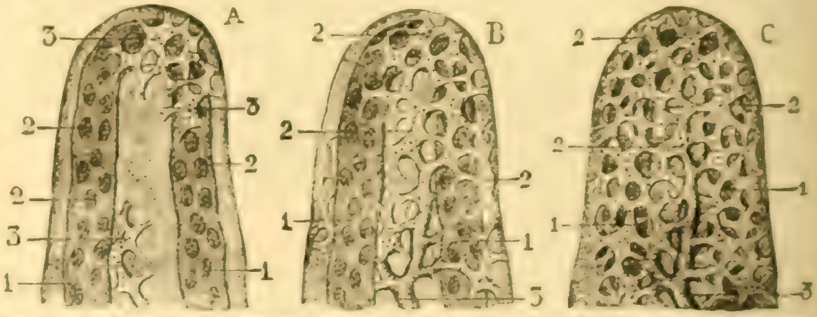

FIG. 5004.—A Simple Papilla from the Corium of the Hairy Skin of the Head, showing the Blood-vessels and Three Stages of Lymphatic Injection. (Sappey, Atlas.) A, a papilla, the simple blood capillary loop (1 and 2) with very few lymphatic lacunæ (3), and no sign of a lymphatic capillary. B, the lymphatic capillary (5) has appeared, and the lymphatic lacunæ and capillaries (2) are very prominent, but the blood capillary loop (1) is still evident. C, The blood capillary loop (1) is almost invisible from the dense net-work of lymphatic lacunæ and capillaries (2), the lymphatic capillary (3) is prominent. This series is an excellent illustration of the structures that remain invisible in ordinary preparations. Probably in very few histological preparations are more than half or one-third of the structures seen.

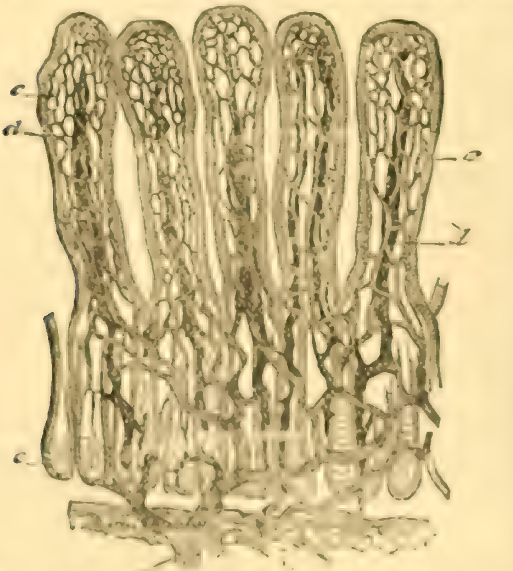

FIG. 5005.—Lacteals of the Intestinal Villi of the Dog. [illegible] a, Artery extending into the villi to form a capillary net-work [illegible]

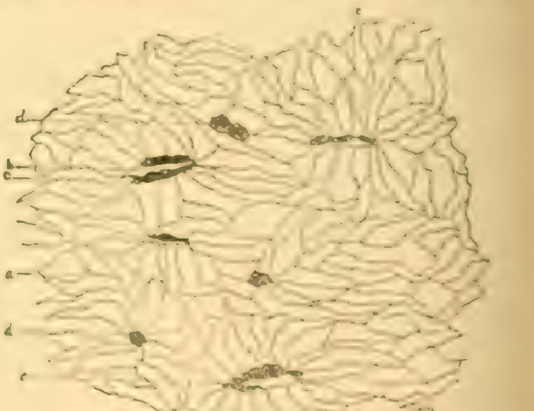

FIG. 5006.—Portion of the Cisterna Lymphatica Magna of the Frog, to show Endothelium and Stomata. (Ranvier.) a, ordinary endothelial cells, the nuclei not being shown; b, b, stomata leading from the peritoneal cavity into the dorsal lymph sac; c, c, germinating endothelium surrounding the stomata; d, germinating endothelia among the ordinary cells; these are frequently called pseudostomata.

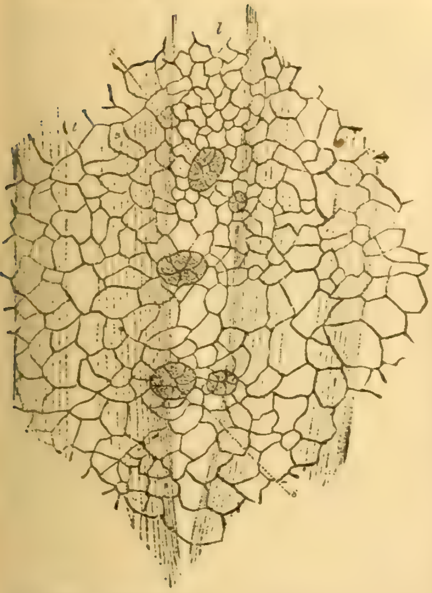

FIG. 5007.—Silver-stained Peritoneal Aspect of the Central Tendon of a Rabbit's Diaphragm, to show Stomata. (Klein[7].) *l*, Lymph channel between the tendon bundles; *s*, *s*, five stomata, surrounded by germinating endothelium and leading into the lymph channel between the two tendinous bundles. Part of the stomata are open and part closed; *t*, *t*, two bundles of the central tendon, between which is the lymph channel into which the stomata open. Over the tendinous bundles the endothelial covering is composed of markedly larger cells than over the lymph channel.

ducts of other glands, as the liver, lymphatics have been shown in great numbers.

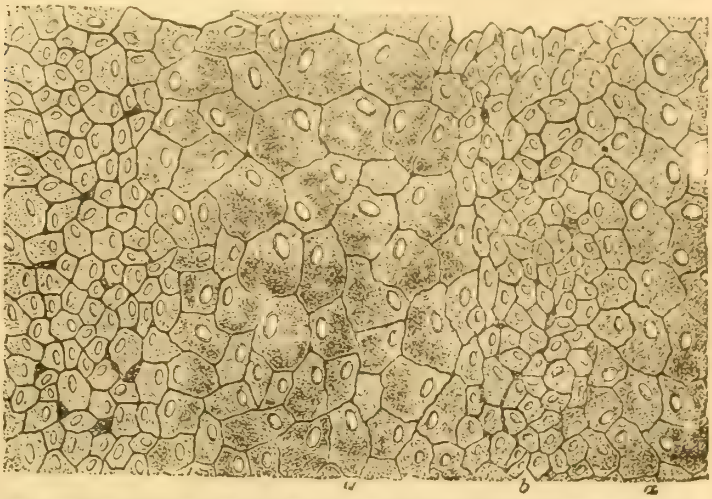

FIG. 5008.—Peritoneal Endothelium from the Central Tendon of the Rabbit's Diaphragm, to show the Difference in the Size of the Cells, and the Pseudostomata between them. (Klein.) *a*, *a*, Irregular rows of large nucleated endothelial cells, corresponding to underlying tendinous bundles; *b*, rows of smaller endothelial cells with numerous pseudostomata between them (the dark spots). The rows of small cells correspond to the lymph channels between the bundles (cf. Fig. 5007).

These net-works or plexuses of origin show considerable variety in different parts of the body. As a rule, the lymph capillaries are considerably larger than the blood capillaries (Fig. 5010), and there is a great tendency to form blind, often ampulliform enlargements (Fig. 5010). In the villi of elongated narrow form, the origin by a blind central vessel is normal, or there may be a simple loop instead (Fig. 5005). In man, where the villi are mostly short and broad, there is a complicated net-work something like the blood capillaries, except that the lacteal capillaries are much larger. The simple blind end and loop are also seen in some of the more elongated villi. The presence of

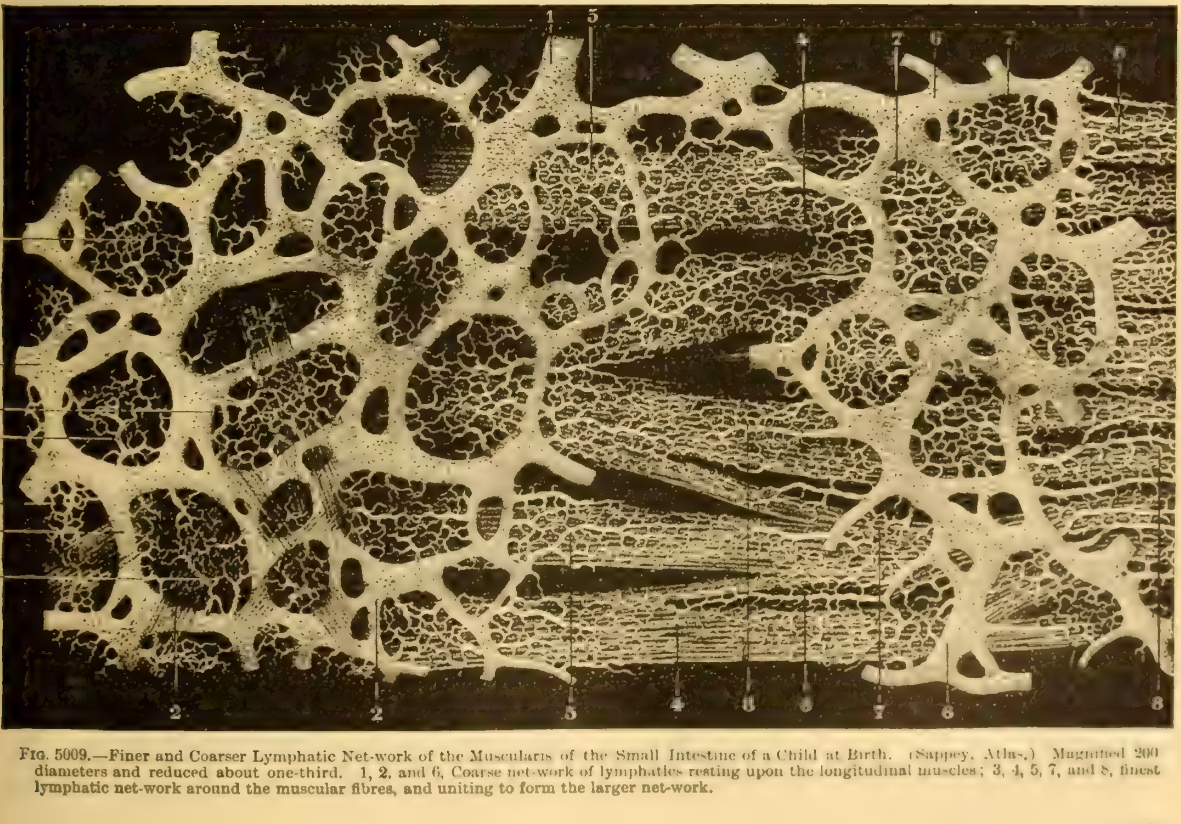

FIG. 5009.—Finer and Coarser Lymphatic Net-work of the Muscularis of the Small Intestine of a Child at Birth. (Sappey, Atlas.) Magnified 200 diameters and reduced about one-third. 1, 2, and 6, Coarse net-work of lymphatics resting upon the longitudinal muscles; 3, 4, 5, 7, and 8, finest lymphatic net-work around the muscular fibres, and uniting to form the larger net-work.

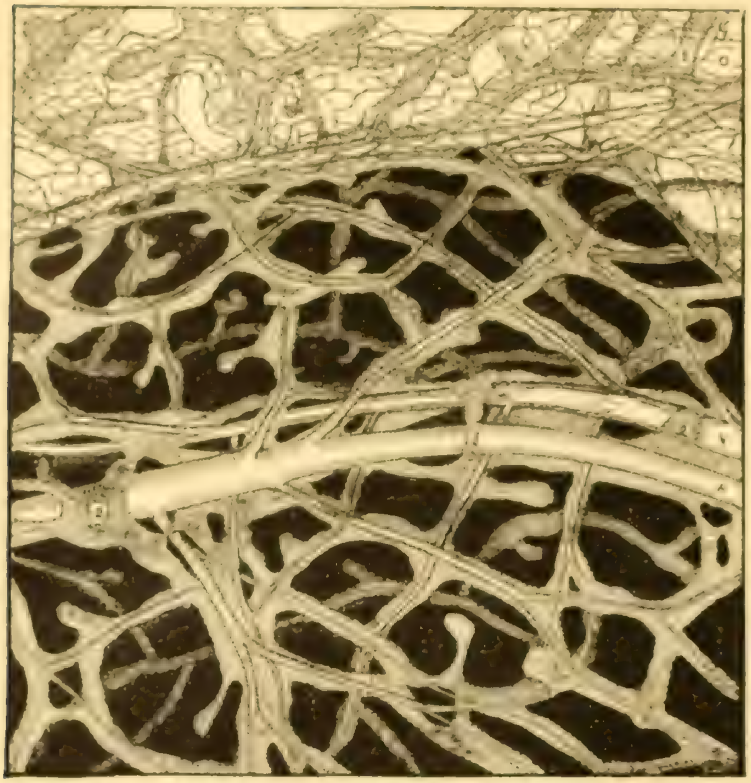

FIG. 5010.—Lymphatic Network in the Submucosa of the Rabbit's Cæcum, showing the Form of the Network and the Relation of the Lymphatics and Blood-vessels. Magnified 55 diameters. (Drawn by Mrs. Gage.) A, A, small arteries; V, small vein; C, the blood capillaries at the upper part of the figure; 2, 2, 2, 2, lymphatic vessels. Many of the vessels have blind projections, and throughout the entire figure is shown the tendency of the lymphatics to follow the blood-vessels and partly surround them. The preparation was made by direct [illegible] into the appendix vermiformis, when it extended into the submucosa of the adjoining part of the cæcum (see Fig. 4997). The blood-vessels were then injected with fine red gelatin mass from the superior mesenteric artery. After the gelatin had cooled the cæcum was distended with alcohol, and the preparation finally mounted in Canada balsam.

ampulliform enlargements, or even blind endings, in a vessel is not enough to determine whether it is a blood-vessel or a lymphatic, for some blood-vessels in muscle (Ranvier) and in the dura of the brain (Key and Retzius) have the form which is usually considered so characteristic of lymphatic vessels. The final test must be the connections of the vessel with a lymphatic gland or with an undoubted blood-vessel.

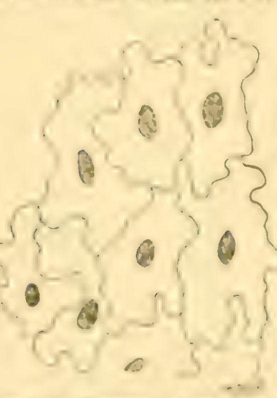

FIG. 5011.—Endothelial Cells from a small Lymphatic Capillary of the Central Tendon of the Rabbit. [illegible] (Gage.)

Structure of Lymphatic Vessels.—Beginning with the lymph capillaries the wall is composed only of endothelial cells arranged mostly in the form of a tube. They may, however, be more like flattened clefts, the walls of which are in apposition except when containing lymph. The lining cells have sinuous edges (Fig. 5011). On the larger vessels the lining endothelium has more elongated cell outlines (Fig. 5012), and there progressively appear coats like those of the blood-vessels, except that they are thinner. The adventitia is easily separated from the vessel, is composed of a network of fine elastic fibres and a few longitudinally arranged muscular fibre-cells. The middle coat has, besides the fine elastic tissue, many circularly arranged muscular fibre-cells. This circular arrangement is not strictly adhered to, especially in the thoracic duct. Finally, the inner layer has its elastic fibres mostly in a longitudinal direction, and the endothelium covers the inner surface. In the thoracic duct there is usually a considerable addition of white fibrous tissue to the middle layer, and, as stated above, many of the muscular fibres of this layer may be oblique or even longitudinal. In general, then, the lymphatic vessels agree with the veins quite closely in structure. The amount and the fineness of the elastic tissue present is supposed to exert a marked influence in causing the speedy return of the vessel to its normal calibre after its distention by the lymph.

Like the veins, the lymphatics are distinguished by the presence of valves, but they are much more abundant, there being, for example, sixty to eighty double valves from the hand to the axilla (Fig. 5013). In examining a well-injected preparation, it is very easy to determine the direction of the lymph stream as the segments of the vessel are approximately conical, the apex of the cone pointing in the direction of the stream (Fig. 5013). This is more marked in the smaller than in the larger vessels.

Valves are not found in the lymphatics of animals below the amphibia, and are much less numerous in amphibia, reptiles, and birds, than in mammals. The development of lymphatic vessels, so far as has been investigated, agrees closely with the development of blood-vessels.

LYMPHATIC GLANDS AND LYMPHOID TISSUE.—The lymphatic glands or ganglia or conglobate glands are rounded or flattened bodies placed in the course of the lymphatic vessels. These glands were known to Hippocrates, but were considered by him as forming a part of the general glandular system. Naturally their true nature was discovered only after the discovery of the lymphatic vessels. In the higher mammals it is believed that no lymphatic vessel reaches one of the common terminal trunks without first traversing one or more of these glands. They do not appear until we reach the birds, or perhaps some of the highest reptiles, but lymphoid tissue is present in all the forms; and as the glands are practically concentrations of this lymphoid tissue their absence is not so important as might at first appear. The glands are sometimes solitary but usually are in groups or chains; they are mostly near blood-vessels, and so placed and loosely attached that they readily move aside to avoid pressure. In the limbs pressure is further avoided by position in the flexures of the joints. The glands vary greatly in number and size in the different mammals. In man they reach the highest number (300 to 600), and vary from a few millimetres to two or more centimetres in diameter.

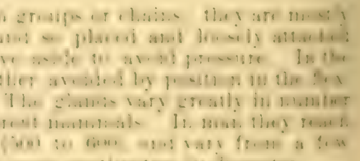

FIG. 5012.—Nucleated Endothelial Cells from one of the Larger Lymph-Channels of the Central Tendon of the Rabbit's Diaphragm, to show the Elongated Form of the Cells in the Larger Vessels. Cf. Fig. 5011. (Gage.)

Afferent and Efferent Vessels.—The vessel approaching a gland is said to be afferent or inferrent; the one leaving the gland is called efferent. On approaching a gland the afferent usually breaks up into several smaller vessels which enter the gland (Figs. 5013 and 5014). After traversing the gland the vessels leaving the surface unite usually in larger trunks than the afferent vessels, and continue to the next gland, where the process is repeated, or the vessel may terminate in one of the common trunks.

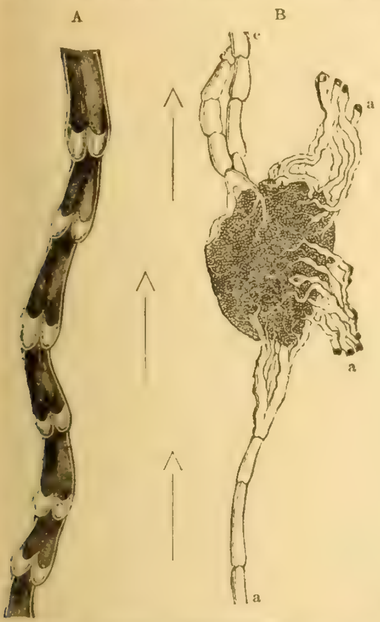

FIG. 5013.—Valves of a Lymphatic Trunk, and a Lymphatic Gland with its Afferent and Efferent Vessels. (Sappey.) A, Lymphatic trunk slit lengthwise and opened to show that the valves are in pairs—they are close together and they are at the level of the enlargements; further, that the intervalvular segments are in general of a conical shape, the apex of the cone pointing in the direction of the current, up in this figure. B, Lymphatic gland; a, a, a, the numerous afferent lymphatic vessels; e, the two voluminous efferent lymphatics.

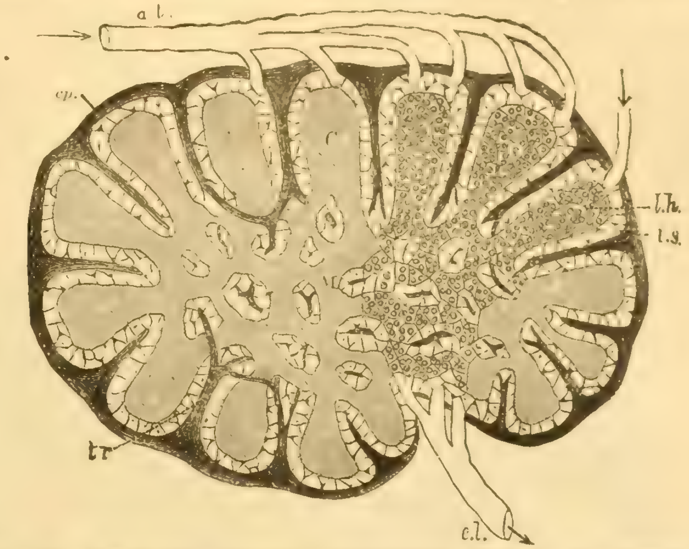

FIG. 5014.—Diagrammatic Section of a Lymphatic Gland. (Sharpey.) *a.l.*, Afferent trunk breaking up into several smaller trunks before entering the gland; *e.l.*, efferent lymphatic trunk formed by the union of several smaller trunks emerging from the gland (the arrows indicate the direction of the current); *C*, cortical glandular substance; *cp.*, capsule sending septa into the gland; *i.h.*, reticulated cords of medullary substance (it is shown in only a small part of the figure; the entire area shaded with lines possesses similar glandular substance); *l.s.*, lymph-sinus or channel; ***M***, central or medullary part of the gland (it is directly continuous with the cortical substance); *tr.*, trabeculæ or fibrous substance continuous with the capsule and forming a coarse meshwork in the gland (in this mesh is the proper gland substance).

The structure of the lymphatic glands was long enigmatical. It was held by many, and is still so held, that the gland was really a kind of fine capillary net-work, like a renal glomerulus or a rete mirabile, of blood-vessels; but it is now quite generally agreed that a lymphatic gland consists of the following parts: (1) A fibrous framework forming an enclosing capsule and sending into the interior a multitude of anastomosing trabeculæ. The capsule and larger trabeculæ may also contain muscular-fibre cells. (2) Embedded in the meshes of this fibrous net-work is the proper glandular substance, which consists of lymphoid tissue; that is, a fine net-work of branching and anastomosing cells and fibres containing in their meshes lymphoid corpuscles or young lymph-cells. Near the surface of the gland the lymphoid tissue is arranged in quite regular masses (cortical lobes or alveoli) by the projecting trabeculæ (Fig. 5014). This is the so-called cortical portion, while in the central part (medullary portion) the lymphoid tissue is in more cylindrical masses (the medullary cylinders or lymphoid cords), but the tissue in the two parts is directly continuous. (3) The lymph-sinus or channel. This is the path taken by the lymph in passing through the gland from the afferent to the efferent vessels. It is a narrow space filled with rather coarse reteform tissue, between the proper glandular substance and the fibrous framework (Fig. 5014, *l.s.*). The relations of this space may be clearly understood by comparing the fibrous framework to a mould and the proper glandular substance to the material poured into the mould and which, upon cooling, had shrunken evenly from the mould throughout the entire gland, thus leaving a narrow space which would represent the lymph-channel. The afferent lymph-vessel penetrates the sheath or capsule of the gland and pours its contents into the lymph-sinus.

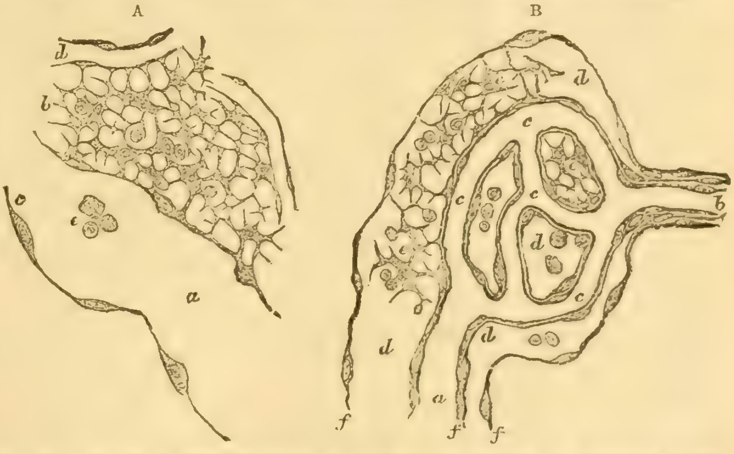

FIG. 5015.—Figures of Fresh Preparations of an Œdematous Omentum of a Guinea pig suffering from Chronic Peritonitis, to Show Developing Lymphatic Nodules seen in Optical Section. (Klein.[7]) A, Perilymphatic or lymphangial nodule; *a*, lymphatic vessel, *b*, a portion of the lymphangial nodule on the side of the vessel; *c*, endothelial wall of the lymphatic seen in profile; *d*, blood-capillary of the nodule; *e*, lymph corpuscles in the lymphatic vessel (this nodule is like the reticular substance forming the proper glandular substance of the lymphatic glands, and as seen both in A and B the cells of the reticulum are in direct connection with the endothelium of the lymphatic vessel). B, An endolymphatic or lymphangial nodule in which the reticular tissue is within instead of being on the side of the vessel *a*, vein; *b*, artery; *c*, blood-capillaries; *d*, a lymphatic vessel enclosing the whole system of blood-vessels; *e*, reticulum of nucleated branched cells or lymphoid tissue connected with the wall of the lymphatic and filling the entire lumen.

The lymph thus slowly moves among the labyrinthine channels until it reaches the efferent vessels, when it enters them and continues toward the common lymph trunk. In passing through the sinus the lymph bathes the glandular substance and probably leaks into it. Along the edge of the channel the newly developed lymph cells enter the lymph-stream and are carried along to the efferent vessel.

Blood-vessels are very abundant in the lymphatic glands and are found almost exclusively in the proper glandular substance. These blood-vessels are also accompanied by nerves. In some glands the efferent vessel and the blood-vessels are found mostly in a small depression which, in analogy with the kidney, has been called the hilum. This is not a marked feature and is absent in many cases.

In infancy and youth the glands near the surface are grayish in color while those in the interior of the body are pinkish. In adult and advanced life the glands are usually somewhat atrophied and darker in color, and those of the bronchial plexus are often dark brown or even black.

Lymphoid or adenoid tissue is like that described for the proper glandular substance of the lymphatic glands; that is, a fine net-work of branching and anastomosing cells or fibres with the meshes crowded with lymphoid cells. Sometimes this tissue is quite sharply defined, when it is called a follicle or simple lymphatic gland; in other situations it is diffuse. The tissue is abundantly supplied with blood-vessels, and the lymphatic vessels on its surface and emerging from the interior are in great abundance (Fig. 5016). The diffuse and follicular form of the tissue is found in great abundance in the alimentary canal of man and the lower animals. In the tonsils and the pharyngeal tonsil it is aggregated in considerable masses; so also in the Peyerian patches, which are simply an aggregation of lymph nodules, follicles, or solitary glands. The mucosa of the vermiform appendix of the rabbit (Fig. 4997) is almost entirely occupied by a great Peyer's patch; and the so-called solitary glands (Fig. 5016) are lymphoid nodules or follicles with a dense mesh-work pervaded by blood-capillaries and filled with lymph corpuscles. They are surrounded by a capillary net-work which helps to separate them somewhat from the surrounding less condensed lymphoid tissue (Fig. 5016).

[illegible] 1, [illegible] Lymph-follicles [illegible]; 2, 2, 2, 2, Lymphatic [illegible] in the depth of the follicle and ascending to the surface; 3, 3, 3, [illegible] formed by the orifices of the [illegible]; 4, 4, four of the crypts of Lieberkühn.

PHYSIOLOGY.—The blood- and lymph-vessels form part of the great circulatory system by which fluids are conveyed to and from the tissues, carrying in solution all the elements needed for nutrition and growth and removing waste. In describing the more marked part taken by each division of the system the blood-vessels have been very aptly described as a system of irrigation channels, and the lymphatics as drainage canals. This does not of course express the whole truth, for the veins are likewise drainage canals, and the lymphatics and their continuation, the lymph channels, supply nutriment and remove waste in situations where no blood-vessels are found, as in the cornea.

In the first enthusiasm over the lymphatic system, especially the lacteals, whose function seemed pre-eminently that of absorption, it was believed that all the absorption done in the body was by the lymphatic system. The blood-vessels conveyed the nutritive media to the tissues, and all waste or superfluous matter, and all food, found their way to the blood through the lymphatics. But the careful experiments of Magendie and others on absorption from the alimentary canal, the real stronghold of the lymphatics, showed that the blood-vessels also absorb, and the final outcome physiologically is that the lymphatic system is considered simply as an aid to the blood-vascular system. It is a remarkable fact that while with all the mammals the intestinal lymphatics absorb a great amount of the emulsified fat so that the connecting trunks are white from the contained chyle, in the animals below the mammals—at least, the birds, reptiles, and amphibia—the lymphatics of the intestine never appear white, and the natural inference is that the fatty food does not reach them. This subject of the absorption from the alimentary canal of these lower forms requires a thorough investigation.

Besides the absorptive action of the lymphatic system, it is a great manufactory of white blood-corpuscles

This takes place mostly in the lymphoid tissue in the lymphatic glands, and in this tissue wherever it is found. It is also thought by many investigators that the lymphoid tissue has to do also with the production of red blood-corpuscles.[12]

The movement of the lymph-stream is slower than that of the blood-stream, moving only 230 to 300 mm. in a minute in a large lymphatic of a horse. The flow of the lymph is dependent on several different factors: (1) The vessels, being so well supplied with valves, are able to make all movement due to outside pressure serve to produce an onward current; (2) the walls of the lymphatic vessels are contractile, owing to the muscular-fibre cells present, and these by their slow contraction—a contraction which has been seen to be rhythmical in some cases—aids in keeping the lymph in motion: this contraction has been observed in the lymphatics of man as well as of animals; (3) the intestinal villi contract vigorously, thus giving the chyle its initial movement; (4) the muscular tissue in the capsule, and sometimes also in the trabeculæ of the lymphatic glands, is supposed to compress the gland and thus hasten the flow through it. This would, however, only partly compensate for the retardation in traversing the narrow and greatly obstructed passages in the gland; (5) the aspiration of the thorax. This tends to suck the lymph of the terminal trunks into the veins. With the thoracic duct it tends to fill the whole duct, and then, from the abundance of valves, the pressure of expiration forces the lymph into the vein in jets; (6) on the principle of Sprengel's air-pump the more rapidly moving stream in the larger trunks tends to suck the lymph from the smaller branches, and the rapidly moving blood in the veins has the tendency to draw the lymph into the veins, any reversal of the current being guarded against by the presence of the valves at the openings; (7) doubtless the most important factor in the movement is the pressure at the periphery, a pressure really originating in the left ventricle of the heart.

Methods.—The lymphatic vessels are so thin that unless they contain some liquid or solid they are not visible. One of the first ways of making the general lymphatics visible was to inject water or colored gelatin into the arteries of an organ. The mass exudes and fills the lymph-vessels; this is especially successful if the vein is tied. The lacteals are made evident by feeding the animal some fatty food, like milk, an hour or two before death.

Vessels of sufficient size may be injected centrad with starch or plaster-of-Paris. It is not necessary to tie the cannula in place; simply pressing upon it with the fingers is sufficient. The insertion of the cannula is greatly facilitated by first inserting a beaded bristle into the lymphatic, then by raising the bristle the cut in the vessel may be seen. Where the vessels are too small to be seen, very successful injections may be made by the puncture method. That is, a hypodermic cannula is connected with a syringe or a constant-pressure apparatus, and inserted where lymphatics are supposed to be. The cannula is forced in as in ordinary hypodermic injections, and the mass allowed to flow or it is forced in. If the attempt is successful, the fine net-work and collecting trunks of a limited area will be injected. The toes and the finger-tips of man are favorite places for injection. In animals the pads of the feet and the bare spot on the snout are good. A lymphatic gland is always easy to inject. For a mass, mercury is generally used, but colored gelatin has the advantage of cheapness and of flowing readily through the glands in the course of the vessels. An excellent gelatin mass is Hoyer's chrome yellow: dry gelatin, 15 grams; water, 75 c.c. After the gelatin is added it is melted over a water-bath, and heated to 80° C., then 75 c.c. of a cold saturated solution of bichromate of potash, heated to 80° C., is added to the gelatin; finally, 75 c.c. of a cold saturated solution of acetate of lead is heated to 80° C. and added with constant stirring.

The puncture method was used by Hunter, Mascagni, and Cruikshank. Cruikshank, in his "Anatomy of the Absorbing Vessels" (1790), p. 44, says: "I have sometimes injected the lacteals from punctures made by the side of the veins where I knew they must be, though they were then invisible to the naked eye." He also injected the lymphatic glands by puncture.

Young animals are best for studying the lymphatics, and the leaner the animal the better. In man lymphatics have been demonstrated in organs in the fœtus when they could not be in the adult. Mature animals are better for the lymphatics of the reproductive organs; and for the pancreas an old man or animal is to be chosen.

BIBLIOGRAPHY.

The writer wishes to express his great indebtedness to Professor Wilder for generous supplies of material for investigations in the comparative anatomy of the lymphatic system, for aid in purchasing costly works, and for hearty encouragement; to the library of the Surgeon-General's office for the loan of rare and valuable works of reference, and, finally, to the editor for encouragement and suggestions.

In preparing the article free use has been made of the larger works on physiology: Flint's treatise, Landois and Stirling; Milne Edwards, Leçons, etc. In human anatomy, Allen, Gray, and Quain in English; Sappey in French; Henle, Krause, Gegenbaur, and Hoffmann in German. The clinical remarks are especially complete and satisfactory in Allen; many very suggestive remarks are also made in Sappey's Atlas. In comparative anatomy the works of Owen, Gegenbaur, and Parker's translation of Wiedersheim, in English, and Milne-Edwards' Leçons, in French, are the most satisfactory. For the bibliography of the subject Milne-Edwards, Hoffmann, and Robin (see [5] below) are especially commendable, as is also the Index-Catalogue of the Surgeon-General's library. Specific references have been made to the following:

Simon Henry Gage.

MULTIPLE NEURITIS is a disease of the peripheral nervous system, consisting of a more or less widespread, symmetrically distributed, degeneration in the nerves.

History.—This disease has only recently been generally recognized and diagnosticated. The symptoms which it presents had been for many years known and classified under the terms "alcoholic paralysis," "general spinal paralysis," "acute ascending myelitis," and had been erroneously referred to disease of the spinal cord. In 1864, Duménil,[1] of Rouen, recorded a case of paralysis, in which lesions of the nerves were found after death, and two years later he published another similar case.[2] But no notice was taken of these cases until 1876, when Eichhorst, of Berlin, recorded a case[3] of widespread disease of the peripheral nerves. This article of Eichhorst, and those of Joffroy,[4] in 1879, Leyden,[5] 1880, Lancereaux,[6] 1881, and Grainger Stewart,[7] 1881, attracted attention to the new disease, and many observations followed; so that, in 1884, Buzzard[8] was able, in the Harveian lectures, to present a clinical picture of the affection, and the writer, in 1887,[9] in the Middleton Goldsmith lectures, was able to collect a large number of facts bearing upon the pathology, etiology, and diagnosis of this disease.

Pathology.—The lesions in multiple neuritis are limited to the peripheral nerves, and are found to be more intense in the peripheral branches of those nerves than in the nerve-trunks. The condition found is one of degeneration, similar in all respects to the degeneration present after injury of a nerve (see Neuritis). The medullary sheath of the nerve-fibre is swollen, is divided into segments of semifluid consistency and fatty appearance. Its continuity is broken, and its insulating function suspended. This may be the only lesion in a very mild case, and regeneration may follow the degeneration. In more severe cases the degeneration proceeds, the medullary sheath is broken up into fine granules of fat or into a molecular débris, and is absorbed, and the axis cylinder is not only swollen, degenerated, and divided, but may also be changed into a granular mass and completely absorbed, so that an empty sheath of Schwann alone remains as a trace of the former nerve-fibre. In all the process the sheath of Schwann participates, its connective-tissue nuclei being swollen and segmented, and new nuclei appearing inside and outside of it. All these processes may be present simultaneously in various fibres of a nerve.

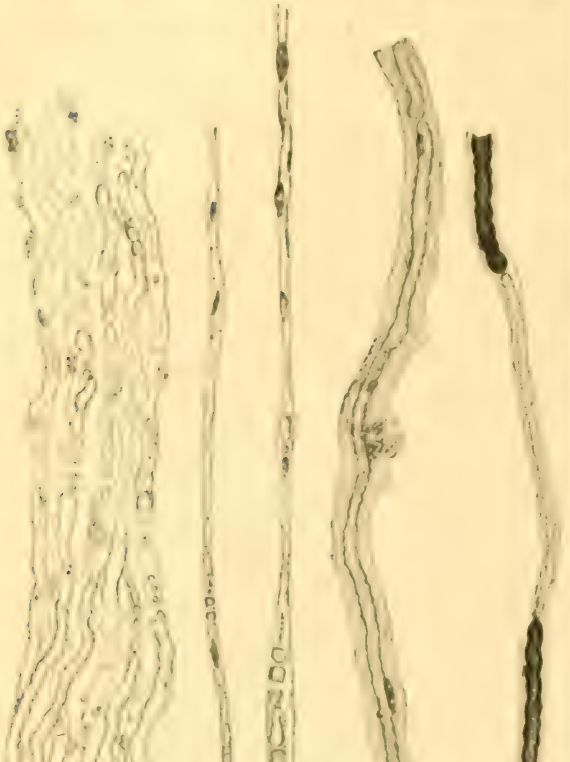

FIG. [illegible].—The Process of Degeneration and Regeneration going on in Normal Nerves. (After Mayer.) a, Segmentation of the myelin; b, remnants of sheath of Schwann [illegible]; c, sheath of Schwann, containing only nuclei and myelin; d, [illegible] in the sheath in process of regeneration; e, regeneration of a single segment after degeneration.

After the degeneration has proceeded for a time, regeneration begins. This takes place either by a development of new axis cylinders and medullary sheaths from nuclei in the old sheath of Schwann, as Neumann[1] holds, or by the growth of new axis cylinders outward from the undegenerated part of the old fibre into the old sheath, as Ranvier teaches.[1] This form of neuritis, in which the changes are especially marked in the nerve-fibres, is termed parenchymatous neuritis, in distinction from the second form, in which the connective-tissue elements take a more active part in the inflammation. Interstitial neuritis appears to have the same origin, and to occur under the same circumstances, as parenchymatous neuritis, but in it the endoneurium and perineurium take part in the process, and the increase of connective-tissue elements in the affected nerves is very noticeable. As far as is known, the process of regeneration does not differ in the two varieties. Lastly, a diffuse neuritis may occur in which both parenchyma and interstitial tissue are affected together.

Etiology.—There are many causes which produce multiple neuritis, and the cases may be classified according to the etiology.

There are, first, *cases due to toxic agents*, of which alcohol, lead, arsenic, bisulphide of carbon, and illuminating gas are the most active. All these agents produce widespread and serious effects upon the nervous system, but in many cases these effects are chiefly manifested in life, and at the post-mortem table, as changes in the peripheral nerves. The majority of cases of "alcoholic paralysis," "lead palsy," and "arsenical pseudotabes" are due to multiple neuritis.

There are, secondly, *cases due to infectious agents*, of which those producing diphtheria, variola, typhus, typhoid, malaria, and tuberculosis have been hitherto recognized. In the course of all these diseases, or as a sequel to them, multiple neuritis may develop, and its occurrence is too frequent to be accidental.

There are, thirdly, *cases occurring in epidemics* in many tropical countries, notably Brazil, India, Japan, Africa, and in the East and West Indies. Sporadic cases of this description developing among sailors on shipboard, occasionally find their way to our seaports. The disease is called kakke in Japan, beriberi in India and Brazil. It presents certain features which differ from those of the ordinary form. It has been ascribed to dampness, to a diet of rice or of fish, and to an infectious micro-organism.

There are, fourthly, *cases supposed to be due to exposure to cold* and dampness, and to *over-exertion*, or in which no cause is known.

In all these forms the clinical features of the disease are essentially the same, although different cases present a variety of combinations of symptoms.

Males are more liable than females. All ages after puberty are equally represented, excepting in diphtheritic cases, which occur chiefly in childhood.

SYMPTOMS.—The individual symptoms of multiple neuritis are very numerous.

The *sensory symptoms* are the earliest to appear and the last to pass away. In the majority of the cases of neuritis from whatever cause, numbness, tingling, or formication ushers in the disease. These forms of paræsthesia begin in the feet and hands and extend to the knees and elbows. They may be associated with burning, stretching, [illegible], or tearing sensations, which distress the patient especially during the onset. But all such sensations usu-

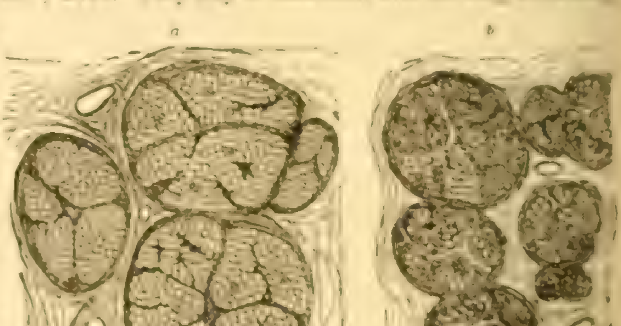

FIG. [illegible].—(After [illegible].) a, Section through normal nerve; b, section through degenerated nerve in a case of multiple neuritis, bundles reduced in size, individual fibres degenerated, their place being taken by débris.

ally subside as the affection reaches its height. Their recurrence, as the case goes on, may be regarded as a favorable symptom, however annoying, for they frequently precede recovery, and are among the last evidences of the disease to disappear. Pain is usually present as well as paræsthesiæ. It may occasionally be sharp in character, but is usually moderate and not continuous. At times it may be lancinating, and so severe as to necessitate the use of morphine. But it is rarely as distressing as in cases of locomotor ataxia. Tenderness in the nerves and muscles is a constant symptom. It may be so marked that the limbs cannot be moved or handled, and thus it may interfere with the application of electricity and massage. When the tenderness and pain are referred to the joints, as not infrequently occurs in the early stage of the disease, the case may be mistaken for one of acute articular rheumatism, and if the joints are swollen or the limbs œdematous, the difficulty of diagnosis is greatly increased.

In addition to these subjective feelings, some demonstrable disturbance of the various sensations is usually present. Hyperæsthesia to touch, and also to electricity, is not infrequently observed during the first few weeks. It is usually followed by some anæsthesia, although this rarely becomes complete. In some cases the loss of tactile sense is quite evident from the onset, either limited to the cutaneous distribution of some special nerve, in which case oddly shaped areas of insensibility will be found; or, as is most often the case, about uniformly distributed over the distal parts of the extremities. When the anæsthesia is at its height the patient has difficulty in locating a touch upon the limb, even though he feels it. The transmission of pain and temperature sensations is always delayed, but the impressions are usually felt quite acutely. The sense of pressure has been tested in only a few cases, and in those it was decidedly impaired. The muscular sense escapes being involved in some cases, but in others it is the most profoundly disturbed of all the senses. When it is involved, the inco-ordination and ataxia are well-marked symptoms, and, as already stated, some of the cases have been mistaken for locomotor ataxia, because of the predominance of the disturbance of muscular sense.

These sensory symptoms are usually limited to the forearms and hands, and to the legs and feet. In a few cases they have involved the entire extremities, and even the trunk; and one case of facial tingling, with anæsthesia, has been recorded.[12] The skin reflexes are usually preserved. In a very few cases the sensory symptoms have been entirely wanting.

The special senses are rarely affected in multiple neuritis. It is true that optic neuritis has occurred in a few cases, and in two cases hearing as well as sight has been affected. These cases prove that no nerve can be said to be exempt from implication in this disease, but the liability to affection seems to be slight in the case of the nerves of special sense.

The *motor symptoms* are as marked and as important as the sensory. Paralysis, beginning as simple weakness, with a feeling of fatigue on any exertion, gradually increases in severity, until at the height of the disease it becomes complete. It usually comes on rapidly, so that within two weeks the patient is helpless; but it may be less sudden, and not deprive him of the power of walking and of using his hands for two or three months. In a few cases a very acute onset is recorded, all the symptoms developing within three or four days. The distribution of the paralysis is not uniform at the outset. It may develop in the muscles supplied by a single nerve, and advance to others; it may begin in all the muscles of the legs, and then involve those of the forearms; it may commence in all four extremities at once. It is always more severe in the muscles which move the joints of the feet and hands, and the ankles and wrists. It rarely invades those which move the knees and elbows. When the disease is fully developed, all the muscles below the knees and elbows are much weakened, or totally paralyzed. In a few cases those of the thighs and arms are involved also, and occasionally the muscles of the trunk and those of respiration become affected and the patient dies. In some cases of multiple neuritis the motor cranial nerves become involved; those of the eye and of the face being most liable to invasion. It is only in fatal cases that the action of deglutition has been affected; and when the pneumogastric is invaded, and the heart becomes rapid and irregular, the prognosis is always grave. Spasms rarely occur.

The paralyzed muscles are relaxed, flabby, and atrophied; they may or may not lose their mechanical irritability, but their normal tone is always lost, and hence the so-called tendon reflexes are abolished. To the electric current their excitability is very rapidly and markedly changed; but the conditions which have been observed are quite various. Sometimes there is a simple diminution of excitability, and then a very strong faradic or galvanic current is needed to produce contractions. Frequently all faradic excitability is lost, and then the muscles react to a galvanic current only. In this condition it may require a very strong galvanic current to produce contraction, and this fact is quite pathognomonic of neuritis. For in anterior poliomyelitis, where the muscles respond to galvanism only, it does not require a strong current to cause a motion until some months after the invasion. The action of the different poles is not uniform. In many cases the contraction of the muscle when stimulated with the positive pole is greater than when stimulated with the negative pole, and the contractions may be sluggish. Then the reaction of degeneration is present. But in some cases the normal condition is found, and the negative pole produces stronger contractions than the positive pole. If the muscles that are not paralyzed be tested, the same electrical changes may often be discovered in them. A loss of faradic irritability and a marked decrease in the galvanic irritability of the muscle and nerve are, therefore, important symptoms of multiple neuritis. And as the disease goes on to recovery a gradual increase in the galvanic irritability occurs, a fact which is often of much aid in prognosis, if careful measurements of the strength of current used be made by the galvanometer.

As a result and accompaniment of the paralysis, *abnormal positions* are assumed by the limbs. The dropped wrist and dropped foot are quite characteristic of multiple neuritis. But other deformities may be present. In a few cases there have been extreme contractures of all the extremities in flexed position. And not infrequently the appearance of the claw-shaped hand, and some one of the various forms of talipes, indicates a serious shortening of one set of muscles, and corresponding weakness of its opponents. These deformities usually subside as the power returns, or if they do not they can be corrected by proper manipulation and by apparatus. In a few cases it has been necessary to resort to tenotomy, but a permanent deformity has not been recorded.

The *vaso-motor and trophic symptoms* are less constant than those already described. They are present in the epidemic form in all cases, and are especially severe. In some cases marked œdema has been an early and a permanent symptom. This may develop in the feet and hands, or may appear about the joints. It usually is temporary. The circulation is not impaired any more than is customary in a limb whose muscles are inactive, and coldness and cyanosis are rarely sufficient to attract attention. Sometimes profuse perspiration is a noticeable symptom, being limited to the paralyzed parts. It may be offensive, and by its evaporation always causes a complaint of coldness. In other cases glossy skin makes its appearance early, and remains until regeneration of the nerves begins. Its disappearance in one of my own cases was the first sign of recovery in the lower extremities. Other forms of trophic disturbance are rarely met with in multiple neuritis. And this is quite remarkable in view of the fact that it has been the tendency of late to refer such trophic affections as ulcerations, bed-sores, gangrene, pemphigus, and various eruptions to lesions of the nerves. It is true that inflammations of the joints, resembling those appearing in acute rheumatism, sometimes occur at the onset of neuritis, but as they disappear quickly, while other symptoms remain, it is improbable that they are to be traced to the changes in the nerves. They may be due to the infectious agent, or to the same toxic cause which sets up the neuritis, or they may be evidence of an attack of acute articular rheumatism, which is in turn followed by neuritis; but they cannot be described as typical symptoms of the disease, otherwise they would be more constant in their occurrence and more permanent in their duration.

One feature of alcoholic paralysis remains to be noticed, viz., the cerebral symptoms. These are hardly ever wanting. There is at first the excitement rising to the degree of active delirium, with illusions and hallucinations of the various senses; there is the insomnia, which so much exhausts the patient if it is not controlled; there is the loss of memory, especially of recent occurrences; and the lack of power of attention or concentration, which prevents intelligent conversation. The indifference to bodily wants may be so great as to lead to uncleanliness, and since paralysis of the sphincter is the rare exception, incontinence is usually to be ascribed to the mental state. It is useless to attempt to get any reliable history of their illness from these patients. Their statements are unintelligible or unreliable. And here it may be well to notice a symptom first remarked by Strümpell. These patients will relate occurrences as having happened recently, with much elaboration of detail, when, as a fact, the story is entirely a product of their imagination. Thus one patient of my own, who had been confined to bed for many days, told me one afternoon that she had been out to see an eminent gynecologist during the morning; had gone to his office and waited for him several hours; had seen other patients there; and finally had been told by the doctor's brother that he would not return in time to see her, so she had come home again. And this was all related in apparent good faith, so that I have no doubt that she believed that what she said had occurred. With the possibility of such delusions in view, it is evident that the statements of these patients cannot be accepted regarding anything, especially as to their own history.

One patient, who was admitted to Bellevue Hospital during my service there, told me a different history of her case every day for a week, and it was only by interviewing her friends that the correct account was obtained.

A negative symptom of some importance is the absence of any interference with the automatic acts controlled by the sphincters, in the majority of cases.

The onset is usually sudden, and is sometimes, in toxic and septicæmic cases, accompanied by a marked febrile movement, with chills and temperature of 102° to 104.5° F. The fever may persist for several days, but usually subsides spontaneously, and does not recur. In a few cases there has been a constant elevation of temperature from one-half a degree to one degree and a half above the normal; and an increase in the rapidity of the pulse throughout the disease has been noticed. A pulse of ninety need give no alarm, but if it rises up to one hundred and forty, and becomes irregular, there is reason to believe that the disease has attacked the vagus nerve, and then the prognosis becomes serious, though not by any means hopeless.

The duration of the disease varies considerably in different cases. An average of twenty-five cases gives seven months as the probable time required for complete recovery. But in these cases the duration varied from two months in the most favorable to sixteen months in the most refractory.

Diagnosis.—It is by reference to the etiology and to the course of the case, as well as to the combination of symptoms present, that the diagnosis of multiple neuritis must be reached. The most important diagnostic symptom is tenderness along the course of the peripheral branches of the nerves and in the muscles. The cases most liable to be mistaken for multiple neuritis are anterior poliomyelitis, locomotor ataxia, and diffuse central myelitis. The following tables present the differences usually found:

ANTERIOR POLIOMYELITIS.	MULTIPLE NEURITIS.
Sudden onset with fever and development of paralysis in one day, [illegible] muscles not tender.	[illegible] are very tender.
Sensory symptoms not present, [illegible]	Sensory symptoms are common, and muscles and nerves tender, [illegible]

Paralysis, atrophy, reaction of degeneration, coldness of the limbs, loss of tendon reflexes, preservation of bladder control, are common to both diseases.

LOCOMOTOR ATAXIA.	MULTIPLE NEURITIS.
Pains are paroxysmal, [illegible]	Paræsthesia is more constant than pain.
Nerves are not tender.	Pain is produced by pressure on nerves.
Ataxia develops slowly and after a period of pain.	Ataxia is an early symptom, develops rapidly, and may exist without pain.
Anæsthesia and analgesia in patches.	Anæsthesia is [illegible] total.
No marked paralysis or atrophy.	Paralysis with atrophy.
No change in electric reactions.	Changes in electric reactions.
Argyll-Robertson pupil present.	Pupils react normally.

There are very few symptoms of diffuse myelitis which are not found in cases of neuritis. But cases of diffuse myelitis of the type of Duchenne—paralysie générale spinale subaiguë ascendante—are very rare, and, indeed, by Leyden it has been affirmed that all such cases are multiple neuritis. Other authorities dispute this assertion and leave us to establish points of difference. These are as follows: In neuritis affections of the functions of micturition and defecation do not occur. Girdle sensation is very rarely mentioned as a symptom; bed-sores and cystitis have not been observed. The advance of the paralysis is rarely from the legs to the thighs and trunk, and then to the arms; it is usually from the legs to the forearms, the trunk and thighs escaping, and, as a rule, the distal portions only of the extremities are paralyzed. If the muscles of the abdomen and respiration are involved, it is only in rapidly fatal cases. In neuritis there is usually some ataxia, and loss of muscular sense is quite evident; while in some, at least, of the cases of myelitis of Duchenne, there were no sensory symptoms at all. Finally, the tenderness of muscles and nerves, and the absence of tenderness to pressure or to heat in the spine, would decide in favor of neuritis. The diagnosis from meningitis of the cord, from tumors or hemorrhages into the cord, or from general paralysis of the insane, would rarely present any difficulty to one who was familiar with the symptoms in these affections, and who knew the prominent features of multiple neuritis.

There are certain common types of the disease, a familiarity with which may aid in the diagnosis. If a patient known to be alcoholic complains for a time of tremor and muscular weakness, and then is suddenly paralyzed in the legs and arms, develops fever, becomes delirious, and shows great tenderness of the limbs and rapid loss of faradic electric reaction in the muscles, the diagnosis of multiple neuritis can be made. If a patient who has been taking arsenic medicinally for some time, begins to complain of paræsthesia, clumsiness and fatigue, and soon shows a marked ataxia in hands and feet, with tenderness along the nerves, some atrophy in the weak muscles, and a change in their electric reactions, the diagnosis of multiple neuritis can be made. Lead palsy is easily recognized. Diphtheritic paralysis is usually limited to the muscles of the pharynx or of the eyeballs, but the sudden onset of marked ataxia without a preceding stage of pain after diphtheria warrants the diagnosis of neuritis. If a tuberculous individual suddenly develops pain and tenderness and weakness in both arms or both legs, and this is followed by paralysis and atrophy in a few symmetrically situated muscles, the diagnosis of multiple neuritis can be made. And lastly, if any one of these clinical pictures is presented by a patient who has been exposed to cold or to wet, or has overstrained himself severely, and a careful examination fails to reveal the characteristic symptoms of general diffuse myelitis, while the limbs are very tender to pressure, multiple neuritis may be suspected.

The cases of *beriberi* are divided into two general classes, according to their severity.

There are, first, slight cases, in which the onset is gradual, being usually preceded by a little fever, coryza, and conjunctivitis, which cease when the actual symptoms commence. The patient first notices a weak and heavy feeling in his legs, and finds that he tires so easily that he cannot walk as much as usual. The tired feeling is soon associated with numbness and pain in the legs, and with a slight œdematous swelling. Then, if not before, palpitation of the heart, oppression and weight in the epigastrium, loss of appetite, and general malaise are felt, and the patient finds it necessary to apply for treatment. An examination then shows some diminution of power in the feet and legs, and also in the hands, with loss of tendon reflexes, and much tenderness in the muscles, which show a diminished electric excitability. There is never any ataxia, though the patient sways when his eyes are closed. There is discovered a slight degree of anæsthesia, of irregular distribution, chiefly in the legs and in the radial-nerve region on the forearms. Though the patients look pale, it is usually impossible to find anæmia by examination of the blood. The circulation in the extremities is sluggish. The heart is irregular and rather rapid, and the œdema of the extremities indicates a failure of its power. Dr. Wallace Taylor[13] finds that a sphygmographic tracing is characterized by a sudden high upstroke in ventricular systole, by a precipitous descent from the apex of the percussion-wave, and by dicrotism. Beyond this point these cases, which make up the majority, do not advance. They usually recover in a few days, or at most a month; although a few become chronic and require several months before the cure is complete.

There are, secondly, severe cases. These may present three different types. There is the atrophic or dry type, in which, after an onset similar in nature to that in the slight cases, but much more rapid, the weakness develops into a true paralysis, associated with marked wasting of the muscles and reaction of degeneration, with great diminution of galvanic excitability. Within a week the patient has to go to bed, and then the paralysis soon spreads from the legs to the arms, and may involve the trunk and even the face. The entire muscular system wastes away till the patient is a mere skeleton. In addition to the motor symptoms there is great sensory disturbance. The suffering from pain, paræsthesiæ, and general muscular tenderness is extreme, and the patient lies totally helpless, and unable to tolerate the lightest touch. The skin may be glossy. There is usually some anæsthesia, but it is never complete, although it may involve the entire body. The temperature sense is seldom affected. Pain may be delayed in transmission. There are no gastric symptoms, and no œdema. Some cases prove fatal from general exhaustion, or intercurrent disease, but the majority recover after a convalescence which lasts a year or more, during which the muscular system is rebuilt.

There is, secondly, the hydropic or wet type. In these heart-failure appears early, and is associated with a marked decrease of arterial tension and much œdema of the entire body, effusion into the cavities being added to that beneath the integument. The swelling of the œdematous parts conceals the atrophy which is going on in the muscles, but this is indicated by the paralysis, which is as severe as in the preceding form, and it becomes evident during recovery when the œdema has subsided.

There is, thirdly, the acute pernicious type. In this all the symptoms of the two former types appear in rapid succession, and, in addition, gastro-intestinal symptoms and a suppression of urine combine to make the condition an alarming one. Effusions into the pleura and pericardium appear early. The pulse becomes small and irregular, and cyanosis indicates the heart-failure which precedes death.

Prognosis.—The prognosis of multiple neuritis is good, excepting in severe alcoholic cases, and in the very severe forms of beriberi just described. The progress of the recovery may be slow, in some cases two years may elapse before it is complete, but seven months may be considered the average duration, and slight cases may get well in three months.

Treatment.—The majority of the cases being toxic in origin, the most important indication is to remove the cause. Total abstinence from alcohol is necessary for at least two years after recovery to prevent a relapse. Lead and other poisons must be eliminated from the system. Such hygienic measures as may be used to counteract influences of an infectious kind must be employed. The direct treatment of the disease is aided by the spontaneous tendency to recover in a person whose constitution is sound, and whose strength is maintained by general tonic treatment. It is possible to hasten the process of regeneration by the use of full, nutritious, and especially fatty diet, including cream and cod liver oil; and by the administration of strychnine, phosphorus, iron, and arsenic, no one remedy being continued for more than three weeks at a time. The use of warm and cold douches to the paralyzed limbs, of skilful massage when the tenderness has sufficiently subsided, and of mild (10 ma.) constant stabile galvanic currents along the limbs, probably aids the regeneration by stimulating the circulation and increasing metamorphosis of tissue. The daily use of the interrupted galvanic current to the muscles, of sufficient strength to produce contraction in them, gives them proper exercise to maintain their tone. Rest is enforced by nature for some time, but moderate exercise is indicated during recovery, but should not be carried to the point of fatigue. *M. Allen Starr.*

MUSCULAR RHEUMATISM is an indefinite and unscientific term, applied to certain painful states of the voluntary muscles. That it is a misnomer in the great majority of cases, at least, there can be no doubt, for the fact is established that the essential pathological conditions, and many of the important symptoms pertaining to rheumatism, are wanting in this affection.

The term myalgia has been proposed as a substitute, and as a proper designation of most of the disorders usually grouped as muscular rheumatism. Myalgia signifies merely muscular pain, and suggests no erroneous theory as to its cause and nature. Sensation, however, is not an endowment of muscular fibre, and, in its last analysis, this symptom must be referred, not to the muscular tissue proper, but to the sensory nervous filaments supplied to the part affected.

Whether the prime cause of the painful sensations conveyed through the nerves resides in the ultimate nervous fibrils themselves, in the neurilemma, in the muscular fibres, or in their enveloping sheaths, must be left for future researches to determine. But with the light before us the pain appears to be neuralgic—neuralgia which does not involve the nervous trunks or their larger branches, and, consequently, which does not follow their courses, and which presents no painful points—the *points douloureux* of Valleix; a neuralgia affecting possibly only the primitive nerve-fibrils or the smaller fasciculi, and the tissues, perhaps, in intimate relations with them, and therefore diffused, and more or less uniformly distributed through a single muscle or a group of muscles.

Morbid changes in the affected muscles are rarely found. The symptoms have been ascribed to hyperæmia, to slight effusion or exudation, and to subacute infilamentation of the tissues. The gross features of inflammation are not present, but this fact does not prove that inflammatory action in some of the tissues composing the muscular fasciculus never exists. On the contrary, there is reason to believe that in many of these cases slight inflammatory processes or changes do occur, and it is not unlikely that with a growth of pathological knowledge it may be shown that several affections, dependent upon different morbid states, are included in the general term muscular rheumatism. At present it must be admitted that muscular rheumatism has no settled or uniform anatomical character.

The affection is of frequent occurrence. It may be acute or chronic. The advent of an attack may be gradual, commencing as a dull pain in a muscle or a group of muscles, and becoming more and more severe; or it may develop suddenly, and be violent from the outset.

Pain is always the prominent, and it may be the only, appreciable symptom. The character of the pain varies in different individuals, or in different attacks in the same individual. It may be sharp and excruciating, cramp-like and tearing, or throbbing and continued. The pain may be constant though slight, and intensified to an extreme degree by contraction of the affected muscle; or it may cease when the muscle is absolutely quiet, only to be aroused upon movement or by involuntary contraction of the muscle.

The pain as a rule remains fixed and does not shift from the point of original attack, though it sometimes changes from one muscle to another. There are no external visible signs of the local trouble; no heat, redness, or swelling, and usually little or no tenderness. Where tenderness on pressure exists, it is generally moderate in degree, and is diffused over a whole muscle or over a set of muscles. There is but little if any constitutional derangement, and usually no febrile disturbance in uncomplicated cases. The pulse is but slightly or not at all affected. The urine is normal. Cardiac complications do not occur.

The acute form lasts for from a few days to a week, and gradually subsides. Sometimes the acute symptoms recede, and the attack lingers in a subacute or chronic form indefinitely. In the chronic form exacerbations provoked by slight exciting causes are commonly experienced. Age appears to influence the localization of an attack. The muscles of the neck are prone to suffer in younger subjects, while the muscles of the back and limbs are more liable to invasion in older persons. The muscles affected for a considerable period of time, or which sustain frequently repeated attacks at short intervals, are apt to become atrophied.

Attacks of muscular rheumatism are usually attributed to exposure to cold, especially to a cold and damp atmosphere after severe fatigue or muscular strain. Debility and overwork and defective nutrition, either general or local, invite attacks. The rheumatic and gouty diatheses have been regarded, and are still considered by some observers, as predisposing causes. The direct relation of cause and effect is denied by others, who affirm that localized muscular pain is of no more frequent occurrence in the subjects of acute articular rheumatism and of gout than in persons who do not suffer from these diseases, which act as predisposing causes only by inducing a state of general debility. Muscular rheumatism frequently occurs during the course of wasting diseases, and during convalescence from exhausting and severe illness. Any condition which impoverishes the blood, and which diminishes the resisting capacity of the system, may be regarded as holding a causative relation to this affection.

By close attention to the history of a given case, to the physical signs and to the symptoms, and by a process of exclusion, a correct diagnosis may readily be reached.

Muscular rheumatism is most likely to be confounded with inflammatory diseases of the thoracic viscera, with structural disease of the spinal cord, with spinal meningitis, spinal caries, deep-seated inflammation, lumbar abscess, certain functional disorders connected with the spinal cord or spinal nerves and with the genital organs, with sciatica, coxalgia, perinephritis, renal calculus, abdominal aneurism, and with the onset of some acute diseases characterized by lumbar pain.

The prognosis in acute cases, under favorable circumstances, is good. It is always good as regards complications and serious results. Chronic cases are apt to prove obstinate and rebellious to treatment. They are difficult to cure, and manifest a tendency to frequent relapses. Success in eliminating the disorder is influenced largely by the physical condition, by the occupation, and by the hygienic surroundings of the patient.

Relief of pain, rest of the affected muscle or muscles, and general or local invigorating measures, constitute the important indications for treatment.

Rest alone will often suffice to relieve the pain. If, notwithstanding complete relaxation of the sensitive muscles, pain continues, anodynes may be demanded. Opium, in some form, may be prescribed with confidence. It may be advantageously combined with belladonna or with atropine. Quinine, salicylate of soda, and salol are used with advantage; acetate of potassium or acetate of ammonium, the iodide of potassium, and colchicum are commended. Stimulating or anodyne liniments, dry or moist warmth, dry cups, and blisters are serviceable. Galvanism and the ether spray to the part sometimes act like magic. Local depletion is not indicated. Cathartics may be required. Faradic electricity is at times useful in stimulating the nutrition of wasted muscles after the pain and tenderness have been relieved. In severe cases rest, even rest in bed, is demanded by the disturbing effect upon the patient of excessively painful muscular movements. Enforced quietude of certain muscles may be secured by the judicious application of bandages or of adhesive strips.

Invigorating measures of treatment have reference mainly to the regulation of exercise, to a pure atmosphere, to suitable clothing, to a generous regimen, and to appropriate general and digestive tonics.

OCEAN SPRINGS. *Location and Post-office*, Ocean Springs, Jackson County, Miss.

Access.—By the Louisville & New Orleans Line of the Louisville & Nashville Railroad.

Analysis (J. L. Smith).—One pint contains:

	Grains.
Chloride of potassium	Trace
Chloride of sodium	5.471
Chloride of calcium	0.486
Chloride of magnesium	0.621
Protoxide of iron	0.589
Iodine	Trace
Alumina	Trace
Organic matter	Trace
Total	7.166

Gases.	Cubic in.
Carbonic acid	1.32
Sulphuretted hydrogen	0.31

Therapeutic Properties.—This water is a mild saline-chalybeate, containing also sulphuretted hydrogen. This rather unusual combination renders it effective in the treatment of persistent skin and scrofulous diseases.

These springs are situated fifty-seven miles west of Mobile, and eighty-four miles east of New Orleans on the railroad connecting the two cities, and are a favorite resort of the citizens thereof. They are about half a mile from the beach, from which fact is derived the name. *G. B. F.*

PERFORATING ULCER OF THE FOOT. As described by Treves this ulcer appears at a spot on the sole of the foot upon which pressure bears, usually over the metatarso-phalangeal joint of the great toe or over the corresponding joint of the little, or on the pulp of the great toe. The skin thickens, and from the pressure that it exercises upon the soft parts beneath it some inflammation of an insidious type follows. Suppuration then appears beneath the corn, and spreading in the direction of least resistance, advances into the soft parts of the sole, moving toward the bone. Possibly the column of soft parts compressed beneath the corn, and the bone beneath which it lies, may perish almost *en masse*, as would appear to be the case with the tissues in acute bed-sores of spinal origin. A sinus forms leading to the bone, while around the margin of this opening the epithelium continues to heap itself up. The sore appears to be set upon a mound of hardened, thickened integument, and it thus happens that the depth of the ulcer or the length of the sinus is greatly increased.

Perforating ulcer of the foot is generally solitary, but may be multiple. It is occasionally hereditary. While a corn may be in many cases the exciting cause, a central or peripheral nerve-lesion is now generally regarded as the predisposing cause. Similar ulcers are met with in anæsthetic leprosy, in locomotor ataxia, and in paralyzed limbs. The sensory nerve-fibres distributed to the affected foot in perforating ulcer are generally diseased.

Perforating ulcer is treated by Treves as follows: The patient is put to bed and the foot is kept continually poulticed with linseed meal. This causes the epithelium to soften and swell up, so that at the end of twenty-four hours the ring around the sore appears as a very prominent, softish, white mound. All this redundant epidermis is then shaved away with a scalpel, and the poultice is reapplied. At the end of another twenty-four hours the deeper layers of epithelium, that were not affected by the first poulticing, have become swollen and prominent. They are in turn cut away. The poultice is again applied and the scalpel used day by day, until the whole of the epidermic mass has been removed. This will be accomplished at the end of from ten to fourteen days. By this time the skin about the ulcer will, as a result of the continued poulticing, have peeled off in a thick white layer, and around the sore will be nothing but thin, fresh pink epidermis, looking active and healthy. The ulcer, in the meantime, will be found to have become clean, and in consequence of the loss of its cutaneous boundary, it will appear less deep. The poultices are now discontinued, and to the sore is applied a paste, of the consistency of thick cream, composed of salicylic acid and glycerine, to which is added some carbolic acid, in the proportion of ten minims to the ounce. This ulcer soon heals, and when the patient gets up he is instructed to wear over the part a thick pad of felt plaster with a hole in its centre that corresponds to the scar of the recent sore. The plaster should be always worn.

Unfortunately this treatment is often unsuccessful, and it is necessarily so if the bone is diseased. In that case the carious bone must be removed, or the toe or the foot must be amputated; but even then the disease is apt to return in neighboring parts. As a last resort, Messrs. Savory and Butlin recommend the use of an artificial leg attached to the bent knee, so that the foot may be carried without having to take any part in supporting the weight of the body (McCall Anderson).

PHARYNGEAL BURSA, NEUROSES OF THE. That the nasal pharynx is exquisitely sensitive to reflex-producing impressions is a fact which has been known for some time, and the older medical literature contains isolated examples of neurotic phenomena of various kinds emanating from pathological conditions of this region. These reflex neuroses of the nasal pharynx were, however, almost unknown, except to special workers in this field, until the publication of a brochure by Dr. Tornwaldt,[1] of Dantzig, in which prominent attention was drawn to the subject, and which invested the so-called bursa pharyngea with a pathological importance hitherto unrecognized and undescribed.

According to Tornwaldt, this bursa is a constant integral part of the rhinoscopic picture, and can always be recognized, sometimes as a furrow, sometimes as a blind cul-de-sac, directly in the middle line in the centre of a curve drawn from the upper edge of the posterior nares to the atlas. This sac is the frequent seat of various pathological processes—hyperæmia, cystic formations, hypersecretion, and simple and purulent inflammation; and these often lead to reflex disturbances, such as asthma, cough, nasal polypi, various ear troubles, neuralgia, inflammatory conditions of the naso-bronchial tract, etc. He furthermore maintains the proposition that naso-pharyngeal catarrh has its starting-point, in very many cases, in a localized pharyngeal bursitis, and that its cure is possible only after destruction of the bursa itself. His treatment accordingly consists in the obliteration of the bursa by means of nitrate of silver, following insufflations of this agent (1 to 10) with the application of the fused stick directly to the sac. Tornwaldt's hasty enthusiasm carries him to the startling statement that, of 892 cases of naso-pharyngeal disease examined by him, 202 were primary affections of the pharyngeal bursa.

There are many objections which may be urged against the theory of Tornwaldt. In the first place, the very constancy and existence of the pharyngeal bursa is a subject of dispute among distinguished anatomists, and besides, according to my experience, the appearances described by Tornwaldt are by no means constant in the rhinoscopic image.

In the second place, when we consider the changes which take place in the pharyngeal vault during the different stages of inflammatory affections of the nasal pharynx—the frequent formation of cysts of varying shape and contents, the formation of depressions, furrows, and other conditions of the pharyngeal tonsil (see for fuller account the article on Chronic Naso-pharyngeal Catarrh, Vol. V. of this HANDBOOK, pp. 207–208), it will be readily understood how easily mistakes in diagnosis may occur, or how difficult it often is to differentiate between well-recognized appearances in the pathological anatomy of post-nasal inflammation and the theoretical primary bursitis of Tornwaldt. That such errors have indeed been committed, is evident from some of the recent literature on the subject.

It is highly improbable, nor are there any just grounds for belief, that an organ of such comparatively trifling anatomical and physiological importance should be vested with the peculiar privileges assigned to it by the followers of Tornwaldt. Since I became aware of Tornwaldt's researches, I have searched in vain for what might be unequivocally termed a primary pharyngeal bursitis. When the bursa has been involved, it has invariably been so in connection with well-marked and far-advanced naso-pharyngeal disease; so that, from the standpoint of my own clinical experience, I am unable as yet to confirm the observations of Tornwaldt. Naso-pharyngeal disease is the most common affection of this climate, and the innuendo of Carroll Morgan, that the postulate of Tornwaldt regarding the great frequency of primary disease of the bursa, living, as he does, in a city of small population, has not been confirmed by the vast majority of specialists residing in large cities, and commanding an immense amount of clinical material, may possibly carry with it considerable force.[2]

While, then, Tornwaldt's observations must, for the present, be taken with a considerable amount of reservation, they have, at least, directed prominent attention to a field of naso-pharyngeal pathology of exceedingly great interest and importance. From them we may learn the lesson that, in order to dissipate certain inveterate naso-pharyngeal affections, we must not rely on astringents, alteratives, *et id omne genus*, but we must *destroy* the source of the discharge.

My own observations concerning this class of naso-pharyngeal neuroses, may be briefly summed up in the following propositions:

1. The nasal pharynx is, in quite a large proportion of individuals, exceedingly sensitive to reflex-producing stimulation.

2. The areas chiefly involved are the posterior portions of the turbinated erectile tissue and various points along the upper and posterior portions of the nasopharynx.

3. In consequence of this extreme sensitiveness a local pathological process, which in many persons would give rise to no reflex vaso-vascular changes, may awaken a host of neurotic phenomena, referable not only to the region primarily involved, but also to other and even remote regions of the body. These may include cough, asthma, and various neuralgic affections, or the local structural lesion may be the starting point of the various sympathetic affections of the respiratory tract.

4. That these naso-pharyngeal neuroses are explicable on the same general principles as those laid down in the article on Neuroses of the Nose, in Vol. V. of this Handbook, and the pathology of the nasal and post-nasal affections is, therefore, one and the same.

5. That the treatment should be carried out according to the general directions laid down in the article just mentioned.

6. That when the morbid process originates in the pharyngeal tonsil, attention should not be directed to the bursa alone, but an endeavor should be made to extirpate the tonsil, as far as possible, in its entirety.

7. That, while a favorable prognosis cannot be safely predicted by treatment of the bursa alone, extirpation of the pharyngeal tonsil often offers the most favorable prospect in long-standing cases of post-nasal inflammation. *John N. Mackenzie.*

[1] Ueber die Bedeutung der Bursa Pharyngea, etc. Wiesbaden, 1885.
[2] Maryland Medical Journal, March 19, 1887.

PLACENTITIS. DEFINITION.—This term is applied to inflammation of the placental tissue, which may be acute, terminating in suppuration, or chronic, resulting in the formation of fibrous or cicatricial tissue. It may, according to Simpson, be confined to the cotyledons or to the membranes. It should be stated that authorities are at variance regarding the true character of the morbid changes, some considering them as ordinary retrograde processes and not of inflammatory origin.

HISTORY.—The first mention of this condition is contained in Guillemeau's "Œuvres de Chirurgie." Brachet, in 1828, first clearly described "hepatization" of the placenta, and reported four cases. Stratford and Dance (1829) have also reported cases. Simpson's elaborate paper on this subject was published in the *Edinburgh Medical Journal* for January, 1836. Geoffrey wrote concerning placentitis in 1858, and Joulin in 1867, Millet having previously (1861) published a thesis in which he expressed doubt concerning its existence, in which opinion he was upheld by Charpentier.[1] We are indebted to Whittaker[2] for a lucid presentation of the existing knowledge concerning this affection. Maréchal[3] has given a *résumé* of the recent French views. He states that not over twenty authentic cases have been recorded.

ETIOLOGY.—The causes of this condition are very obscure. Brachet attributed some cases to mental shock, or to a blow or fall during pregnancy. He also traced it to a pre-existing metritis and endometritis. The latter explanation was accepted by Simpson, and more recently by Schroeder. Some confusion has arisen from the tendency to include syphilitic changes in the placenta under the head of true placentitis. The former are essentially chronic, while the writers who originally described placentitis evidently limited this term to an acute inflammatory process, which might subsequently become chronic. Moreover, by reference to the supposed causes of the latter condition, it will be evident that it is an acute process that develops in a placenta previously healthy, while the changes due to syphilis may be coincident with the origin and growth of the placental tissue. The anatomical [illegible] is less clearly defined.

PATHOLOGY.—Brachet, in describing the anatomical changes in placentitis, seems to institute a close comparison between it and lobar pneumonia, since he distinguishes three stages, viz., congestion, red and gray hepatization, and suppuration ([illegible]). Robin, on the other hand, says that "what has been taken for infiltration of the placenta is nothing else than a condition of transformation of blood-clots at various periods." "What has been regarded as pus," he continues, "is only fibrin in the course of disorganization; and in those cases in which true pus has been found, the pus did not come from the placenta, but from an infiltration of the tissue of the uterine vessels and an accidental depositing in the tissue of the placenta." The absence of capillaries in the maternal portion of the placenta, as Whittaker properly objects, renders it impossible for us to conceive of the existence of a true round-cell infiltration, according to the modern theory of Cohnheim. In describing the pathological anatomy of placentitis, therefore, we follow the teaching of the earlier writers, especially Simpson, which is open to serious doubt on the score of accuracy. The disease may begin in one lobe of the placenta or in several simultaneously. It may originate in, and be confined to, the placenta (decidua serotina), or may be secondary to endometritis; the uterus is rarely affected secondarily.

Stage of Congestion.—The vessels of the affected portions are engorged with blood, and the placenta becomes swollen and of a darker hue than normal. According to Simpson, in simple congestion the entire placenta is hyperæmic and swollen and not merely isolated lobes as in the condition now referred to. Vessels may rupture in consequence of increased blood pressure, giving rise to hæmorrhages on the fœtal surface of the placenta.

Stage of Hepatization.—The parenchyma, in consequence of infiltration with blood and serum, becomes solid and inelastic, and has a deep red color. On section a quantity of sanguineous fluid escapes. Later, the diseased tissue becomes more fibrinous, has a grayish-yellow color, and is much more dry than before. The membranes are at the same time thickened, and may become adherent to the uterus or to the fœtus. The stage of "gray hepatization," as Simpson calls this change, is doubtless simply fatty degeneration, with or without the accompanying formation of new connective tissue.

Stage of Suppuration.—This mode of termination is rare, only ten cases having been reported in which circumscribed abscesses developed. Brachet describes one that involved three-fourths (¾) of the placenta, while O'Farrell reports a case in which an abscess containing twelve ounces ([illegible]) of stinking pus developed in the placenta after a blow upon the abdomen. The patient was delivered of a macerated fœtus, and made a good recovery. Cruveilhier[4] mentions cases in which there was general purulent infiltration of the placenta, the fœtal surface being covered with plastic exudation. Dance[5] once observed a layer of pus between the uterus and the placenta, which was apparently derived from the latter. Breschet[6] reports two similar cases. These abscesses are said to have no pyogenic membrane. It must be evident to the reader that in most of these cases there is a strong probability that the pus was derived from the inflamed endometrium, and that its occurrence in the placenta was accidental.

In short, as before stated, the three stages just described are so clearly defined as to awaken the suspicion that they have no existence except in the imaginations of observers who saw, but misinterpreted, certain appearances which are readily explained in the light of modern knowledge. What really occurs is probably congestion, effusion of blood between and on the surface of the cotyledons, and the usual retrograde changes in the effusion. Changes occurring in the adventitia of the vessels (fibrous thickening) result in obstruction of their lumina and fatty degeneration or fibrous atrophy. Collateral hyperæmia in unaffected portions of the placenta may lead to fresh ruptures and extravasations. In syphilitic placentitis, in addition to the vascular changes, the villi are thickened and their cells undergo cloudy swelling, while gummata are scattered about between the cotyledons.

RESULTS.—If the inflammatory process is circumscribed, the unaffected portion of the placenta may suffice to nourish the fœtus, which reaches maturity before being expelled. The hæmorrhages on the surface of the placenta may be the direct cause of abortion; or, in consequence of the obstruction to the circulation through the placental vessels following fibrous atrophy of the placenta, the fœtus may be deprived of nourishment, and will then be expelled prematurely. After delivery portions of the diseased placenta may be retained, either because it is so softened as to tear readily, or in consequence of the adhesions between the placenta and the wall of the uterus.

Symptoms.—These are so indefinite that even Simpson lays little stress on them. The patient usually complains of severe pain in the uterus and loins. In one instance the woman had chills and elevation of temperature in the middle of pregnancy, accompanied by irregular discharges of blood from the uterus. *H. C. Coe.*

POULTICES were formerly one of the most common, as well as most popular, applications for all local inflammations, whether or not complicated with open wounds. Being readily obtained, quickly and easily prepared, inexpensive, and grateful in their effects, they have from time immemorial entered largely into the treatment of very many of the inflammatory affections of the body. Although supplanted in many instances in later years by antiseptics, more particularly in open wounds, yet they are still a favorite application, and justly so, with many practitioners.

Unless otherwise specified in this article, the term poultice will mean one applied hot, *i.e.*, at a temperature of about ninety-two degrees. Poultices act as a local stimulant. By their effect upon the nerves of the skin and of the vaso-motor system, the circulation is increased, congestion is relieved, tension is diminished, the temperature is lowered, absorption is hastened, and resolution, or suppuration, according to the degree of the inflammation, is promoted. It is more than doubtful if the application of a hot poultice determines the formation of pus. That process depends more upon the type of the inflammation and the susceptibility of the individual, than upon any local application which may have been made. Properly prepared and applied, and frequently renewed, a poultice is to most people a most grateful and comfortable remedy. Occasionally it produces irritation of the skin, showing itself in the form of small pustules or acne, and more rarely it increases rather than diminishes the pain and discomfort.

It may be laid down as a general rule that poultices are indicated in any acute localized inflammation attended by the usual symptoms of heat, throbbing pain, congestion, and swelling. Hence they are called for in cases of circumscribed cellulitis, as abscesses, boils, and carbuncles, inflamed lymphatic vessels and glands, phlebitis, diffused cellulitis, and phlegmonous erysipelas. Acute synovitis and acute rheumatic inflammations of the joints are often benefited by this mode of treatment. A jacket poultice in pneumonia is a favorite application with many practitioners, and for a day or for a few days it is often very grateful to the patient. But, as in acute peritonitis, it soon becomes irksome from its weight and disagreeable clamminess. In the early stages of local peritonitis and in pelvic cellulitis, a poultice is one of the most satisfactory applications. But in this, as in most other affections, the feelings of the patient are to be consulted. The effect of a blister is increased and prolonged by the immediate and continued application of a poultice. Chronic synovitis of the knee or other large joints is well treated by the repeated application of small blisters, one or two inches in diameter, and poultices. This treatment, of course, does not preclude fixation, pressure, and aspiration.

Poultices with an occasional blister form a good method of treatment in buboes, and inflamed lymphatics in other localities. They promote resolution or suppuration, as the case may be, and under many circumstances they may be continued even after suppuration has taken place. The writer is confident, however, that the best treatment for suppurating glands is free incision and thorough curetting, followed by careful antisepsis. This opinion is based upon a pretty large experience in a metropolitan hospital, too often a constant abiding-place for this class of patients. These inflamed, broken down glands act as a foreign body, and the process of removal by suppuration and ulceration is a long and tedious one.

Poultices are desirable in the removal of crusts and scabs in certain forms of skin disease, and neglected sores and ulcers. They also serve a good purpose in many instances as a placebo, by preventing the application of all sorts of harmful materials, and that constant meddling and fussing which is so irresistible for some people, until the character of the affection is sufficiently developed to indicate the proper method of treatment. A poultice seldom does harm, even if it does no good, a statement which cannot be made of several applications in common use. Occasionally the tissues become soft, sodden, and flabby, from a too long continuance of poultices. Under these circumstances, repair is more rapid under other dressings. Poultices have been applied to cases of strangulated hernia, under the impression that an abscess was forming, and thus valuable time has been lost. But this was the fault of the diagnostician, and not of the application. Objections have also been made that poultices are not cleanly, and that they become matted. That depends upon the way in which they are made, the material used, and the care taken in their application and renewal. Properly managed, these objections are of little account.

Poultices are made of flaxseed (linseed) meal, slippery elm bark, bread and milk, crackers, hops, poppies, arrow-root, starch, charcoal, yeast, bran, ice, etc., to say nothing of the multitude of domestic articles which enter into their composition, such as apples, carrots, potatoes, turnips, cranberries, tomatoes, spices, etc. Whatever may be the material of which a poultice is made, it should be soft, smooth, moist, free from lumps and other irritating substances. It should be applied as hot as can be borne comfortably, should be well covered and secured in place, and should be changed as often as it becomes cool, stiff, or otherwise uncomfortable. It may be necessary to renew them every hour in some cases; in others they may be left on for from six to twelve hours, according to circumstances.

Poultices may be variously medicated, as with laudanum, digitalis leaves in suppression of urine, carbolic acid, chlorinated soda, permanganate of potash, etc.

For ordinary purposes flaxseed meal makes as good a poultice as anything. It should be freshly ground, as it then contains a considerable amount of oily and glutinous materials, which are very desirable. It is to be stirred into boiling water to the consistence of a thin batter, and is to be thoroughly mixed. It should be smooth and pasty, free from lumps and sticks. It may be spread about one-half or three-fourths of an inch thick upon any kind of moderately firm cloth, lying upon a hot plate or other warm surface. It is then covered with cheese-cloth, muslin, or other thin material, to prevent the meal from drying and adhering to the skin. The edges having been turned in, or, what is better, basted together with a needle and thread, the poultice is to be applied gently and slowly to the part, to accustom it to as great a degree of heat as is desirable without pain or shock. The poultice should be several inches larger than the inflamed area, and is to be covered with oil-silk or paper, rubber, or other impervious material to confine the heat and moisture. Over all may be placed a layer of cotton wadding or batting (the former is more convenient), and the whole should be secured firmly in place by a roller or many-tailed bandage, or by a swathe. It is to be renewed every two to four hours, as a rule. If allowed to remain too long it becomes stiff. Dr. Gross considered the slippery elm poultice as the best that could be made; it is particularly useful in burns.

A most admirable poultice is made of starch, the

"Watertown" starch being the best. Mixed first with cold water, and then added to boiling water and cooked for a few moments, it forms a smooth, cleanly mass, which can be applied hot or cold. The coolness can be readily augmented by allowing hot or cold water to run over it just before it is applied. This poultice is peculiarly adapted to acute, indurated swellings in the cellular tissue, as in the legs, and about inflamed glands and veins. Some forms of eczema and eczematous ulcers are greatly benefited by the application. Arrow-root also makes a good poultice, and it is similar in its properties, in its effects, and in its preparation, to the starch poultice. I have found the latter very useful in preventing bed-sores. One patient with caries of the spine has lain upon a starch poultice for over a year with great comfort.

Charcoal, mixed with an equal quantity of flaxseed meal, is a desirable dressing for foul and gangrenous ulcers, the principal objection to it being that it discolors and thus obscures the parts somewhat. A much better application for this class of affections is the yeast poultice, made of yeast and water, with enough flour to make a thin batter. It is allowed to rise by being placed in a warm locality, and it should be applied in a loose bag, as the process of fermentation goes on for some time, and room is required for the expansion. It should be renewed every eight to twelve hours. For gangrenous affections or bad-smelling sores I know of no better application than the yeast poultice made according to the rules laid down in the U. S. Dispensatory.

One part of "fine-cut" tobacco, added to ten parts of flaxseed meal, is thought highly of by some as an application in acute orchitis. Occasionally it produces symptoms of collapse, and hence care is requisite in its use.

In the absence of ice-bags or cold-water coils, an ice poultice is sometimes a desirable application. It is made by spreading a layer of cracked ice between two layers of bran, and confining the whole in a bag. Care is to be taken to prevent the water from drenching the patient, and the same caution is to be exercised about too great a degree of cold coming in contact with the skin, as in using ice in other ways.

While the poultice is still a valuable application in many cases, yet its use has been very much limited in the treatment of open wounds by the introduction of antiseptics, especially in hospitals. To one accustomed to both methods of treatment, the difference in the results is very striking indeed. The amount of suppuration seen in cases of cellulitis, etc., treated by poultices, was often prodigious. Convalescence was prolonged, and hence pain and suffering were increased, the strength of the patient was more exhausted, the liability to septic and other complications was greater, and much more labor was requisite in taking care of the wounds. The advantages of antiseptics in the treatment of most open wounds calls for no argument in these days. Their value, like that of anæsthetics, has been determined by the crucial test of experience. Time and further experience only confirm the favorable opinion already so universally prevalent the world over. *George W. Gay.*

RACE AND NATIONALITY, INFLUENCE OF, UPON DISEASE. Under this designation it will be appropriate to enumerate and discuss such peculiarities or characteristics associated with the phenomena of infectious and contagious diseases, as are perceived to be dependent upon, or attributable to, differences of race and nationality. It is not difficult to conceive that the various communities of mankind, situated as they are in such dissimilar circumstances of climate, soil, geographical position, and social condition, should manifest contrasts in their morbid proclivities as well as in their physiological tendencies. Man, complying with the general law of adaptation, which pervades and permeates the whole series of living organisms, conforms to the rigid conditions of his existence. Corresponding with fluctuations in the environment there are always fluctuations of adaptation in the internal functions, else the creature perishes or degenerates. While it is essentially true that disease-producing causes or conditions are pretty general in their distribution among every race and people, and each is more or less susceptible to them, so that few or none have complete immunity from any, still observation reveals that these propensities are indicated in very varying and very unequal degrees. Boudin in this connection has remarked: "Man is not born, does not live, does not suffer, does not die the same at all points of the earth. Birth, life, disease, and death all change with the climate and soil; all are modified by race and nationality."

In essaying to estimate the several influences that contribute to the establishment of the disparities that will appear upon a study of the different diseases among different races, it must not be presumed that the determining factors are the same as the normal distinctions usually employed by the ethnologists in discriminating between races. Conclusions based upon such characteristics as color of the skin, quality of the hair, appearance of the tongue, and size, shape, and proportional dimensions of the skull and face, which in themselves could have no possible practical bearing upon morbid conditions, will, therefore, not be considered in this article. An endeavor is now being made by those who hold certain views bearing on this question to demonstrate that variation in susceptibility to infectious disease depends largely upon qualities—vitalities—that pertain to cell life. It is supposed that the difference lies in the contending activities of the pathogenic germ on the one hand, and the vital reaction of the cells of the organism on the other. Changes in the structure and function of each race or nation bring about corresponding differences in their susceptibility to and immunity from disease. As to exactly what this consists of, and as to how these peculiarities originate, we know that a race indigenous to a certain country acquires through many generations characteristics, the formation of which can be traced to circumstances of environment—to those particularly of telluric influence and climate. Again, we know how habits of life definitely determine the susceptibility and non-susceptibility to certain diseases, and that change of environment always induces changes in the physique, mental traits, and morals of any man, group, or even nation of men. These external conditions of life are always intimately associated with the occurrence of disease, statistics showing that any people are exempt from the influence of disease in proportion to their ability to cope with the evil effects of improper hygienic and climatic conditions.

Among these factors of environment that have an unmistakable influence upon the advent and type of disease none is more remarked than that of climate. Considering this in the light of the definition given in Vol. II., p. 185, of this work, that it is "habitual weather," its importance can be readily seen in this connection. Of course, climatic relations of themselves are totally incapable of generating in the system specific disease, yet that they do foster the special causes in certain countries and create constitutional peculiarities and tendencies through molecular modifications in the tissues, which gradually become permanent and capable of transmission through heredity, is a well-established conclusion of a large majority of observers in all tropical countries. Reference to the latitudinal position of the various races of the earth will demonstrate that each one has its own special limits of health defined by rigorous laws of climate. The Icelander who emigrates to Copenhagen is liable to perish from consumption, the tropics of India are wholly inimical to Europeans, and the Dutch have been totally unable to populate Sumatra and Java. The white race is the only one that has been able to colonize at all, and even this seems possible only to a limited extent. It has been found that unless the organism can readily adapt itself to the new external medium, by a readjustment of its internal medium, it deteriorates or dies. In this we see the whole rationale of acclimatization. The white races enjoy the most perfect health and the highest type of physical and intellectual development in the temperate zones, above 40° in the Western and above 45° in the Eastern Hemisphere.

Whenever they migrate many degrees below these lines a series of profound physiological changes set in, which continue in proportion to the length of residence. On the other hand, if we look at the intertropical races approaching the latitude of the white race, we see a host of deleterious influences begin, that gradually grow worse, in proportion to the distance from the equator. As the varied regions have their natural order of fauna and flora, so they have their appropriate races of man; neither can transgress its fixed limits without endangering its existence or incurring deterioration. Man, like the animals and plants, bears the stamp of geographical areas, and while he is able through his intelligence to overcome many of the usual obstacles of climate, yet these digressions are sooner or later found to react upon him, frequently leading to disaster or even death. In some countries everything tends to hinder. Volney says, "that neither the Mamelukes, who were a Caucasian race, nor the Turks, who are Mongolians, unless they married native women, which the Mamelukes never did, could continue their race in Egypt, all their offspring perishing in the first or second generation." Dr. Kenneth McKinnon says of the children in Bengal, that "even where there is no tangible disease, nutrition and oxygenation do not appear to go on favorably; the skin is pale, the muscles wanting in substance and tone; the joyous spirit of children is absent, the body is inert, the mind listless." Children born of English parents in India sicken and die when they pass the age of about six years (Peschel).

This is so well authenticated that the late Mr. Twining states that after much search and careful inquiry, he was unable to find anywhere a sample of the third generation from unmixed stock of Europeans.

No Asiatic race has ever shown that it possessed the power of resistance or the power of progress. The Hindoos were of Caucasian origin, but having been exposed during countless generations to the same succession of depressing influences of climate, a temperament has been developed which differs widely from that of Europeans. This is seen in their want of energy, their incapacity to withstand disease, and their tendencies to early exhaustion, possessing, as they do, neither muscular nor nervous power. In approaching the equator from each side, it has been found that the mortality is increased as we come nearer, and consequently the average duration of life is shortened, observation going to show that the proportional number of individuals who attain a given age always differs in different climates, and the warmer the climate, other things being equal, the shorter the duration of life. An early puberty is always associated with an early decline. In the limits of Europe we find this illustrated, the longevity varying from twenty-eight in the Roman states to forty-six in England. In an estimate made a few years since by Dr. C. F. Campbell[1] upon the adult male members of the order of Odd-Fellows of the United States, he found that the death-rate in the Southern or tropical States was just twice as great as that in the temperate ones of the North, the figures being 30 for the former and 15 for the latter annually per 1,000.

With regard to morbidity, he found that the average sickness in weeks for each hundred was .266 for the Northern States, and .946 for the Southern. Dr. Eklund, of Stockholm, in an investigation of the mortality rates among children under one year of age, in the various nations of the earth, found the lowest among those in England, Belgium, Denmark, Sweden, and Switzerland, where it fluctuates between 14.3 and 26.2 per 100 annually, and the highest in Austria, Russia, and Germany, where it varies between 31 and 48 per 100, the average being, for all Europe, twenty-five per cent. of all deaths. These illustrations are capable of wide elaboration, and they indicate the potent influence of climate and race in *predisposing* the system toward the onset of disease.

Passing to the consideration of another factor that also exercises a very marked influence in determining the character of disease, we do so under the heading of *class* or *social condition*. There can now be but little, if any, question but that this is a very important element in the inception and sequelæ of disease. Among many of the members of the darker races, who exist under the most imperfect hygienic and sanitary surroundings, this influence is widely felt. It has been found that in London the death-rate among the rich is from 12.5 to 25 per 1,000, and for the poor it is from 25 to 35.5 per 1,000. The well-to-do in England have an average life of fifty-five years, while that of the artisan class of Lambeth is only twenty-nine and a half years.

The effects of class upon infectious and contagious diseases has been ably worked out by Körosi, a statistician of Buda-Pesth, and he finds it as follows: Excluding deaths in infancy, he found that the upper class had a longevity of fifty-two years, the middle class of forty-five years, and the poorer class forty-one and a half years. In the matter of susceptibility to disease, he found that cholera, small-pox, measles, and typhoid fever were more prevalent among the poor; and diphtheria, croup, pertussis, and scarlet fever in the well-to-do. Zymotic diseases, as a whole, were sixty per cent. more frequent among those living in basements than in higher domiciles. But the increased mortality in underground tenements applied only to certain diseases, especially measles and pertussis, while diphtheria and scarlet fever were ten per cent. less fatal than in people living above ground. In regard to other statistics of this character it has been shown that, in Dublin, in the first class of society, including professors and independent people, the mortality was 22.5 per 1,000. In the second, or middle class, it was 25.4 per 1,000. For the third class, composed of shopkeepers, artisans, etc., it was 26.1 per 1,000; while for the fourth class, occupants of workhouses, jails, and those in general service, it was 37.5 per 1,000.

Along with these elements that act as predisposing conditions to disease, we have others, doubtless equally or more influential. There seem to be certain qualities of the individual organism that have a very potent influence in warding off or inviting pathogenic factors. So far investigation has not furnished much that is tangible and certain in this field, yet the future appears to be filled with great possibilities for science. In a series of articles published in *The Lancet*, in 1888, upon the pathology of infectious and infective diseases, the well-known pathologist, Joseph Coates, of London, states his conclusions as follows: "We have seen that, in the case of a large number of diseases of this class, inheritance, whether we take it more broadly in the race or more particularly in the family, has an undoubted and frequently a very great influence on the susceptibility to infection. This varying degree of susceptibility exists in the case of diseases which are demonstrably due to the action of micro-organisms, and we are driven to the conclusion that a micro-organism which is pathogenic in the individuals of one race to a high degree, is non-pathogenic, or nearly so, in the individuals of another race. Recurring to our remarks on the general principles of inheritance, it seems necessary to refer this difference in susceptibility to fine differences in the structure and activity of the tissues. We have seen that the differences in the races depend on variations in the details of their tissues, such as might singly seem to be of comparatively little moment. The differences in individuals of the same race are still more minute, and depend on still finer variations in the details of the tissues. Coming to undoubted cases of inheritance of morbid conditions, we saw by illustration that it was variations in the details of structure and function which are the subject of inheritance. In ichthyosis it is the structure and mode of growth of the epidermic cells; in hæmophilia it is the structure, presumably, of the blood-vessels; in Daltonism, the finer details of the structure and function of the retina.

"In all these cases it is the structure and activity of the finer elements of the tissues concerned that are at fault. When we find that the varying susceptibility to infectious and infective diseases is also related to inheritance, then we must, I think, relate it to the same kind of variations as those which we have found to be the subject of inheritance, both of normal and abnormal structure. It is, again, the structure and vital activities of the elements of the tissues with which we have to do. If, as we have seen, the negro race differs very markedly in its susceptibility to infectious diseases from the European races, then we are led to believe that this depends on the differences in the structure and activity of the tissues, such as determine the characters of race. It is the living activities of the tissues with which we have to deal, and it is peculiarities in these, determined by inheritance, which, I believe, constitute the differences."

The foregoing illustrates very lucidly the influence of heredity, and shows how diatheses may contribute certain conditions favoring the reception of disease germs. However, there are good reasons for supposing that there are many other circumstances in this same connection which are equally potent in their influence. Experience demonstrates that a large majority of the individuals of every race and nation are born, it would seem, with more or less susceptibility to acquire certain of the diseases belonging to the zymotic class—a class presumably due to morbid animal poisons. There is evidently in the organism some inherent principle or ingredient, the character of which we now understand very imperfectly, though clearly it is in no way essential to life or health, by which the human species, and in some instances animals also, are rendered liable to these diseases. That this liability is in some way closely allied to the constituents of the blood, seems highly probable. The germ theory of the cause of this class of diseases, rests upon the principle that bacteria can only become noxious after entering the circulation, and are hurtful in exact proportion to their capacity to multiply there. Ziegler says of the factors which determine bacteria in the blood, "there must be a certain predisposition to favor their development." This is but another name for susceptibility, of which we have two kinds, the congenital and the acquired. As to the congenital form we have seen that it consists in peculiarities of tissues, such as it is possible for the factors of environment to originate, though they are transmitted from parent to offspring under the influence of heredity. In the acquired form of susceptibility, which may be absent at one period of life and present at another, it seems probable that the system is changed by similar circumstances from its original character, and rendered liable to the assaults of the pathogenic causes, though it is possible for other causes to operate in the same manner, as will be seen from the following:

In an article in the *Centralb. f. Med. Wiss.*, 5, 1882, Rossbach has shown that the injection of papayotin into the vessels is followed by a rapid development of micrococci in the blood of the heart, so that in two hours it was found swarming with them. From this it appears that the composition of the blood is capable of being so altered by the addition of a chemical substance as to cause it to develop germs. In other words, that the addition of a vegetable substance has brought about a special predisposition or susceptibility. The evidence appears to show that the presence of germs in the system, aside from the influences that go to favor their entrance, is properly ascribed to certain ingredients in the blood that occupy the relation of pabulum to the bacteria, and in the absence of which their existence and propagation is impossible.

With regard to the immunities that are found to favor certain races with respect to certain diseases, several theories have been advanced in explanation. The first of these is known as the exhaustion theory. We know as a matter of common experience that an immunity is secured, as a rule, by single attacks of such parasitic diseases as small-pox, measles, typhoid fever, and the like, and that an individual is thereby rendered apparently insusceptible to future attacks. Reasoning from analogy, it would appear that the second attack is guarded against by the removal from the system, through the first attack, of some ingredient or condition necessary for the sustenance of the pathogenic microbe that stands in the relation of cause. This, then, in brief, is the basis of the theory of exhaustion. The second of these theories, known as the antidote theory, presumes that the organisms in multiplying and growing in the system generate chemical substances, ptomaines or other poisonous matters, that act as antidotes to future infection. The artificial cultivation of micro-organisms is now carried on to such an extent as to enable everyone to appreciate how small a change in the composition of "culture fluids" will often frustrate the growth and life of the contained germs, since the addition of an infinitesimal amount of any substance inimical to their welfare is attended with the most striking and frequently disastrous results. For example, one part in sixteen hundred thousand of nitrate of silver added to the culture fluid of the aspergillus niger, stops the growth of the plant and reduces its productive capacity three-fourths. Now, supposing this to be a human parasite—a living contagium—capable of self-multiplication in the blood and tissues, and of so altering them as to induce disease or death, then the introduction into the system of a minute portion of this salt of silver would insure, if not the total effacement, at least the neutralization of its powers for harm. This relation of the organism to its medium is one of the most fundamental of biological data, and applies to every form of life and every condition of existence. The third of these theories holds that the tissues concerned in the conflict with the morbid causes possess an educated capacity, through the first attack, to withstand future attacks by the same infection. This is the tolerance theory. It assumes that each generation of cells has transmitted to it by parent cells certain peculiar qualities which enable it to resist future encroachments. This, of all the explanations furnished, seems most worthy of acceptance, interpreting as it does both the immunity following a single attack of these diseases, and that which is known to exist in certain people as a congenital peculiarity.

Metschnikoff says the white blood-corpuscles, in disease, are eaten up by the bacteria, but when the individual is in perfect health they are successful in the contest, destroying the microbes as fast as they enter the organism. Hess confirms this in a manner, and says "after inoculation in those species of animals that are immune to the virus, the white blood-corpuscles were loaded with bacteria." Whether the active mediums of resistance be chemical substances, the activities of the cellular tissues, or the white blood-corpuscles, or all of these in combination, the investigations of Maurel show that the blood of the different races presents variations as to the number of corpuscles. In his observations he found that in each cubic millimetre of blood the Hindoos had 5,549 white corpuscles; the Khmers, 5,519; Europeans, 5,000; Chinese, 4,611; Annamites, 4,123, and the Blacks, 3,823. Of course the quality and quantity of food has an important influence upon these components of the blood, but there are also differences in the number of red blood-corpuscles, and while the black races have the lowest number of white blood-corpuscles they lead in the matter of red blood. The differences in the several races were found to be, in each cubic millimetre of blood, as follows: Blacks, 5,412,256; Indo-Europeans (Europeans), 5,000,000; Hindoos, 5,008,222; yellow races: Khmers, 4,474,751; Chinese, 4,584,861; and Annamites, 4,298,781.

How far these discrepancies are to be taken in explanation of the various degrees of susceptibility and immunity that are found to characterize the different races and nations, in the accounts that follow, is still a question requiring solution. Viewing "the blood as the life," and that a capacity to resist any and all diseases of this class is directly proportional to its perfectness in composition, it can readily be seen that the blood may also act the part of a protecting agency, one capable of thwarting the assaults of the pathogenic micro-organisms. The struggle for existence between these minute organisms and cells is doubtless just as real and important to life as those grosser changes that can be seen and appreciated. A detailed description will now be given of the various diseases that observation has found to be characterized by differences of susceptibility and immunity, in connection with their history as manifested among the different races and nations. It is but just that the author should here express his indebtedness to "Hirsch's Handbook of Geographical and Historical Pathology" for much of the data contained in the accounts of diseases that follow.

PHTHISIS.—No race or nationality enjoys complete immunity from phthisis, but with respect to frequency there are marked contrasts as to place and people. Taking the mean death-rate for the whole world at 22 per 1,000 of population, and the average of phthisis to be 3 for 1,000, we find that the deaths from consumption to be nearly one-seventh of the whole mortality. The following table, taken from Hirsch, shows the variations, with regard to its frequency in Europe and other portions of the earth :

Locality.	Period.	Deaths per 1,000 population.
Norway	1854 to 1867	2.21
"	1871 to 1875	2.53
Sweden	1861 to 1876	3.5
Denmark	1876 to 1883	(For small towns) 2.12
Germany	1877 to 1880	3.6
England	1848 to 1855	3.0
"	1859 to 1869	2.5
Wales	1848 to 1855	3.3
"	1859 to 1869	3.1
Holland	1869 to 1874	2.46
South Holland	1869 to 1874	2.28
Switzerland	1865 to 1869	1.86

These figures are as reliable as it is possible to obtain, and they show very marked differences in the death-rates from consumption as to time, place, and people. Among the most noteworthy facts associated with the distribution of phthisis is, that it is as common in sunny Italy as in foggy England, and that it is absent from the islands of the northern latitudes, such as Iceland, Faröe, Shetland, and the Hebrides, where the disease is practically unknown. It seems to be more common in Sweden than in Norway. In the island and mainland of Denmark it stands at about the average mean of frequency, and the same is true of Russia in Europe. In England the heaviest mortality is in London.

In Ireland consumption is the chief source of mortality ; indeed, wherever the Irish race is found, this liability and destructiveness of tuberculosis crops out. As to the lightness of the death-rate in Switzerland generally, where the average is the lowest, being only 1.86 per 1,000, there are marked contrasts in different localities. In Frieburg it is as low as 0.81, while in Baselstadt it is as high as 3.57 per 1,000.

In France the centres of mortality are cities, the same being true of Spain. Italy has a general average of 2.45, which varies in places from 0.89 at Basilicata to 3.34 in Lombardy. In the eastern countries of Asia, such as Persia, Syria, and Armenia, the disease has but little influence on the death-rate ; these parts being almost totally free from it. The nomadic life of the people in these countries has doubtless much to do in keeping off this disease, since when they exchange their tents for houses it is seen to occur. M. Robinson, of Constantinople, sent a communication to the "Congress for the Study of Tuberculosis," held in Paris, July, 1888, in which he states that, notwithstanding the fact that the inhabitants lived much in the open air, and under the best hygienic conditions, tuberculosis was now very prevalent, and ten per cent. of all his patients were suffering from this disease. It is said that the disease is rarer in India than in corresponding zones of the Western Hemisphere, though there it is upon a gradual increase. Boudin maintains that there exists an antagonism between malaria and phthisis. This is corroborated by M. de Brun, of Syria, and Piot, of Cairo. The type of the disease as it occurs in some places, such as Ceylon, China, and Japan, seems to be particularly malignant. Verrier says it is very common in all the yellow races. Within the last fifty years there has been a considerable increase in phthisis in the interior of Brazil and the other states of South America. In Victoria, Australia, in 1866, this disease caused six per cent. of all deaths, while in Melbourne it rose between 1865 and 1869 from 2.22 to 2.52. The mortality at present among the inhabitants of South Australia is 1.008 per 1,000.

Among negroes and Indians this is the leading cause of death, but whether these preponderances are due more to race peculiarities or to unpropitious circumstances of life, there seems to be some doubt. That change of climate does have a considerable effect is well known. Of the British soldiers sent to the Bahamas, the deaths were—for each 1,000 of whites 2, and of negroes 7. Among those sent to Gibraltar, the proportions were 6.1 for whites, and 33.5 for negroes, in each 1,000 soldiers. In 1803 and 1810 the British Government imported three or four thousand negroes into Ceylon ; in 1820 there remained only four hundred and forty all told.

Says Bartolacci, in his book upon Ceylon : "It is a remarkable fact that of nine thousand negroes, from the East Coast of Africa, who have been employed as soldiers by the Dutch Government, scarcely a trace of them remains." Here we have a very pronounced confirmation of the fact that migration to a colder climate by the negro is always followed by a rise in the susceptibility to phthisis. Pruner calls attention to the fact that at Khartoum, latitude 17° N., with a temperature lower than that of the mountains around, consumption ensues among negro captives, as well as among the Arabs of the desert, whenever they lay aside their nomadic habits and live in houses, even when it is in a warmer climate. This certainly has an important bearing upon the question of the increase of phthisis among the negro population since the Civil War. The change in their mode of life has brought about an effeminacy of constitution which has greatly added to their liability to enthetic diseases.

In the United States the censuses of 1850, 1860, and 1870 show that for this period the whole country had a mortality ranging between 2.51 and 2.54 per 1,000 population, though in the Western States it was as low as 1.11 and 1.34. A comparison of the cities of the North and South shows that the average in the North is 2.82, while in the South it is 4.25 per 1,000 population. We must look for the causes of this disparity in the preponderance of the colored element in the Southern cities. This affords an interesting proof of the observation that phthisis is largely diffused through the urban population, and that it is at these centres that we find the highest death rate. In the convict prisons of this country, from 1829 to 1845, the average mortality among whites dying from phthisis was 11.16 per 1,000, but in the penitentiary of Pennsylvania it was for blacks 40.74, and for those in Maryland prisons 28.49. The negro population of New York, under the same restrictions, had an annual mortality of 11 per 1,000. Corson, of Savannah, in his observations upon "The Future of the Negro in the United States," says that the mortality of the race from phthisis according to his experience is twice that of whites.

PNEUMONIA.—This takes rank with the universal diseases. In the cooler and temperate latitudes of Europe and the United States the deaths are found to average about 1.5 to 1,000 of the population, the proportion sinking as low as 1.1 and rising as high as 2.5. The following table will give an idea of where the contrasts are found:

Place.	Period.	Deaths per 1,000 inhabitants.
[illegible]	[illegible]	1.6
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]

	[illegible]	[illegible]
New York	[illegible]	[illegible]
Philadelphia	[illegible]	[illegible]
	[illegible]	[illegible]

From the foregoing it will be seen that Philadelphia has the lowest record of any city, and Paris the highest. The British Collective Investigation Committee, in 1884, ascertained from 1,059 cases that there were 704 males with 120 deaths, being a mortality of 17 in the 1,000, and 356 females with 71 deaths, being a mortality of 19. This shows that while the disease is less frequent in women than in men, yet it is more fatal. Dr. Billings says that "the evidence furnished by the census does not favor the theory that this is a disease dependent upon or favored by cold." In the northern sections of Europe it is moderate in extent, and not more severe than in the warmer climates; while the southern countries of Greece, Turkey, and Italy, have it very often and severely. The death-rate from pneumonia for Rome is 4.1, Bologne, 2.7, and Genoa, 2.9. Venice is known to have a peculiarly fatal form of the disease.

While immigrants from the northern latitudes to subtropical or equatorial regions enjoy comparative immunity from inflammation of the lungs, the natives of the tropics, and most of all the negro, are subject to the malady in quite a peculiar degree; this is not merely so when they go to colder climes, but also in their natural habitat. In North America, epidemic pneumonia among negroes is prone to take on the dreaded typhoid form, in which case it is signally fatal. The pneumonia of the desert, which has been often epidemic in the Soudan, Zanzibar, and in the West Coast of Africa, generally destroys all those attacked. Lower Egypt and Tunis are said to enjoy exemption; but, on the other hand, the negroes of the Upper Nile basin suffer. In the West Indies the negro race is said to furnish by far the largest contingent of sick. The islands most subject to the disease are Cuba, St. Thomas, and St. Domingo; those most exempt are Guadeloupe, Barbadoes and Martinique. From the coast of Cayenne all observers agree in reporting the frequency of pneumonia in negroes, creoles, and natives. The same is true of the South American countries of Brazil, Peru, Chili, and Paraguay.

GOITRE AND CRETINISM.—These diseases are very narrow in their bounds and are always apparently associated with definite conditions of locality. On European soil the headquarters are the western and southern slopes of the Alps of Italy, Switzerland, and France, and the eastern continuation of the chain into Austria, the Pyrenees, the Vosges, and the Jura.

Sormani has shown that, in Italy, out of 2,000,000 men liable to military duty, 20.9 per 1,000 were disqualified owing to goitre. In France it has been shown that the proportion of goitrous persons is 10.4 per 1,000 and of cretins 5.0 per 1,000 of the whole population. Spain is none the less liable, and here, too, we find the disease widely prevalent. For Switzerland the proportion to the whole population was in 1868 1.7 per 1,000, one-seventh of these being confined to the canton of Valais.

The distribution of goitre in Austria is found to vary in the different sections, being for Cilli 2 per 1,000 and Judenburg 21.3 per 1,000. In Germany it is found in the Black Forest, along the Danube, and in Halle, where it is 1.54 to each 1,000 of population.

The amount of goitre found in England is proportionally very large, especially in the southern and midland counties. Scotland is much less subject to it, and in Ireland it may be considered as absolutely rare, though Law (*British Medical Journal*, 1882) has reported its presence in a few localities. Cretinism is very rare in Great Britain, and it has been known to occur only in few places and at considerable intervals of time.

The higher countries of Scandinavia are almost entirely free from both diseases. Russia in Europe has little or none, though in Siberia in some villages the number of those affected reaches as high as twenty-five per cent.

It occurs in Asia, especially on the slopes of the Himalayas, where Fayrer estimates the disease to affect as high as ten per cent. of the population in certain sections. Very little of this disease is known in Africa, though there is sufficient evidence of its presence in Egypt, Algiers, Morocco, and along the coasts.

A noticeable fact associated with the distribution of these diseases is that while goitre is widely spread in the Western Hemisphere, cretinism occurs much more rarely than it does in the Eastern, or than it does on the continent of Europe in particular.

Greenhow says for India, and Barton for America, that they have never seen a case of goitre among the white natives, whereas according to the experience of Fayrer and Wilson, the disease is equally common among all races. For Nicaragua, the accounts of Bernhard and Guzman agree in stating that goitre is most frequent among the Indians and rare among those of mixed blood. Barton says that it is epidemic among certain of the American Indians. Praslow says that it occurs among the Indians of California ("Der Staat Californien," 1857). Smith found goitre very frequently among the negroes and whites of Peru, but rarely among the mestizos and Indians. Tschudi says for Brazil, "it is equally common among negroes, mulattoes, and whites."

How far these reports can be harmonized, and the conflicting statements made to agree, does not appear. Whether these differences, such as they are, in the amount of the disease in mixed populations are attributable to race peculiarities appears somewhat doubtful. At all events, the above facts as well as the fact that the disease is endemic among Indians (Barton), among the Malays of Sumatra, Java, and Ceylon, among the Mongols in Ladak and China, and among the natives of Algiers and Morocco, make it very doubtful whether any race or nationality enjoys an immunity from it. In New Granada it appears from the statements of Humboldt and Roulin that the disease is rather uncommon among the Indians, though the latter adds, "it is very common among the negroes and whites." It occurs in the countries of South and Central America, Mexico, and as far south as Chili. In some sections of Nicaragua and Costa Rica (Bernard and Swalle) whole towns are afflicted with it, though cretinism does not seem to be associated.

SYPHILIS.—This is a disease which is thought to be pretty generally distributed over the entire globe, yet when we come to examine the statistics regarding its visitations we shall doubtless be surprised at the contrasts presented. There are certain sections, among which may be mentioned Iceland, Greenland, Newfoundland, South Africa, Madagascar, and the adjoining islands, which seem to be particularly free from the ravages of this disease. Syphilis has been imported twice into Iceland, once in 1756 and again in 1824, which infected the inhabitants to the extent of twenty-two cases. Finsen says of his own personal experience there, in a practice of nine years, that he saw only five cases and these in strangers. Of Newfoundland, where it came with the first settlers of the island, Gras says, "I have not found a single trace of it having been developed, and I have never seen an infant that would justify its being transmitted by heredity." Lange says of Greenland: "It is a remarkable fact that there is absolutely no syphilis here; about the fact there is no doubt, and the strangeness of it will be less when we remember that the same is true of Iceland. The circumstance is explicable simply and solely on the ground that Greenlanders and Icelanders have immunity from syphilis, for there is no lack of opportunities for infection, since vessels frequently visit here with syphilis on board, and prostitution is far from uncommon."

In this connection Fritsch has said: "Syphilis is rare (in Central Africa) and it occurs in Bechuana Land only in scattered cases, mostly imported from Cape Colony, though there are materials with which to controvert the assertion that the disease does not hold with pure Ethiopian blood." Borius and Darwin say that the negroes in Madagascar are exempt, while the Hovas, of the Malay race, are frequently and seriously affected with it. It has been found that Europeans infected at Chinese ports are much more severely affected with it than the natives. This seems also to give rise to the notion that syphilis contracted from the darker races is serious in the whites, something which my professional experience corroborates. The first cases of this disease that reach a country are generally the worst. Aborigines, as a rule, suffer more than immigrants. In contrast to the assertions made by Livingstone, it has been found that the negroes of both coasts of Africa have it badly and suffer equally with any race. From a study of two hundred and thirty-one cases occurring in negroes, Dr. Henry R. Carter ("Report of Surgeon-General Marine Hospital Service," 1883) was enabled to make the following deductions: "To conclude, it may be stated that syphilis pursues a mild course in the negro race, milder than in the white. It is marked by but few cutaneous lesions; . . . nodes and periostitis rare, caries and deep ulcerations rare in early syphilis."

How far the factor of race is accountable for this exemption, is not plain. The Icelanders belong to the Scandinavian stock, which pays a heavy tribute in Norway, Sweden, and Denmark. The Greenlanders are of the same blood as the Eskimos inhabiting the west coast of North America, and the latter have had terrible visitations from it in the past.

Livingston says, in his "Travels:" "A certain loathsome disease which decimates the North American Indians and threatens extirpation to the South Sea Islanders, dies out in the interior of Africa without the aid of medicine. And the Bangwakatse, who brought it from the West Coast, lost it when they came into their own land southwest of Kolobeng. It seems incapable of permanence in any form in persons of pure African blood anywhere in the interior of the country. In persons of mixed blood it is otherwise, and the virulence of the secondary symptoms seems to be, in all the cases that came to my care, in exact proportion to the greater or less amount of European blood in the patient. Among the Coronnas and Griquos of mixed blood, it produced the same ravages as in Europeans; among the half-blood Portuguese it was equally frightful in its inroads on the system, but in the pure negro of the central parts it is quite incapable of permanence."

The last census shows that forty-three per cent. of those reported as dying from venereal disease were children under five years of age. In those parts of the country where distinctions are made between white and colored and Irish and German parentage the proportions are: Colored, 3.0; whites, 1.7; Irish, 1.4; and German, 1.3 per 1,000 deaths from known causes. In England and Wales the deaths from syphilis were, in 1880, 4.1 per 1,000 deaths from all causes. The Pacific coast shows the highest rate of any section, being for San Francisco and Oakland 7.38 per 1,000 deaths. In an article published in the *Philadelphia Medical and Surgical Reporter*, June 9, 1888, the writer called attention to the fact that "syphilis is more common—both the hereditary and the acquired forms—in the Southern negro than in the white race, and is, as a rule, more amenable to treatment than in the white or mixed races" ("Diseases of the Southern Negro"). Corson, of Savannah, says of syphilis: "The most aggravated cases in my practice have been among the colored, the secondary and tertiary symptoms are severe and prolonged, and the inherited form is very fatal," which, by way of contrast, shows that experiences are liable to differ.

Measles.—Susceptibility to the pathogenic factors of this disease is seen, from its general geographical distribution over the entire earth, to be almost uniformly shared by the whole of mankind, of whatever race or nationality. Among the colored races it is seen in its worst forms and leads to disastrous results exceptionally often as compared with the experience of the whites. The reason for this has been thought to lie rather in their unfavored conditions of life than in any pronounced physiological peculiarity inherent in them. This disease seems to be quite independent of all climatic influence, though it does occur mostly during the colder seasons of winter, spring, and autumn. It seems to run an equally mild course in tropical and subtropical regions as in the temperate, though in some particular sections, as in the Himalayas, in Madagascar, and in Honduras, it takes on a particular malignancy of type. Fuchs says in this connection: "There are certain parts of England, France, and Holland where the disease is most malignant, especially in the presence of malaria."

Squire has written in the *Medical Times and Gazette* for 1887 an account of the epidemic in the Fiji Islands which destroyed 20,000, or nearly one-fourth of the entire population. In the epidemic which prevailed in 1865 among the Confederate forces engaged in the Civil War, there occurred 38,000 cases, and 1,900 deaths, a mortality of 52.0 per 1,000, which in some instances reached as high as twenty per cent. in the hospitals.

During the siege of Paris (1871), out of 215 of the Garde Mobile who contracted measles 86, or forty per cent. perished. Masterman says of the epidemic that swept through the National Army of Paraguay, at the beginning of the war with Brazil, that it carried off nearly one-fifth of the entire army in three months. It is known that among uncivilized people the mortality from measles is sometimes truly appalling, since it is always here that the disease assumes its worst type. In an epidemic occurring in 1749 among the Amazons, of Brazil, 30,000 died; in some instances scarcely a vestige of tribes remained. At Astoria, in 1849, among a tribe of Indians, one-half perished from measles; the disease was equally fatal at Hudson Bay, in 1846, and also among the Hottentots in 1852. Fuchs says: "In the north and in the elevated districts, the inflammatory form occurs, while in the south and in the flat places it is more usually the asthenic and putrid forms."

Hirsch considers malignancy due more to mistakes in dieting and treatment than to other influences, and he accounts for the great diversities in epidemics upon these grounds. Corson (New York *Medical Times*, 1887) says: "The eruptive fevers go hard with the colored. I have seen three epidemics of measles, which were very severe and which carried off many (colored) children."

Small-pox.—It is a matter of common experience that the colored races, and especially negroes, are, *ceteris paribus*, in greater danger from small-pox than the whites. Sir Ranal Martin says he has never seen a case in India in a European child, but that there was not a year in which it did not occur among the natives. Hirsch looks upon India and Africa as the native foci for this disease, and certain it is, that the disease is very common among the yellow and black races of the East. "The members of the human family," says Pruner, "that are most susceptible to this poison are negroes. Not only in their native lands, but in other parts of the world as well, they are the first to succumb to the epidemic influence, and the last also."

He says further: "It is no unusual thing to see negroes attacked as soon as they arrive in Egypt (where they certainly change their ways of living as well as climate; and that, too, in those where the disease does not exist among the other inhabitants." Similar statements, equally positive of the liability of negroes to the disease, are made by Daniell for the west coast of Africa, by Rufz for Martinique (according to his observations in the epidemics of 1836-37 and 1848-50), by others for Curaçoa and Cayenne, and by [illegible] for Peru. During the epidemic which spread over Boston (1792) there died 10.8 per cent. of the whites and 24.7 per cent. of negroes.

In the epidemic of Baltimore in 1880 the deaths in 10,000 were 8.1 for whites and 14.5 for blacks. In a city of sixty thousand, several years since, the author had a personal experience with about one hundred cases of small-pox, in which the mortality was between eight and ten per cent. among negroes, and of the few cases among the whites none died. Climate and season appear to have very little influence upon the type of the disease, although the more northern countries of Europe suffer very severely in some epidemics.

Carson says: "In the years 1865-1877 small-pox prevailed in Savannah, and the death-rate among the colored was very high; the disease was invariably severe and left the patient deeply pitted."

SCARLET FEVER.—The area of diffusion of this disease is much less than that of either small-pox or measles. That the continents of Africa and Asia, which are the principal seats of these two diseases, have never been extensively or severely visited by scarlet fever is somewhat remarkable. As a rule this disease occurs less frequently than any of the exanthemata, and in some places ten to twenty years elapse between its visitations. Withering, one of the earliest and best authorities upon scarlet fever, states, upon the experience of his Birmingham practice of 1778, that the disease raged severely in many elevated and dry places, while the dwellers in low, damp, ill-ventilated parts of the town suffered to only a slight degree. Graves, in his "System of Medicine" (1843), says of the epidemic of 1839 in Ireland: "The nature of the disease was not in the least affected by the situation of the dwelling, it being equally bad in Dublin as in the hills." The origin and first habitat of scarlet fever is involved in obscurity, and in its early history it was linked with measles. The influence of place, time, and race are very marked upon the types of this disease. Pruner says that so far as he knows the colored races are exempt from scarlet fever. According to Moulin it occurs very rarely among the negroes of Senegambia. Frick, of Baltimore, has an account in the *American Journal of the Medical Sciences* for 1855, from which it would seem that the negroes and whites of the United States at one time suffered in nearly equal proportions, the ratio being, in the epidemic at Baltimore, in 1850-54, for whites a mortality of 13.8 per 10,000 population, and for blacks 10.8 in the same number of people.

According to the accounts of Brunel, Sigaud, and others, in South America, the disease is often of the same type among the colored races as among the whites. Matthewson (*Edinburgh Medical Journal*, 1849) says that the negroes really suffered more than the whites. Of the North American Indians, in Canada, Stratton says: "In epidemic scarlatina it appeared to me that the Indians were less susceptible of an attack than the whites." This disease has always been rare in the Southern States and the contrast is now greater than ever. The last census reveals that the mortality from this cause is for whites 28.9 and for blacks only 8.9 per 1,000 deaths from all causes. The large cities show a preponderance of deaths. With regard to nationalities the Germans have a death-rate of 30.1 and the Irish 24.0 per 1,000 deaths from all causes. Scarlet fever is more prevalent in the northern part of the United States and in Europe than in other countries. It appeared in England and Scotland in 1601 (Sibbald, "Scotia Illust.," 1684). When and where it first appeared in Asia and Africa cannot now be even approximately stated. It first showed itself in North America in 1735, in South America in 1829, and in Australia and Polynesia in 1847. It occurs commonly in Germany, France, Scandinavia, and Russia, going as far north as Iceland, though Greenland has escaped, and it is seen rarely in Newfoundland. In this country and in England and Wales this disease has shown a very marked decrease in the number of cases during recent years.

DIPHTHERIA.—This has become one of the most common diseases of modern times, both in its wide geographical area and in its general prevalence among races and nations. Since 1856 the disease has become diffused throughout North America and Europe. The statement of Odriozola, that the negro is protected in Peru against diphtheria as he is against yellow fever, is contradicted by Tschudi, who says very emphatically that it is just the children of the negroes in that country that suffer most from malignant sore throat, an assertion that has found support in the published experiences of Goldsmith, of Oakland, Md., and of Smart, of the Bermudas. Unfortunately we have little or no reliable information of this disease among the natives of the interior of Africa in their natural habitat. The only instances of its occurrence among them being in Senegambia, and the west coast, where the cases were sporadic, although in South Africa there was an epidemic in 1866, of which we have few or no details. On the eastern coast the disease has been more or less indigenous since 1857. Pruner found it in Egypt, and it is said to occur also in Algiers and Tunis. With regard to its manifestation in the mixed population of this country the last census reveals the fact that the mortality among the whites (52.63) is more than twice that of the negroes (23.27), the Indian coming between the two with a mortality of 37.36 per 1,000 deaths from all causes.

The inference drawn from these figures would seem to indicate that there is some protecting influence surrounding the colored race, but whether this is due rather to want of disease-producing causes than to insusceptibility on the part of the race is still to be determined. There have been several epidemics in India, the first, a disastrous one, occurring in 1800. Persia was visited by the dread affliction in 1874-78. It is stated that Syria, up to 1868, had not been visited by any serious forms. Asia Minor and Smyrna suffered severely from an epidemic in 1865.

The deductions made from the exemption of the Chinese during the epidemic in Victoria, that the Mongolians are not liable to contract the disease, has not been borne out, since, according to Dudgeon, it is widely diffused through Northern China and has also not spared the Japanese. It is stated that during the epidemic at Pekin in 1866 there died from diphtheria no less than twenty-five thousand Chinese. Southern China, according to the English reports, has so far escaped the disease, though Japan was visited by an epidemic in 1877, and Yokohama suffered severely. The mortality from this disease fluctuates widely during different periods of time, but experiences drawn from the study of statistics would lead us to conclude, upon the whole, that the disease has a decided preference for those of the white race living in the northern latitude, and that the proportion of susceptibility ranks first for the white race, secondly for the yellow, and lastly for the black.

CHOLERA INFANTUM.—With regard to the influence of race upon this disease, it should be mentioned that Frick, of Baltimore, in 1855 (*American Journal of the Medical Sciences*, 1855), regarded the mortality as being twice as great in the white as in the colored race. However true this may have been during his day, the opposite is now nearer the true condition of things. This disease certainly occurs all over the globe and is proportionally worse in those localities where impurities of water and soil exist, together with great heat and a crowded population. We are indebted to Benjamin Rush for the earliest account of cholera infantum in this country. The last government census gives the deaths from this disease as follows: Whites 99.1, colored 71.2, Irish parentage 68.0, and German parentage 90.1, per 1,000, though it must be added that the term employed by the enumerators—

Diarrhœal Diseases—also embraces dysentery, enteritis, cholera infantum, and cholera morbus. The death rates in the large cities of the United States is a little over ten in a thousand more than for the rural parts. The regions showing the greatest prevalence of this disease are the Upper Mississippi Valley, Texas, part of Missouri, Kansas, Georgia, and South Carolina. In Massachusetts and Michigan the deaths from cholera infantum amount to 15 per cent. of the total mortality, and in Boston it is 22.18 per hundred. In New York City, the deaths from 1805 to 1837 were nearly 2 per 1,000 of the whole population. During recent years these figures have increased considerably. In Philadelphia the mortality, in 1872, was reckoned at 2.6 per 1,000 population ("Transactions of the Pennsylvania Medical Association, 1873"), while from 1819 to 1860 it amounted to from one-fourth to one-third of the deaths from all causes. This disease is attended with a frightful mortality in some of our larger cities. In St. Louis (1841 to 1843), and at Memphis, which has been denominated the graveyard of children, it is very high (Grant, *American Journal of the Medical Sciences*, 1853).

We possess little information of this disease in Mexico, Central and South America. At St. Pierre, in Martinique, according to Rufz (*Arch. de Méd.*, Nov., 1869), it is the chief cause of death among children during their first year.

At Barbadoes, Jackson says that "it is by no means as common as might be expected from the tropical situation." For Asiatic countries there are no accessible data, but the inference would be that it is very fatal, owing to the general prevalence of choleraic disorders. Richardson asserts (*Edin. Medical Journal*, 1869) that the mortality from this cause is large in Australia. For Africa the only mention of the disease is at Port Said. Of its occurrence among the colored children of the Northern States little has been written. Corson, of Savannah, in an article in the *New York Medical Times*, 1877, claims that the deaths from this cause among negroes are double those of the whites. My experience leads me to believe that the colored children who suffer from this disease in nearly every instance die, the bad qualities of the lack of diet and attention telling fearfully upon them. In European countries the opinion is unanimous that this is one of the leading, if not the first cause of death in children. There is little difference in the statistics of the cities of the Eastern and Western Hemispheres. In Berlin the death-rate per 1,000 population was (1877 to 1882), 2.6; in Hamburg (1874 to 1884), 1.9; in Stuttgart (1873 to 1878), 2.4; in Königsberg (1858 to 1865), 1.85; in Birmingham (1873 to 1875), 2.04.

Trismus Neonatorum.—One of the most remarkable points in the geographical distribution of this disease, as compared with tetanus in adults, is the much greater prevalence of the former in the higher latitudes, and even in the extreme polar regions of both hemispheres. This is particularly true of large and populous towns, where most of the deaths from trismus of the new-born are among the poorer classes and in ill-kept foundling asylums. There seems to be but one opinion on the question of race influence upon this disease, and that is that the negro is exceedingly liable to its attacks. In Cayenne this disease produces terrible ravages. According to Hancock, in British Guiana trismus kills upon an average more than half of the children born. In Jamaica twenty-five per cent. of the negro children die each year from it. It is equally destructive in Barbadoes, Grenada, and St. Thomas. In the States of South America trismus is particularly fatal. Bourel-Roncière estimates the deaths from this cause in Rio Janeiro at twenty-five per centum of all the children born. In the city of Buenos Ayres, with a population of 200,000, and an annual increase of 1,000, the deaths from trismus in 1875 were 445, though they have steadily declined since 1880, when they were only 108 for the first six months of the year. Mantigazza witnessed a dreadful epidemic at Monte Video in 1852. In the tropical regions of the eastern countries this disease is fully as severe, notably so in India, Africa, and the Malay Archipelago. It is peculiarly common among the Jewish and Mohammedan children, owing to the traumatism resulting from ablation of the foreskin. According to Wylde (1854) it was common in Ireland. Patema also mentions it as occurring in Italy. In the Dublin Rotunda Hospital the death-rate from 1757 to 1782 was 16 per cent. and most of these were ascribed to trismus neonatorum. It has been endemic in Iceland, where it has caused a frightful loss of life. The Westmannö Islands, off the southern coast, were visited in 1839, and the mortality reached, according to Schleisner, 64 per cent. In New Orleans there were, out of a total mortality of 6,617, 249 deaths from trismus, a rate of 3.7 per cent. Baldwin and Dowell have described its ravages among the negro children of the South. Corson says, "trismus nascentium in the negro is of frequent occurrence as compared to whites. I have never seen a case recover."

Whooping-cough.—The first distinct account of this disease is given by Baillon as occurring in the sixteenth century. The native habitat of the disease is probably very narrow, and does not correspond to its present distribution. In Europe, whooping-cough is found to be pretty generally diffused, though the most fatal forms are found in the northern portion. The Scandinavian countries are great sufferers. In Sweden, from 1749 to 1764, according to Rosenstein, more than 43,000 children died of it, and from 1862 to 1881, 86,000 are reported according to the official returns. It is reported as equally fatal in Norway, Russia, and Denmark. In Prussia, from 1875 to 1880, the deaths reached the appalling number of 85,000. In England and Wales the mortality reports show, for 1848 to 1855, that the deaths were 72,000, and from 1858 to 1867 they were 120,000. The disease is common in Holland, Germany, Belgium, France, and Ireland. In the last-named country, according to Wylde's account (*Edinburgh Medical and Surgical Journal*, 1845), it has the character of an endemic malady, with a mortality that ranks fifth on the list of death causes. During the present century only four cases have been recorded as occurring in Iceland. Finsen, in a practice of seven years, claims to have never seen a case. There have been only three epidemics in the Faröe Islands. Tobler asserts that it has been epidemic in Palestine, and it is known to occur in Greece and Turkey. In India it ranges from the sea-coast up to altitudes of from 6,500 to 8,000 feet. It occurs in Java, Sumatra, and Borneo, as well as in China and Japan.

Australia has been visited by epidemics since 1830, the principal ones occurring in the years 1843 and 1855. According to Heyman and Waitz ("Diseases of Children in Hot Climates," 1851) the disease in the East Indies is found as often among the children of the Malay and Japanese population as among those of the Europeans. Milroy, Mackay, and others speak of its occurrence in India, among the native children, in ordinary terms.

In Africa it has occurred only in a few regions; Mauritius, Madagascar, and Cape Colony, South Africa, the Soudan, and Algiers have had visitations. In Egypt, according to Pruner, it is said to occur among children of every color. Experience shows that this is a disease that possesses little or no regard for either race or country. It occurs in all classes of society, though it seems to be more fatal among the poor than among the rich. The high mortality that appears to characterize the colder countries must be attributed to climatic factors rather than to race peculiarities.

Tetanus.—A noticeable fact connected with tetanus is that the influence of race upon its frequency is well marked. It is more common in all the darker races, and the liability seems to increase in a direct ratio with the depth of color; and while it is comparatively rare in the white race, it is particularly common in the negro. This facts holds good not only for those regions where the dark-skinned races, and especially negroes, have been introduced, such as the Southern States, West Indies, and Brazil, but also for their native seats, as is shown by the general prevalence of tetanus in Senegambia (Thevenot) and other countries of Africa. Swartz mentions the occurrence of tetanus on the West Coast, among the colored population of Cape Colony (Kaffirs in particular); it is found also among the dark races of India and the East

Indies, and among the Indians of Brazil (Sigaud) and the islands of the West Indies. It seems highly probable that this unusual susceptibility depends upon special vulnerability of the nervous system, or upon congenital instability to convulsive disorders in colored races, though some causative factor may reside in the heightened sensibility of the skin; that is to say, there may be a predisposition to be affected by sudden and chilling effects upon the surface. The colored races certainly possess peculiarities in this respect, and when we consider that the circulation (dependent upon continuous exposure to the excessive heat) in the skin is greater in these races, it may be that the differences are explicable upon these grounds.

This latter view is all the more tenable from the fact that even the creoles and acclimated residents in Cayenne, according to Sigaud's experience, are much more subject to the disease than the new arrivals from Europe, who would not have begun to develop that sensitiveness of the skin which always ensues upon a protracted residence in a tropical climate. If we look for another reason for the greater amount of tetanus among negroes, we may find it in the fact that they are much more exposed to the usual causes of the disease, i.e., going about imperfectly clad and barefooted, sleeping on wet ground, and being often wounded in the feet, circumstances that have a large influence in determining the disease. Tetanus is said to be very rare among the opium-smoking Chinese, and according to Bertillon does not occur at all. This people, as a rule, possess very little nervous excitability to any form of disease. Martin, of India, says that the Hindoos are highly susceptible to it. The census shows it to be very common in the rural districts of the Southern States, especially among negroes, being for the males 9.6 and for females 7.3 in each 1,000 deaths from all causes. In Charleston, S. C., it is very high, being in every 1,000 deaths 76.2 for males, and 44.7 for females. On the Gulf coast, throughout the rural sections, it is 32.0 for males, and 29.5 for females. In the city of New Orleans the deaths are, for males, 45.4; females, 44.8; the proportion for the whole of this region being 33.5 for whites, and 59.3 for negroes, in each 1,000 deaths. The extreme contrast to this is found on the North Atlantic coast, where the deaths from tetanus in the rural districts are only 0.7 for females, and 0.2 for males.

EPIDEMIC CEREBRO-SPINAL MENINGITIS.—Until quite recently this disease seems to have been largely confined to Europe; the countries where it has been oftenest seen being France, mostly in the southern part; Italy, particularly in the provinces of Sicily; and Sweden as far north as 63°. It has been prevalent, though slightly and rarely, in Ireland; also in Russia, Denmark (previous to 1848), Hungary, Austria, and Greece; but is absolutely rare in the Iberian Peninsula, Roumania, and Turkey. England has so far escaped with the mildest forms; the Netherlands and Switzerland with very slight and occasional attacks. Belgium, Scotland, North and Central Italy, and Iceland, have as yet complete immunity. The only reference to this disease in the far East is in Syria, Persia, and Asia Minor, although some few cases have been reported from India. The West Indies, Mexico, and Central America seem to be entirely free from it. At the present time, and for a few years past, this country seems to be its chief seat, and it has prevailed from time to time over every portion of the United States. The first outbreak occurred in 1814 in the New England States, and lasted until 1816. The remarkable fact associated with this epidemic was that it occurred almost wholly among children, the different outbreaks since showing many differences in this respect. With regard to the susceptibility of the different races, it is said that at the time of the first outbreak of the disease in Algeria the Arabs suffered as severely as the whites.

In several of the epidemics of the Southern States the negroes have suffered with particular severity. Of 85 patients treated by Ames, of Alabama, 22 were whites and 63 were blacks. In the New Orleans epidemic of [illegible] Faget says the negroes suffered the most, and it was chiefly among them that the disease was found. The same is true of the disease in Memphis, Tenn., during the outbreak among the colored troops in 1862-63. In the "Transactions of the Mississippi Medical Congress, 1878," Hughes calls attention to the unusual susceptibility of the negro race in the Mississippi epidemic of 1862-63, in the Maryland one of 1864, and in Mobile in 1864-65. Williams, of Montgomery, found that during the epidemic of 1848 out of 84 patients 10 were under ten years, 23 between ten and twenty, 27 between twenty and thirty, the remainder being between thirty and forty years of age. At the time of the occurrence of the disease in Philadelphia, in 1867, Guthrie says that it was severe in the negro.

MALARIA.—This is a disease of all times and peoples. The predisposition to it is highest in Caucasian races, not only in Europe, but also among the Arab population in the Barbary states and in India, where the Mohammedans and Hindoos suffer to the same degree as do foreigners. This is not less true for the Malays and Mongolians, and also for the Indians of North and South America. The tendency seems to be less in the Ethiopian races than in others (though this is limited to particular localities), which, however, do not enjoy complete immunity, though they are as a rule less frequently and less readily attacked than other people.

For this statement we have the experiences of Thevenot in Senegambia, and of Daniell for the West coast and for Nubia, and also the testimony of others, equally reliable, for other parts of Africa, as well as for malarious regions of the world to which negroes have migrated. There are some reasons for supposing that this immunity is an acquired one rather than congenital, as may be learned from the number of deaths among children. The predisposition is lessened or becomes weaker in proportion to the length of time that the individual is continuously exposed from birth to maturity. That this exemption may be entirely lost again, is fully exemplified by the history of the negroes in the South, who, previous to the late civil war, were remarkably free from malarious influence; but now, through the changes incident to freedom, cares, intemperance, and alterations in life generally, they are peculiarly liable to it, the death-rate being 48.3 per 1,000, from all causes, for blacks and only 30.7 per 1,000 for whites.

Trotter says that, "the constitution of the negro, whether of African or American birth, requires an habitual residence in Africa to be exempt from the fever of that country." Some authorities have denied that there can ever be such a thing as acclimatization in a malarious region, since this is peculiarly the very disease in which one attack always gives a predisposition for the recurrence of another. But that continuous exposure does have some influence in keeping off or mitigating the disease can scarcely be denied or refuted, since it is known that those who are born and live amidst it with impunity, will, if they leave their native country for a season, suffer from it upon their return.

In the malarious districts of Europe, the indigenous population sicken much less frequently than people who come there from regions free from malaria. In India the type of the disease appears to be altered with regard to the natives and Europeans, being for the former paroxysmal in character, and for the latter continued, and often associated with grave cerebral affections. In Costa Rica, says Frantzius, "the severe forms of malarial sickness occur among the blond-haired and blue-eyed Europeans and the residents of the cooler regions of the highlands, while the settlers and acclimated are affected but little; the negroes and mulattoes showing the greatest resistance of all."

Barat says of the severe malaria of Mauritius, that the Kaffirs and Malagasys suffered less than any others. The malaria of China is prone to take on a typhoid type ("Report of Medical Mission of China," 1888).

TYPHOID FEVER.—This is now known to be a ubiquitous disease, although until quite recently the tropics were considered to be free from it. There seems to be unanimity among observers that the immunity acquired through acclimatization is more perfect in tropical and subtropical regions than in the higher latitudes.

Bryden has conjectured that high temperature predisposes the newcomer to the disease in India. This same observation has been made with regard to those newly arriving in New Caledonia, where it is stated that the natives are totally exempt from typhoid fever. It is said that the Arabs of Algeria are scarcely ever attacked, though the disease is both common and fatal among Europeans resident there. This disease is rarer and milder in lower latitudes than in higher, but whether this is to be attributed to climatic factors rather than to others remains to be proven. The influence of race is manifested in this disease to the extent of the negro being less liable than the white; this is especially true as regards the former in their natural habitat, though change of residence is known to extinguish this protection and bring about susceptibility.

Tidyman (*Philadelphia Medical and Surgical Journal*, 1826) calls attention to the frequent occurrence of typhus (typhoid) fever among the negroes of the Southern States, who at that time were free from malarial influence. Of forty-three cases of typhoid fever treated by Sutton, of Georgetown, Ky., in 1846, thirteen were among negroes. Lewis says that hundreds of negroes died in the winter of 1835–36, of this disease, in central Alabama; and Gaston (*New Orleans Medical Journal*, 1844) speaks of its frequent occurrence among the negroes of South Carolina.

The influence of class is seen in this disease in that those of the higher walks of life are less susceptible, though when attacked they suffer the most. During the year 1885, the death-rate from typhoid fever was found to be, in each one hundred thousand of population, as follows: Paris, 63; London and Berlin, 17; Vienna, 14, and Marseilles, 149. In the year 1887, the mortality from this disease was stated to be, in each 1,000 deaths from all causes, as follows: London, 46.8; Dublin, 16.05; Paris, 17.06; Berlin, 44.0; Geneva, 23.8; Vienna, 20.9; St. Petersburg, 29.0; Lisbon, 14.5; Cairo, 38.8; Philadelphia, 28.8, and New York, only 8.01.

The tenth census gives the mean age of death for this country at twenty-seven years. The rate among each 1,000 deaths from all causes is 30.19. In comparing the rural and urban sections, the mortality for the former is given at 36.0, and for the latter at 16.7, indicating that this is not altogether a disease dependent upon sewerage and filth. Figures relative to the mortality in the different races show that the whites have a death-rate of 33.9, and the negroes one of 31.7 per 1,000 deaths from all causes. The Irish show a smaller, and the Germans a larger, death-rate than the average for the whole country. In its geographical distribution typhoid fever is found to be especially common in the central States, and also in those of Georgia, Tennessee, North Carolina, Alabama, and Texas.

Yellow Fever.—Measured by its range over the earth, yellow fever holds a low rank among infectious diseases. This limited area necessarily limits the study of its comparative features, still there are sufficient data to enable us to distinctly discern the influence of race and nation upon its phenomena. The early history of this disease is involved in obscurity, and the first reliable account comes from the middle of the seventeenth century. The distribution of yellow fever extends, in the Western Hemisphere, from 35° 54′ (Montevideo) south latitude, to 44° 39′ (Halifax) north latitude. In the Eastern Hemisphere it goes from 8° 48′ south (Ascension) to 51° 37′ (Swansea) north. Regarding the manifestation of susceptibility among the different nations and races, there is one prominent feature, and that is, the newly arrived stranger, in a yellow fever district, is the one most liable of any; and this is found to depend somewhat upon nationality and the distance of his former residence from the equator. Under this heading we have the careful data obtained by Barton upon each 1,000 deaths in New Orleans, in the year 1853:

Native Creoles		3.54
Strangers from	West Indies, Mexico, and South America.	6.14
" "	Southern United States	13.22
" "	Spain and Italy	22.06
" "	Middle United States	30.69
" "	New York and New England	32.83
" "	Western States	44.23
Strangers from	France	48.13
" "	British America	50.24
" "	Great Britain	52.19
" "	Germany	132.01
" "	Scandinavia	163.26
" "	Austria and Switzerland	220.08
" "	Netherlands	328.94

Blair states, from his experience in Guiana from 1837 to 1845, that "the lower the isobar in the native country of those attacked, the more severe the sickness, so that, while the mortality among the West Indians amounted to 6.9 of those sick, it arose to 17.1 in the Italian and French, 19.3 in the English, 20.2 in the German and Dutch, and for the Russian and Scandinavian it was as high as 27.7."

It has been considered a matter of doubt whether there was anything like congenital immunity due to peculiarities of race. So far as this pertains to the white race, there seems to be little reason for further entertainment of the question. While the relative immunity that the creoles enjoy is a fact, yet this can be reasonably referred to acclimatization, and partly also to the circumstance that they might have had the disease in childhood, and have thus acquired immunity. Concerning the colored races, the question is not so easily determined. There are so many remarkable occurrences, associated with the negro and yellow fever, that point to his being protected in some manner, that we are forced to conclude that he does possess some congenital immunity. That this is born in him, and not acquired, may be inferred from the fact that the same exemption occurs wherever he exists, and even when he has not been acclimated, and it is more pronounced in those that possess the racial characteristics the strongest. A noticeable fact connected with the outbreak, in 1888, at Jacksonville, Fla., was that thirty-eight cases occurred among the whites before a single negro was attacked.

Daniell says of the epidemic in Savannah, 1820, "that not a single case occurred in three hundred blacks that had just been imported."

Nott, who attended through five epidemics at Mobile, never had a case in the pure negro, though he saw two or three in mulattoes.

Fenner says that the least mixture of the blood of the white race produces liability, and this is directly proportional to the amount of white blood. He further states: "It is a well-established fact that there is something in the negro's constitution which affords him protection from yellow fever." Doughty expresses himself to the same effect: "In the natural African the constitution appeared to me as secure against yellow fever as a person who has had small-pox is against its recurrence." These opinions are amply corroborated by the learned Dickson, Moultrie, Arnold, Leblond, and Curtis. Blair says of the epidemic of 1852 to 1853 in Guiana, of 7,890 negroes not one had the fever. Of the 500 negroes from the Nubia and Soudan regions, which are free from fever, who went to Mexico with the French army, not one had the fever; whereas the French and Mexicans were decimated by it. The American Indians, those of Mexico and Brazil, and the Coolies (Hindoos), according to Kerhuel, in Cayenne, have no immunity.

On the other hand, the Mongols, like the negroes, are more or less exempt. "The Chinese," says Eysaguire, "settled in Lima, are like the native negroes, almost exempt from the disease."

Dengue.—This is a peculiarly tropical malady, being limited to places on the coast between 32° 47′ north latitude, and 23° 23′ south latitude. It manifests an almost absolute independence of circumstances of race, nationality, sex, and age. Only a few observers, such as Squaer, Maxwell, and Stedman, in the West Indies, have found that the negro had the sickness more rarely or more mildly than other races. In the Java epidemic, in 1872, according to De Wilde, that race enjoyed an almost complete immunity. In the instance of the epidemic at Benghazi, Pasquar says, "it was notable for the remarkable immunity experienced by the blacks;" but he adds, that this race at the time had no exemption in Egypt, Senegal, or elsewhere.

Christie is also of the opinion that the natives of Zanzibar suffered less than the Europeans. On the other hand, Kennedy, of Guzerat (1828), and Manson and Müller, at Amoy (1872), met with more numerous and more severe cases among the natives than among Europeans. In Cochin China, according to the opinion of Breton, cases of dengue sickness were much more frequent among the Annamese part of the population than among the Chinese.

Wise, in the Dacca epidemic of 1872, appears to have detected a peculiar predisposition to dengue in persons who were suffering from surgical disease. According to [illegible], children enjoyed a certain exemption in the Mauritius epidemic of 1873. These conflicting reports are of such a nature as to leave the question of race susceptibility in a very unsettled condition.

In Lallemand's account of the disease at Rio de Janeiro, 1846–47, he says, "on the *fazenda*, whole gangs of negroes fell ill, ships were abandoned, and schools deserted."

In Calcutta, during the epidemic of 1871–72, the number of cases was estimated at seventy-five per cent. of the whole population, the disease being first developed among the Jews, and the poorest and those living in the most densely populated parts of the town. Maxwell says, concerning the epidemic at Jamaica, that "almost the whole population, both white and black, were affected sooner or later." In 1818, only a few of the seventy thousand inhabitants of Lima escaped.

PUERPERAL FEVER.—This disease, as a rule, seems to be one that primarily occurs among civilized and thickly crowded populations of the higher latitudes. According to Peschel, a European woman in the Dutch possessions in India reflects maturely before she consents to marriage, for the first childbed usually costs the life of the mother. Rowley, the English missionary, says "even the Portuguese women at Tete, on the Zambesi, succumb to this dread fatality." Sir Ronald Martin, speaking of India, gives his experience as follows: "Puerperal fever I never saw in Calcutta, and I remember very few instances of children born dead." However, others equally deserving of confidence have stated that puerperal fever occurs here in its worst types. Dr. Clark observes that on the coast of Coromandel "parturition is not attended with such great danger as in Bengal, neither is puerperal fever of such a putrid nature." The London *Lancet*, for 1845, says that in Australia and New Zealand the disease is quite rare. In South America it visited Montevideo, in 1875, with a disastrous epidemic. Turkey, and Constantinople in particular, is said by Rigler to have less puerperal fever than any part of Europe, yet the disease does occur there sometimes. It is said to be very rare both in Iceland and Greenland. In the populous parts of this country it is equally as common as in Europe. It is very rare in Central America and the West Indies. Africa is said by only one authority (Pruner) to be visited by it, and this in Egypt, where it is both slight in degree and uncommon. In India, according to Webb,[2] it is by no means infrequent among Hindoo women, in whom it prevails often to a great extent.

ERYSIPELAS.—The occurrence of this disease among the various races is attended with some marked peculiarities. The continent of North America seems to be the particular seat for epidemics, having been visited by seventy from 1822 to 1880, the territory invaded extending from Louisiana to Greenland. Holmes says (1854): "Nearly every year we hear of it either in Michigan, Wisconsin, or Minnesota. It also occurs in the wet, cold spring months in Louisiana and Texas." Seven of these epidemics were in New England, and eighteen in the eastern central States. This disease has been in the past limited to the temperate zones of both hemispheres.

We have various accounts of its occurrence in the warm and subtropical climates of Turkey, Asia Minor, Syria, Persia, Algiers, and Egypt. It has visited Iceland, Greenland, and the Faroe Islands, according to Martins and Lange. Whether the purely tropical climates are exempt from erysipelas, as has been claimed, is still a debatable question, and conclusions on this point should be drawn with great caution. Coindet[1] says he did not see a single case during seven years of practice in Mexico. Carlisle is reported as knowing of only one case in a practice of five years at Zanzibar. MacKinnon and other authorities of India say that it is a rare disease in those regions, though Annesley and Morehead say that traumatic erysipelas is sometimes common enough to become an epidemic. Material available for correct conclusions regarding the influence of race upon this disease is very meagre, and there seems to be much confusion in its classification. Tschudi says that it is much more common in the "Puna" regions of Peru (inhabited by Indians) than in the Eastern Slopes.

CHOLERA.—It is a matter of difficulty to estimate the influence of race and nationality upon this disease. The elements that enter into a mixed population are very variously circumstanced as to food, drink, habitation, and living in general. However, there seem to be some grounds for the common belief that the negro race is in greatest danger from the disease. Christie, in the London *Lancet*, 1871, says, from his experience on the east coast of Africa, that this was the case there. At Durban and Mauritius authorities say the same. With reference to Reunion, Petit and Vinson say: "On the east coast of Africa the mortality is 6.5 per cent. in the Hindoo population, 10 per cent. in the Arab, and 25 per cent. among the negroes." Again, Beaugendre says of Mauritius, in 1819, that "twenty-two thousand negroes died in two months; likewise in 1854 the African race presented by far the largest contingent to the sick-list and death-rate." At this same place and time, the Chinese who were present suffered only in isolated cases, notwithstanding that they lived in the districts chiefly affected.

The report of Petit, of Reunion, in regard to the epidemic of 1859, says: "They fell down (the negroes) in a stupor, as if they had been paralyzed . . . . Men who were in full vigor and life immediately before were prostrated in the course of three or four hours." In the Dutch East Indies, during the epidemic of 1873, the mortality among the natives was 35.3 per cent. of the sick, and among the Europeans 51.5 per cent., while it was nearly 60 per cent. among the negroes. In Ceylon, 1859–67, an average of 4.9 sickened in every 1,000 troops (Europeans), and 2.38 died, while the numbers among the negroes were 8.7 and 4.87 per 1,000.

According to Walther[3] the proportion of deaths among the population of Guadeloupe, during the epidemic of 1865, was as follows: Chinese, 2.7; Hindoo coolies, 3.26; whites, 4.31; mulattoes, 6.32; and negroes, 9.45.

In the United States Army, in 1866, of the white troops, 77 in each 1,000 were attacked, while of the blacks 135 per 1,000 suffered. Anglo-Indian physicians have made some very conflicting reports regarding the occurrence of cholera among the Hindoos as compared with the Europeans. By Bryden and Cunningham, the statement is made that the disease was more common among Europeans stationed in India than among the Sepoys, but there are reasons to think that these differences are due to their mode of life, which is more simple and temperate than that of the English, rather than to race peculiarities. From 1861 to 1870 the mortality in Bengal was, for Europeans, 2.12 per 1,000, and for Sepoys 4.27 per 1,000. In Punjab it was for Europeans 5.63 per 1,000, and for Sepoys 1.63, showing quite a contrast in different localities. There seems to be no question but that the type of the disease is the same in both these localities and among both people.

All observers are in accord with the statement that the natives of Lower India, including Siam, Annam, and Burmah, suffer much less from cholera than the European settlers. As to the question of individual resistance, it has been found that this is directly proportional to good hygiene and cleanliness, experience showing that groups and classes of population suffer in a direct ratio to the unhealthfulness of their surroundings.

J. Wellington Byers.

REPRODUCTION. To the growth of every organism there is a definite limit, and until that limit has been reached or approached the material gained by the organism by the assimilation of food-stuffs is applied to its increase in size; but as soon as this normal limit of size is approached there supervenes a tendency toward a separation of a portion of protoplasm to form a new individual, more or less similar to that from which it had its origin. In this way extinction of the species is guarded against, and this process of separation from the parent of a portion of its substance capable of leading a more or less independent existence is termed Reproduction.

Among the most simple forms of life the various modifications of the reproductive process may be reduced fundamentally to such a simple separation of a portion of the tissues of the parent as has been indicated above, and there is no question of a union of two elements, or *gametes*, to form a single descendant. In forms a little higher in the scale of life there is, however, such a union, and since in this process there is required the co-operation of two elements, and a more or less perfect distinction of sex is indicated, it is termed the *sexual* method of reproduction, in contradistinction to the more simple method, which is known as the *non-sexual*, or *asexual*.

There can be no doubt but that the non-sexual method is the more primitive of the two, but even in forms of a relatively very low grade of organization the sexual method occurs, and as one ascends the scale, both in plants and in animals, one finds it becoming more and more important, until, finally, as a means of perpetuating the species it entirely supplants the more simple method. In the majority of animals and plants, however, both processes occur, and even in the highest forms the non-sexual method is to be observed in the individual cells of which they are composed, not, however, strictly speaking, as a process of reproduction, but simply as a mode of growth. In multicellular organisms a process termed the "physiological division of labor" occurs in all but the simplest forms; the various cells composing such an organism do not all retain all the functions which a simple unicellular organism presents, but certain cells take upon themselves one principal function, losing to a greater or less extent the power of fulfilling the others. Thus certain cells assume the function of assimilation for the entire organism, disregarding the other functions, such as respiration, motion, sensation, reproduction of the species, etc., which are respectively performed by other groups of cells. Thus these various cell-groups, or organs, each with a different function, are dependent one upon the other, and are united to form an organism whose vital activity is the sum of the vital activities of its component organs. Now the function of reproduction of the species is assigned to, or assumed by, certain definite organs, known as the ovary in the female and the testis in the male; but the individual cells of the other organs retain, for a time at least, the power of non-sexual reproduction, whereby new cells, similar structurally and functionally to those from which they originated, are produced, and the organ and the organism thus increase in size, or grow.

Growth, in fact, in such multicellular forms, depends essentially upon the increase of the number of cell elements of which the organism is composed, this increase being brought about by the division, *i.e.*, the non-sexual reproduction, of the cells already present. The difference between growth and reproduction lies simply in the fact that in the former the newly formed cells do not separate themselves from their fellows and lead independent existences, but remain in organic connection with them and with each other (see article on Segmentation). Hence reproduction has been well defined as discontinuous growth.

Non-sexual Reproduction, or Agamogenesis.—This method of reproduction is essentially the division of the parent organism into two or more parts. In unicellular forms the new parts formed are necessarily also unicellular, but in multicellular organisms the parts separated off may be multicellular and include cells from various regions of the body. The process is best illustrated, however, by what take places in unicellular organisms, or by cases in which a single cell of a multicellular structure reproduces independently.

The simplest form of the process is that of *fission*, or *division*, in which the parent cell splits into two equal or nearly equal daughter-cells. This is the commonest form of non-sexual reproduction, and can be well seen in many unicellular organisms, both animal and vegetable. It may be observed, for instance, in the Monads, in the Infusoria, etc., among animals, and in the Bacteria and many other unicellular Protophytes among plants. It is also the method usually followed in the multiplication of cells occurring during the growth of an organism, and can be readily observed in the developing ovum of many animals (see article on Segmentation). In a cell about to undergo division remarkable changes in the protoplasmic contents usually occur, affecting principally the cell-nucleus, which, after passing through a series of usually definite changes in appearance, shape, and arrangement of its constituent molecules, finally divides into two parts, which separate from each other, and following this division of the nucleus a division of the rest of the cell takes place. This is well seen in Fig. 5019, which represents a unicellular animal, *Amœba polypodia*, in various stages of fission.

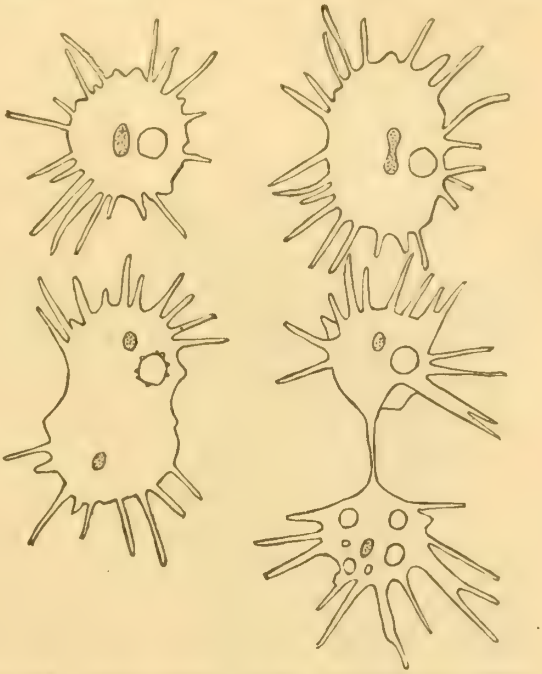

FIG. 5019.—Amœba polypodia, M. Sch. Reproducing by division. (After F. E. Schulze.)

The other modifications of non-sexual reproduction may be regarded as variations of the fission process, differing only in the manner in which the division takes place. *Gemmation*, or *Budding*, includes a number of cases in which the part to be separated forms at first as a small outgrowth from the body of the parent, which outgrowth, gradually increasing in size, is finally constricted off from the mother-cell. A good example of this is afforded by the yeast plant (*Torula cerevisiæ*) as shown in Fig. 5020, which represents a stage in the reproduction of that plant. Not unfrequently, however, the bud does not separate from the parent, but remains more or less intimately connected with it, a colony being thus produced. In multicellular organisms this frequently occurs, the gemmæ,

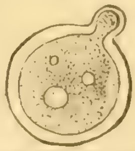

FIG. 5020.—Torula Cell. Reproducing by budding.

or buds, giving rise to more persistent individual members of a colony, and being usually multicellular also. The buds which give rise to the branches of trees are examples of this, since a tree may be considered a colony of [illegible], and among animals the Hydroids, Corals, Polyzoa, and Tunicates furnish numerous examples of the same process.

Endogenous cell multiplication constitutes another modification of the non-sexual method, consisting of the separation of the protoplasmic cell contents into a number of parts. The process of separation is not, however, division in the typical sense, but consists of the formation in the protoplasm of a cell of a number of centres of aggregation, which may or may not be represented by a nucleus, and around each of which a portion of the protoplasm collects, forming a cell. This method is well exemplified in certain Fungi belonging to a group termed the Ascomycetes.[5] Peziza, the common Cup-fungus, may be taken to illustrate the process (Fig. 5021). The non-sexual spores are formed in club-shaped cells termed asci, arranged in a layer, usually brightly colored, upon the concave surface of the cup-like structure. These asci when first formed are densely filled with granular protoplasm which contains a single nucleus (Fig. 5021, *a*). This soon disappears, its substance being distributed throughout the protoplasm, which becomes richly vacuolated (*c*). Centres of aggregation (usually eight in number) soon make their appearance, being in some cases preceded by the formation of nuclei, one for each centre, and around these the granular protoplasm collects to form eight oval spores or cells, which form for themselves cell walls, and are liberated by the rupture of the original ascus wall.

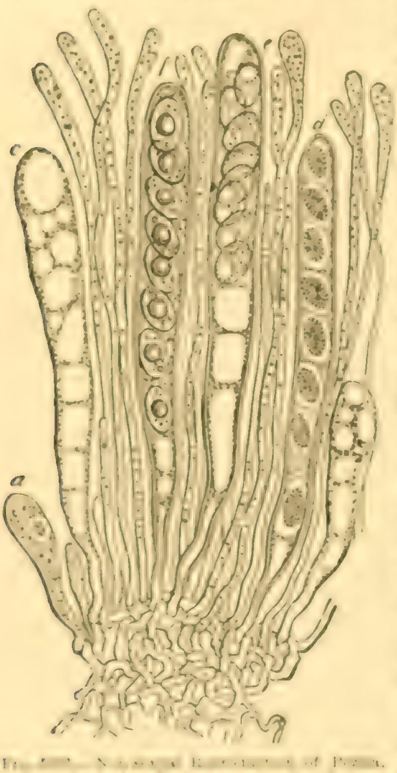

Fig. 5021.—Non-sexual Reproduction of Peziza. (From [illegible].) *a*, Young ascus; *b*, *c*, *d*, *e*, *f*, stages in formation of ascospores.

Among animals this process is not so frequent as in plants, but nevertheless it is to be seen in some forms. The spore formation in some of the unicellular parasitic Gregarinida appears to be to a certain extent at any rate a process of endogenous cell formation, and in the closely related cell parasites, the Coccidia, it is of the same nature. Among the latter there are some interesting examples presenting a series of stages between ordinary fission and the simultaneous formation of a number of cells from the mother-cell protoplasm, *i.e.*, endogenous cell multiplication. The number of spores formed by the Coccidia is in direct proportion to the size of the individual, the larger the mother-cell the greater the number of spores. In the genus *Eimeria* the contents of the encysted mother-cell form a single spore which surrounds itself with a delicate wall, while in *Klossia* and *Isospora* the number of spores formed by each mother-cell is increased to two, formed by a single process of division, and in *Coccidium oviforme* from the epithelial cells of the gall-duct and intestine of the rabbit,* four spores are formed, probably by a simultaneous division of the contracted protoplasmic contents of the encysted mother-cell. Finally, in other larger forms, such as that which occasions relatively large cysts in the kidney of the frog, a considerable number of spores are formed by endogenous cell multiplication.

The case of *Coccidium* is especially interesting. What occurs in that form may be regarded as a case of acceleration of ordinary fission, and many cases of a similar nature might be referred to. For instance, we know that in the segmentation of an ovum the various phases of division appear regularly in sequence, the ovum dividing at first into two parts, each of these then into two more, and so on. In the ova of the Cœlenterate *Renilla* E. B. Wilson has observed a remarkable departure from the normal sequence of the divisions, the ovum at once separating into eight, sixteen, or thirty-two cells, the intermediate stages being omitted, and Brooks has observed a somewhat similar acceleration, not carried, however, quite so far, in the ova of the American oyster. It is unnecessary to draw attention to the similarity of these cases to that of *Coccidium*. They serve to indicate the relation which endogenous cell multiplication bears to ordinary fission.

Encystment.—Before leaving the subject of non-sexual reproduction, attention must be called to a process which frequently accompanies, or rather precedes, this mode of reproduction, especially in unicellular forms. It is the phenomenon of encystment, consisting of a rounding off and contraction of the protoplasm of which the individual is composed, followed by the formation of a wall or cyst, more or less resistant and non-conductive, within which the organism remains for a greater or less length of time in a resting condition (Fig. 5022). It does not seem likely, however, that encystment had originally any connection with reproduction, but occurred under widely different circumstances, either (1) for the protection of the organism and the preservation of its existence when subjected to unfavorable or injurious conditions, such as lack of food, moisture, etc., or (2) when the organism had been supplied with and had ingested a large amount of nutritive substance and entered into a resting stage for the purpose of more rapidly and efficiently assimilating the food stuffs, the cyst being formed perhaps as a protection from enemies.

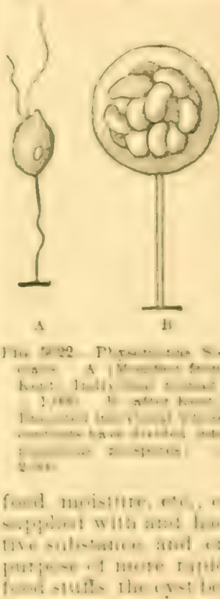

Fig. 5022.—Physomonas Socialis. A, [illegible] (Kent); [illegible]; B, after having become encysted and [illegible] contents have divided into [illegible] zoospores. [illegible]

It is perhaps in connection with the latter case that encystment has become so frequently a prelude to reproduction. Lack of nutrition results in the impairment of the reproductive processes, and, conversely, abundant nutrition favors proliferation. A well-nourished organism which has entered its resting stage is assimilating the food stuffs it has ingested without any such loss or expenditure of energy as it would suffer were it actively moving about, and is consequently under most favorable conditions for reproduction. Hence has arisen the association of the two processes. It must be observed, however, that division is not invariably the direct sequel to encystment, even when the latter is the result of an excessive supply of food stuffs. It may happen that after remaining in this resting stage for some time the organism will finally issue from the cyst in a form similar to that which it possessed before being enclosed, but better nourished and rejuvenated, and reproduction by division may then take place. Such a process only serves, however, to substantiate the theory that encystment and reproduction are not phenomena originally dependent upon each other.

---

* The Coccidium which occurs in the liver cells of man is probably identical with this, as are forms occurring in several different kinds of [illegible].

Sexual Reproduction, or Gamogenesis.—Sexual reproduction consists in the formation of two kinds of reproductive cells, a union of which is necessary for the development of a new organism. In the simplest forms of the process there is no differentiation of the two cells, so that one can readily be recognized as the fecundating and the other as the fecundated cell, but both the elements are essentially similar. This simple form of the process is known as *conjugation*, and is well represented in some of the lower plants, for instance in the genus *Spirogyra*. This consists of filaments usually occurring in masses of a bright green color in stagnant water, each filament being composed of a number of elongated cells placed end to end, and characterized by the green coloring matter, chlorophyll, being arranged in one or more spiral bands. When about to conjugate, processes grow out from the walls of the cells of adjacent filaments (Fig. 5023, *a*), which, increasing in length, finally come into contact (Fig. 5023, *b*). By the absorption of the cell wall of each process at the point of contact, a canal uniting two cells is formed. In the meantime the contents of each cell engaged in the process have contracted to a rounded mass, and after the establishment of the connecting canal one of these masses flows over through the canal into the other cell, and unites with the protoplasmic mass with which it comes into contact there (Fig. 5024, *A*, *a*). The single spore so formed surrounds itself with a more or less dense wall (Fig. 5024, *B*), and after remaining for a length of time in this condition germinates, if circumstances be favorable, and develops into a Spirogyra filament similar to those from which it arose.

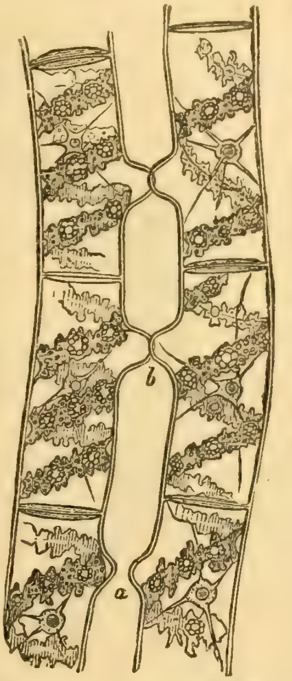

FIG. 5023.—Conjugation of Filaments of Spirogyra longata. *a*, Beginning of formation of processes; *b*, the processes in contact. (From Sachs.)

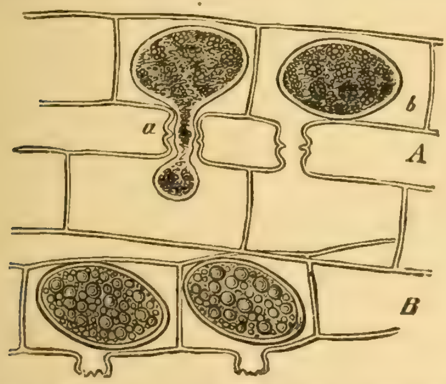

FIG. 5024.—Conjugation of Spirogyra longata. (From Sachs.) *A*, Protoplasm passing from one cell to the other at *a*; *B*, spores resulting from conjugation.

In the majority of cases, however, there is a well-marked difference between the two uniting bodies or *gametes*, as they may be called. One is termed the female gamete or ovum, and is the larger fecundated cell, usually incapable of motion; while the other, the male gamete or spermatozoon is, as a rule, much smaller, and capable of active movement, and is the fecundating cell.

Among animals the ova and spermatozoa are formed at certain definite points by the modification of certain cells of the germ layers. Among the cœlenterates, the ova cells are derived, in some cases, from the ectoderm, and in others from the endoderm; but in higher forms it is usually certain cells of the mesoderm which assume the reproductive function, being aggregated into definite masses, termed the ovaries or testes, according as they are female or male. The gametes when mature are, in the majority of cases, dehisced into the pleuro-peritoneal cavity, and make their way to the exterior by ducts, usually specially modified portions of the excretory apparatus. In most cases the ova are fertilized after they have reached the exterior, though frequently the union of the two gametes takes place within the body of the female parent.

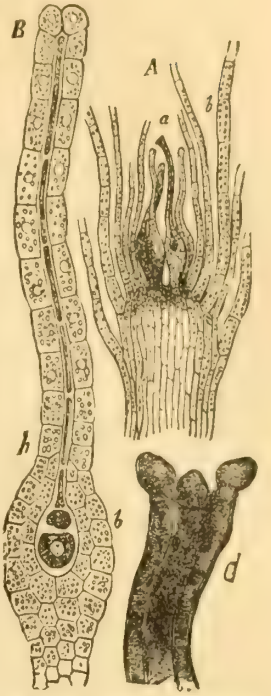

FIG. 5025.—Female Reproductive Organs of Funaria hygrometrica. (From Sachs.) *A*, a cluster of archegonia (*a*) at apex of stem, surrounded by leaves (*b*); *B*, archegonium magnified; *C*, apex of fertilized archegonium.

In plants possessing well-marked male and female gametes, as, for instance, the mosses, the male gametes are minute mobile bodies developed in the cells of a special organ, known as an antheridium (Fig. 5026, *A*). This consists of an external envelope formed of a single layer of cells, and an internal mass of cells in which the male gametes are formed. When these are mature the walls of their parent cells break down and disappear, and the gametes are thus set free in the interior of the antheridium, and on the bursting of its outer envelope they pass to the exterior. The female gamete is enclosed in a special, usually flask-shaped organ, the archegonium (Fig. 5025), which likewise consists of an external envelope enclosing a single axial row of cells. The lowermost of these becomes the female gamete, and the others finally degenerate and are transformed into a mucilaginous mass filling the neck of the flask, through which the male gametes make their way to come into contact with the female element. Only a single gamete is thus formed in each archegonium, while the number of spermatozoids in each antheridium is usually very great.

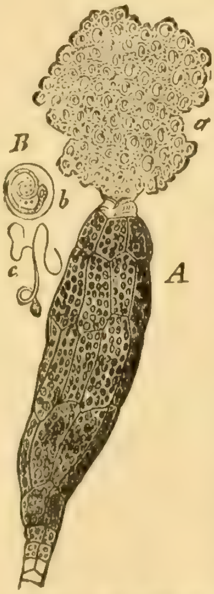

FIG. 5026.—Male Reproductive Organ of Funaria hygrometrica. (From Sachs.) *A*, antheridium; *a*, the male gametes escaping; *B*, a male gamete enclosed within the parent cell, *b*, and free, *c*.

The arrangement just described may be regarded as typical for plants, but in the higher forms, the gymnosperms or cone-bearers, and angiosperms, or flowering plants, many complications have arisen which will be alluded to under the heading of "Alternation of Generations," but for the detail the reader must be referred to botanical text-books.[6]

The Relation of Sexual to Non-sexual Reproduction.—At first sight it would seem that these processes were quite distinct one from the other, and could have no connection with each other. By studying the reproductive processes exhibited by the lower forms of life, a very gradual passage from one to the other can, however, be observed, and an account of some of these processes, both in plants and in animals, will be given.

In discussing the modifications of non-sexual reproduction, no mention was made of the fact that the newly formed cells or spores are in many cases slightly different from the parent cells which give rise to them, the difference consisting in the possession by the progeny of protoplasmic processes termed flagella, by the movement of which locomotion is possible. The simplest mode of formation of these motile zoospores, as they are termed, is to be seen in a unicellular plant, *Protococcus*, common in moist situations, which in its non-motile condition consists of a minute spherical mass of protoplasm having intermingled with it green or red coloring matter, and provided with a nucleus and a cell-wall composed of cellulose—a typical plant-cell in fact. It reproduces rapidly by division under favorable conditions, forming patches sometimes covering comparatively large areas, and under certain circumstances passes into a motile stage. The protoplasm withdraws itself from the cell-wall and develops two long flagella, and by the bursting of the cell-wall the entire contents are set free as a motile zoospore (Fig. 5027, *b*) which, after swimming about for a while, settles down, absorbs its flagella, forms a cell-wall around itself, and returns to the resting stage from which it originated.

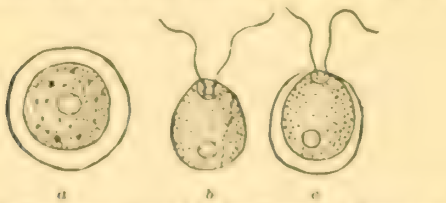

FIG. 5027.—*Protococcus.* (*a* and *b* after Howes.) *a*, Resting stage; *b*, zoospore; *c*, zoospore before it has left the cell-wall.

This process cannot strictly be termed reproductive, but is probably for the purpose of dissemination of the individuals composing a group which is enlarging unduly in proportion to the amount of nutrition obtainable in the locality to which it is confined. By means of the zoospore stage individuals are enabled to wander some distance from their fellows, and so all are relieved from a too intense struggle for existence.

In many cases, however, this formation of zoospores is associated with reproduction by division; as, for instance, in the filamentous alga known as *Ulothrix*,[7] which occurs frequently in considerable quantities in fresh-water ponds and streams. Each plant consists of a green filament, composed of a number of cells arranged in a single row, the basal cell being modified to form an organ of attachment. Each cell of the filament may be compared to a *Protococcus* cell, the entire filament being equivalent to a filamentous colony of protococci. The process of fission is limited to growth, the new cells formed by this process not separating and leading independent existences, but remaining in connection and so producing an increase in the length of the filament. The reproduction consists of the formation of zoospores. In certain cells of the *Ulothrix* filament the entire contents become converted into a single large zoospore with four flagella (Fig. 5028, 2), the process being in this case similar to what occurs in *Protococcus*, but in other cases the cell contents divide into two, four, eight, sixteen, thirty-two, or more parts (Fig. 5028, 1 *b, c, d, e*), each of which becomes a zoospore, the smaller ones or micro-zoospores, *i.e.*, those formed by the division of the cell contents into sixteen or more parts, differing from the larger macro-zoospores, in addition to their size, in having only two flagella instead of four (Fig. 5028, 3 *a*). After swimming about for a while, the macro-zoospores settle down, withdraw their flagella, and germinate, producing a new *Ulothrix* filament. Some of the micro-zoospores do the same, the growth of the resulting filaments being, however, slower than in the case of the larger spores; but—and this is the important point—a considerable number of the micro-zoospores conjugate (Fig. 5028, 3 *b, c*) with others before settling down, the resulting spore (zygospore) producing a filament stronger than that which arises from a single micro-zoospore.

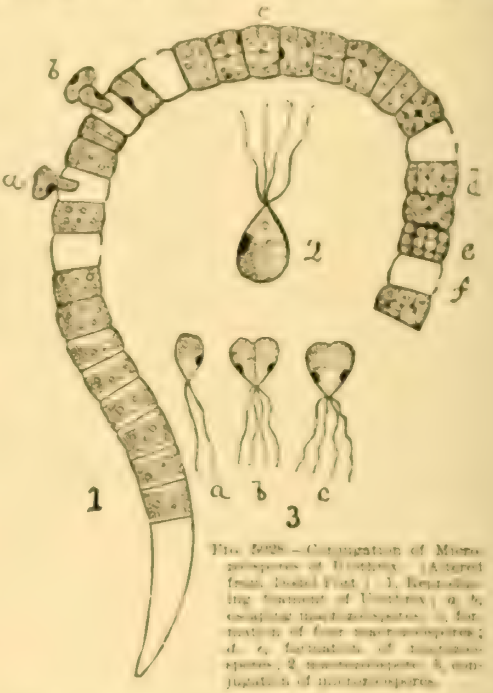

FIG. 5028.—Conjugation of Micro-zoospores of Ulothrix. (Altered from Dodel-Port.) 1, Reproducing filament of Ulothrix; *a, b*, escaping large zoospores; *c*, formation of four macro-zoospores; *d, e*, formation of micro-zoospores; 2, macro-zoospore; 3, conjugation of micro-zoospores.

It is interesting to note (1) that this process of conjugation is not a universal one with the micro-zoospores, but to a certain extent may be regarded as a chance union; (2) that the zoospores which conjugate are exactly similar as far as can be seen—that is to say, there is no sexual differentiation; and (3) that there seems to be a disinclination, if it may be so called, for two zoospores derived from the same original cell to conjugate. Dodel-Port, who made a very thorough study of this form, states that he never saw two zoospores from the same parent cell conjugate. The significance of this fact will be treated of hereafter.

A slightly higher stage in the differentiation of sexual reproduction is to be found in *Ectocarpus*.[8] This alga, like *Ulothrix*, produces in certain cells a single zoospore which germinates without conjugation. Other cells, however, give rise to large numbers of zoospores, which structurally are all similar but are evidently different physiologically. They are small masses of protoplasm provided with two flagella, one of which is directed forward in swimming and one backward. Some of these gametes after liberation swim about for a comparatively short time only, then settle down, withdraw their flagella, and assume a somewhat pyriform outline (Fig. 5029, I, *f*). Others, however, continue to swim about for a much longer period, and apparently tend to collect together in small groups. If such a group (Fig. 5029, II) be carefully examined, it will be found to possess, as the centre of attraction, one of the gametes which have early relinquished their locomotive powers. The anterior flagellum of each of the motile gametes is directed toward the sessile individual, and after a time one becomes entangled with or adheres to the latter, and is gradually absorbed by it, the gamete to which it belongs being thus drawn closer and closer to the attracting gamete, until finally conjugation of the two occurs (Fig. 5029, III).

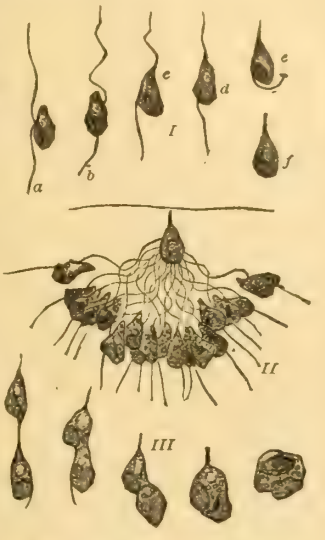

Fig. 5029.—Reproduction of Ectocarpus. (From Berthold.) I, Female gamete; *a* to *f*, changes undergone in settling down; II, group of male gametes collected round a female gamete; III, conjugation of gametes.

In this process a differentiation toward sexuality is to be seen. Of the originally similar gametes, those which quickly become sessile are to be considered female gametes, while the others, which retain for a longer period the power of locomotion, are, on the other hand, to be regarded as male gametes.

In *Cutleria*,[10] another marine alga of simple structure, a still more perfect differentiation of the male and female gametes occurs, the former being many times smaller than the latter; and from this the passage is easy to such a form as the fresh-water filamentous alga *Œdogonium*, in which the female gamete does not leave the enlarged cell whose contents have been transformed into it, but is there sought for, and, access having been obtained through an opening in the cell-wall, is fertilized by the smaller, motile, male gamete. The differentiation of sex, so far as the reproductive elements are concerned, really goes no further than this in plants, almost all complications met with in the higher and more specialized forms being either of a protective nature, or concerned with the phenomenon of alternation of generations which will be described later. Sufficient has been given, however, to indicate the very perfect series presented by plants, from the simplest non-sexual methods of reproduction to the very complicated sexual processes exhibited by the higher forms of plant life. Of course, it must be understood that the variations in the details of the process of reproduction are almost numberless, and although there are many offsets from the main line of progress which has been indicated above, still in all the same fundamental principles are concerned.

In the animal kingdom a somewhat similar passage from the non-sexual to the sexual process can be traced, but perhaps in not quite so complete a manner as in the lower forms of plant life. In the unicellular protozoa, simple division is an almost universal mode of reproduction, occurring in the simplest forms, such as *Protamœba*, and in the most highly organized infusoria. In some forms of the flagellata it is the only method known. In other members of the same group, by a repetition of the fission processes from an original individual organism, a number of descendants are produced which ultimately separate and pursue an independent existence. Such processes form an easy transition to what occurs in some of the chlamydomonadina, a family of the flagellata, some of whom present not a little similarity to the lower plants in their modes of reproduction, and in the possession of chlorophyll.[7] A preliminary of the reproductive process in these forms is usually the encystment of the originally free-swimming chlamydomonad; the next step is the division of the contents. In *Polytoma* this usually results, by a repetition of the process of division, in the formation of four or eight similar parts. By the rupture of the wall of the cyst these young polytomas swim away and, usually a few hours after obtaining their freedom, conjugate with each other, or with similar organisms from other cysts. There is an entire absence of difference of size in the two gametes which take part in the conjugative act.

This is not the case, however, in the genus *Chlamydomonas.* In one at least of its species, the cyst contents break up, in some cases with two or four parts, in others with eight. When they are liberated conjugation takes place, and according to one observer, only between the smaller forms, microgonidia, which are formed by the division of the cyst contents into eight parts. If this be a fact, it forms a stage in the evolution of sexual reproduction corresponding very closely to that offered by *Ulothrix* among plants. Another author, however, asserts that the conjugation takes place between the larger gametes or macrogonidia and the microgonidia, which would indicate that the process had nearly reached the condition exhibited in *Cutleria.* There is not, however, so great an amount of difference in size of the gametes observable in *Chlamydomonas* as in *Cutleria.*

In this respect another chlamydomonad, *Phacotus lenticularis* (Fig. 5030, 1), is more advanced. The macrogonidia in this species are formed by division into two or four parts (Fig. 5030, 2), while in the formation of the microgonidia the number of the parts formed is sixty-four. Whether in this case the conjugation takes place between the microgonidia only or between micro- and macrogonidia only, or irregularly, seems to be uncertain.

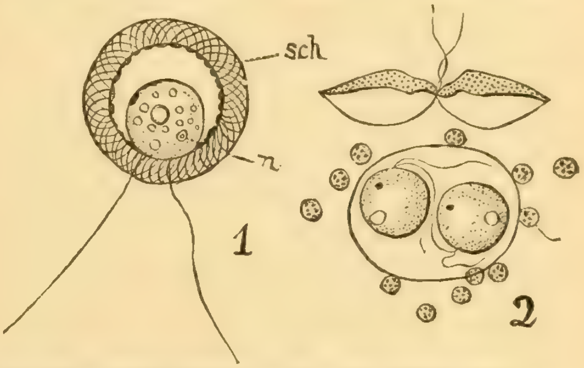

Fig. 5030.—Phacotus lenticularis. Ehrh. (From Bütschli in Bronn. 1. An individual viewed from flat surface; *n*, nucleus; *sch*, shell. 2, Microgonidia with two macrogonidia, the latter still retaining the capsule. Above is the ruptured shell of the mother-cell, from which they were formed.

The facts given above are by no means complete, but they represent fairly the information as to the development of sexual reproduction in animals which we possess. Taking them in connection with what has been described for the lower plants, it is evident that the distinction drawn between the non-sexual and the sexual processes of reproduction is merely an arbitrary one, the two processes merging into one another very gradually. Since the non-sexual method is the only one presented by the lowest forms of life, we must conclude that it is the more primitive process, and that the sexual method has been developed from it. How this development has been brought about can be imagined from what occurs in *Ulothrix.* It is evident that the greater the number of the spores produced, the greater will be the chance of some of them escaping the many causes of destruction to which they are exposed, and accordingly the tendency under natural selection will be toward plants and animals producing as large a number of spores as possible. But facts show that the smaller the spore (that is, relatively to its fellows) the less rapid and vigorous is the growth of the young plant or animal to which it gives rise, and, accordingly, the increase beyond a certain limit will become disadvantageous, and there will consequently be two opposing influences at work; on the one hand there will be an advantage gained by the production of a large number of offspring, and on the other hand the loss of vigor due to the smallness of the numerous spores will prove disadvantageous.

Conjugation, however, now steps in, and the difficulty arising from the minuteness of the numerous spores is obviated, but the number of offspring produced is diminished. Conjugation, however, affords many great advantages to compensate for this loss in numbers, which, moreover, need not be so very great, since the gametes may be reduced considerably below the minimum size of the corresponding spores which can develop. It permits, in the first place, cross-fertilization, *i.e.*, the union of gametes formed originally in distinct cells, or even in the cells of different parent plants, a process whose advantages will be discussed later. Secondly, as a result of the union of the two gametes, a renewal of the vigor of each, or a rejuvenescence, is produced, as is indicated by what has been observed in the Infusoria. Two individuals of a species of *Paramecium*, for instance, come together and fuse by their anterior extremities. In this state they remain for a considerable length of time, during which a rearrangement of the nuclear substance takes place, and finally the two individuals separate, to all appearance the same as before the conjugation, but in reality rejuvenated. Thirdly, as Weismann has pointed out, the sexual method "will tend to preserve the inherited individual variability of the unicellular individual or gamete, will increase it, and, by uniting it in ever new combinations, will allow of the possibility of the adaptation, under natural selection, of the species to new conditions of existence." In connection with this may be mentioned the interesting suggestion of Hatschek as to the part played by sexual reproduction in the elimination of disease. By the non-sexual method any organic disease will naturally be transmitted from generation to generation unimpaired; but sexual reproduction, by uniting diseased gametes with more vigorous, healthy ones, will tend to reduce the extent of the trouble, and will finally eradicate it.

Alternation of Generations.—The complete differentiation of the sexual mode of reproduction does not necessarily result in the suppression of the non-sexual method, but in most plants and in many animals both methods obtain.

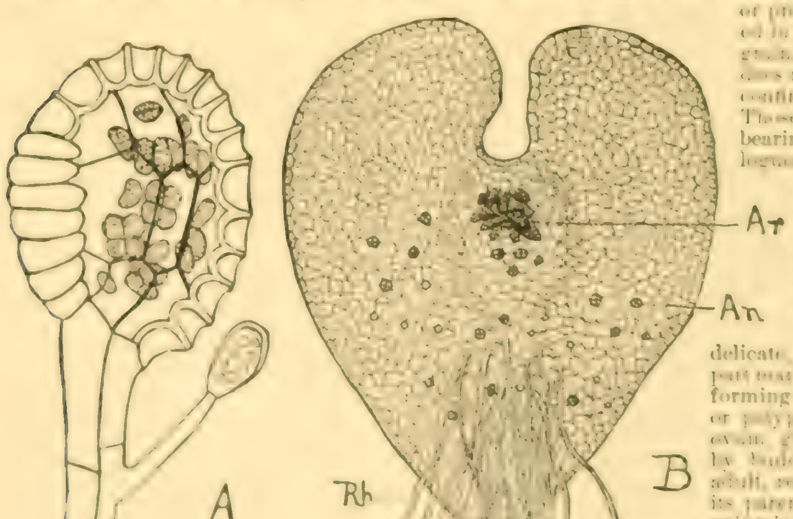

FIG. 3941.—A, Sporangium of Fern; B, prothallium of fern. Ar, archegonia; An, antheridium; Rh, rhizoids. (After Strasburger.)

A good example of this is afforded by the ferns. In the common Bracken (*Pteris aquilina*), for instance, at a certain time of the year there can be found on the under surfaces of the leaflets, close to the margin, small brown, stalked bodies arranged in confluent groups and protected by the reflexion of the edges of the leaflets. These bodies, sporangia (Fig. 3941, A), which, collectively, are known to gardeners as the "fruit," contain spores, and, when mature, burst, allowing the spores to fall to the ground. Should the conditions prove favorable, these spores germinate and give rise, not to another fern, but to a flat, heart-shaped, multicellular structure, technically known as a prothallium (Fig. 3941, B). Upon the under surface of this organs of reproduction, archegonia (Ar) and antheridia (An), develop, and from the fertilized germ-cells of the archegonia ferns develop. In this process we have a typical example of the phenomenon known as alternation of generations.

In these plants and in all "above them in the scale of organization, there is a regular alternation of generations of such a kind, that twice in the life history the plant is represented by a single cell, a spore, which in the one case has been produced asexually, and in the other sexually. The asexually produced spore gives rise to the sexual generation, the sexual generation produces the sexually produced spore, the sexually produced spore gives rise to the asexual generation, which again produces spores asexually" (Vines).

In higher plants the alternation becomes somewhat obscured by the development of sexuality in the non-sexual spores, and by the reduction of the sexual generation or prothallium. Thus, in Selaginellas the non-sexual spores are of two kinds, small microspores which give rise only to male prothallia, and larger macrospores from which female prothallia are developed. The prothallia in these cases are very much reduced in size, so much so that they hardly protrude outside the ruptured spore-walls, and in the gymnosperms and flowering plants the reduction reaches a still greater extent. The homologues of all the parts concerned in the alternation have, however, been made out in the pollen grains and ovules of the plants belonging to these groups, so that in them, as well as in the fern, the phenomenon of alternation of generation occurs. What we term a rose or an oak is the non-sexual generation, the sexual generation, or prothallium, being almost or quite aborted in the case of the microspore or pollen grain, and in the female spore, or ovule, does not form an independent plant, but is confined within the nucleus of the ovule. Those interested in tracing out in the cone-bearing and flowering plants the homologues of the various parts must be referred to the botanical text-books already mentioned.

In the animal kingdom the phenomenon plays by no means so important a part as among plants, but nevertheless it is occasionally to be seen. In its perfect form it is represented by the Hydroids, which are delicate, lowly organized forms, for the most part marine in their habitat.[*] They are colony-forming animals, *i.e.*, the original individual, or polyp, as it is called, produced from the ovum, gives rise to a second polyp-individual by budding. This eventually becomes an adult, retaining, however, its connection with its parent, and in its turn produces another polyp-individual, and so the process goes on until a colony, consisting usually of a considerable number of individuals, all in organic connection, is formed. Frequently all the individuals of one colony are not similar, but a physiological division of labor occurs among them, some being nutritive polyps, others becoming specialized for offence or defence, while others again become reproductive polyps.

These last give rise by budding, *i.e.*, non-sexually, to a number of bell-shaped structures known as medusæ, or popularly "jelly-fish," which in most cases are set free and swim about for a greater or less length of time. In these are developed the sexual reproductive organs, the ovaries and testes occurring in different individuals, and as the result of the fertilization of the ovum another polyp is produced and another colony started. Here we have true alternation of generations, the medusæ being the sexual generation produced non-sexually by the reproductive polyps.

In few cases, however, is the phenomenon so well exemplified among animals as in these forms. More usually when it occurs it consists of a succession of a number of non-sexual generations, the appearance of the sexual individuals being determined by the occurrence of unfavorable conditions, such as the approach of cold weather and the consequent loss of nutrition (see section on Parthenogenesis).

Heterogony.—In certain animals a phenomenon nearly related to alternation of generations, but in reality distinct from it, occurs. It has been termed heterogony by R. Leuckart, and consists of the occurrence, in the cycle of development, of individuals differing in structure from the parent forms and existing under special conditions of nutrition. A characteristic instance of this phenomenon is to be seen in certain parasitic nematode worms, as, for instance, in the *Ascaris nigrovenosa*, which occurs in one of its stages in the lungs of the frog. In this stage the parasites are usually regarded as females, but also possess spermatozoa, which are developed in special genital tubes earlier than the ova. Fertilization takes place within the body of the parent, and the young undergo development there, the reproduction being viviparous. The individuals of this generation make their way to the intestine of the frog, and are passed to the exterior with the fæces, and in moist earth or in water quickly assume their adult form, which differs from that of the parents and is known as the *Rhabditis* form. In this stage the animals are bisexual, and the fertilized females give rise to from two to four embryos, which become free in the body cavity of the mother and feed upon her organs, which degenerate into a granular detritus. When mature these forms make their way into the lungs of the frog, and the cycle of development is completed.

In another form, *Leptodera appendiculata*,[13] which is parasitic on the red slug (*Arion empiricorum*), several Rhabditis generations may succeed each other, otherwise the process is essentially the same as in *Ascaris*.

In some Lepidoptera and Spiders a phenomenon occurs, termed "seasonal dimorphism," which is essentially a heterogony of a lesser degree than that just described. In certain Malayan Papilios,[14] two or more different forms of females, each differing very decidedly in structure and coloration from the others, occur, as in *P. Paumon* (Wallace). Our North American *P. Glaucus* is a dimorphic female of *P. Turnus*.

Parthenogenesis.—In ovum-producing animals and plants it is the rule that fusion with the spermatozoon must occur before the ovum can develop to the adult form. Exceptions to this rule occur, however, especially among animals, an ovum being produced which can develop without fertilization. This phenomenon is known as Parthenogenesis. One of the most familiar instances of this is shown by the common Hive Bee. The ova deposited by the Queen Bee, as is well known, develop into queens or females, workers or sterile females, and drones or males. Dzierzon [2] found that when the queen was prevented from taking her nuptial flight the unfertilized ova which she deposited developed, but gave rise to drones without exception. Von Siebold also showed that in ova taken from thirty worker cells spermatozoa were always present, whereas in not one out of twenty-seven ova from drone cells could they be observed.

Parthenogenesis has been observed in many other insect forms, as, for instance, among the Lepidoptera [7] in *Sphinx Ligustri, Telea Polyphemus, Liparis dispar*, and *Bombyx Mori;* among the Coleoptera in *Gasterophysa raphani;* and among the Hemiptera in *Phylloxera vastatrix.*

In the last-named form the process is rather interesting, inasmuch as the occurrence of parthogenesis gives rise to a process resembling alternation of generations. Upon the roots of grape-vines infected with *Phylloxera* are to be found numerous galls produced by the insects. These root-inhabiting forms are wingless and deposit ova during the early summer, which develop parthenogenetically into wingless females similar to their parents. Several generations of such parthenogenetic forms are produced, but toward the end of the summer some of these females develop wings, ascend from the roots and fly about, thus disseminating the disease. These winged females produce from three to five parthenogenetic eggs of two sizes, the larger of which give rise to females, the smaller to males, destitute of any digestive apparatus, and fitted only for procreation. From a union of these males and females a fertilized egg results, which is deposited either under the bark of the stem of the vine, or in some cases upon the roots, the female having descended below the ground before depositing the egg. From the "winter egg" wingless parthenogenetic root-inhabiting females are produced in the following spring, and the cycle is complete.

Among plants parthenogenesis is a much rarer occurrence, and has been observed only in a few cases, as, for instance, in *Saprolegnia*, a fungoid growth which frequently makes its appearance on dead flies and other insects thrown into water, and even upon fish, etc., living in aquaria.

Parthenogenesis is to be considered a modification of the sexual method of reproduction. The parthenogenetic aphides and phylloxera are provided with a reproductive gland similar to that of the females of the sexual generation, and are in reality dimorphic females without the apparatus for copulation and fertilization which the sexual forms possess. The cells of their reproductive glands are similar to those of the ovaries of the sexual forms, and this fact has been recognized by applying to them the term *pseudova*, the ovaries being likewise denominated *pseudovaries.* Accordingly, it is more correct to regard parthenogenesis as a special form of sexual reproduction than to consider it a non-sexual process, and the parthenogenetic ova non-sexual spores.

It is in this respect that the reproduction of phylloxera differs from alternation of generations, which is an alternation of a strictly sexual with a strictly non-sexual generation. It stands rather as an example of heterogony.

Pædogenesis.—A peculiar variety of parthenogenesis has been observed in certain animal forms, and to it the name of pædogenesis has been applied by von Baer; it consists in the reproduction, parthenogenetically, of embryonic germ-cells. A very simple form of the process has been described by Metschnikoff, in a Medusa *Cunina*. Among the reproductive cells, which in this form are derived from the ectoderm, are found granular amœboid "neutral cells" much smaller than the motionless ova, which are in reality embryonic reproductive cells. They make their way through the supporting layer which separates the two germ-layers in the cœlenterata and passing into the endoderm soon begin to segment in a manner similar to ordinary fertilized ova. The result of this development is the formation of an embryo, and finally of a medusa somewhat different from the parent form. Metschnikoff has termed this sporogony, but it is closely related to the other phenomena usually grouped under the head of pædogenesis, and is essentially a very simple form of that process. Among the parasitic Trematodes which undergo a complicated metamorphosis pædogenesis occurs.[12] In the embryo which hatches from the fertilized ovum, so-called germ-cells, lying in the body-cavity, occur, in all probability corresponding to embryonic ova, which developing, give rise either to embryos similar to those which produced them, or to forms termed *cercariæ*, which are immature or larval stages of a form similar to the original adult parent. A full account of the changes undergone by these forms may be found in text-books on the subject.[12]

A better known instance is, however, afforded by the larvæ of certain dipterous insects (*Miastor, Oligarces*).[15] At that region of the body-wall where later the ovaries form, aggregations of cells take place, one of which enlarges and becomes what is termed a pseudovum, and from this a larva similar to the parent develops. From seven to ten of these larvæ are thus produced, and on the death of the parent they are set free and produce in a similar manner other progeny, a succession of parthenogenetic generations occurring during the summer, the last of which passes into the pupa stage and emerges in the following spring as a two-winged fly.

This process, like that of parthenogenesis, has been regarded as belonging to the category of non-sexual reproductive processes, but inasmuch as it is simply an accelerated parthenogenesis, embryonic reproductive cells being concerned in the process instead of adult ones, the remarks made while discussing the relations of parthenogenesis to gamogenesis apply equally well here.

Hermaphroditism.—We have seen that in the more primitive modes of sexual reproduction there is apparently no sexual differentiation of the two gametes which take part in the process, so that one may be termed the male and the other the female gamete, but both are similar to the zoospores which, as in *Ulothrix*, have the power of developing without conjugation. Since the sexual mode of reproduction is so universal among all but the lowest plants and animals, it might be thought that perhaps those gametes which have the power of developing without previous conjugation, were really comparable with sexual female gametes plus the male gametes which conjugate with them. In other words, the unspecialized gametes capable of developing without conjugation might be considered to be hermaphrodite gametes, containing within themselves both a male and a female part.

This theory, indeed, has been advanced by Minot and Balfour, and has been upheld by them as explaining certain phenomena connected with the maturation of the ovum, such as the extrusion of the polar globules (see articles on Impregnation and Sex). Leaving aside, however, the question as to the hermaphroditism of the unspecialized gametes and of, in fact, all cells, we have here to consider the facts with regard to hermaphroditism in the more complex multicellular individuals.

By hermaphroditism we mean the occurrence in one and the same individual of both male and female reproductive elements. It would seem probable that, in the first inception of the sexual reproductive process, both of the gametes might have been produced by the same individual, but it is also probable that such a condition would soon pass away, and that the advantages which are derived from cross-fertilization would tend to bring about a more complete separation of the sexual elements, the result being the establishment of bisexuality.

Among animals bisexuality is the rule, and in most cases where hermaphroditism occurs it can be shown to be due to some peculiar condition of existence which renders the chances for cross-fertilization few. Under such circumstances it will be advantageous, for the preservation of the species, that each individual should produce both ova and spermatozoa, since then there would be a greater chance of a number of ova being fertilized than if half the individuals produced ova only and the other half spermatozoa. The occurrence of hermaphroditism in the large majority of the higher plants is probably to be ascribed to the advantage thus gained, the danger resulting from self-fertilization being, however, carefully guarded against in most cases.

There is, however, another factor tending to counterbalance, and in most animals to more than counterbalance, this advantage presented by hermaphroditism, namely, the greater perfection of the elements and the higher potentiality for development probably produced by the separation of the sexual organs, and by the limitation of the energies of each individual to the production of a single kind of reproductive element.

In the higher plants, as already stated, hermaphroditism is the rule, though, as in the case of the members of the willow family, bisexuality occasionally occurs. In the ferns, too, examples of the latter condition are frequently found, and in the pteridophytes, in numerous cases, the prothallia are bisexual.

In animals, on the other hand, bisexuality is of much more frequent occurrence. The lowest forms of the metazoa or multicellular animals, the sponges, are hermaphrodites, but the cœlenterates are usually bisexual, the group of the ctenophores, however, being hermaphrodite, agreeing in this respect with their near allies, the turbellarian worms, to which again are closely related the hermaphrodite parasitic trematodes and cestodes. Among the turbellarians, however, bisexual forms (*Microstomum*) occur, and the nemerteans, which are also closely related to them, are as a rule, bisexual. Among the annelidan worms we find, as a rule, as also in the nematodes, bisexuality; those forms, however, which have assumed a terrestrial or fresh-water habitat, such as the earthworms and the leeches, are hermaphrodite. The same rule holds good with the mollusca, the marine forms being bisexual (with the exception of the pelagic pteropods and the opisthobranchs), while the fresh-water and terrestrial forms are principally hermaphrodite, although this condition is not quite so universal in the fresh-water as in the terrestrial forms, since in the fresh-water lamellibranchs it does not occur. The oyster forms an interesting exception to the usual bisexuality of the lamellibranch mollusca, and its hermaphroditism is usually considered to be correlated with its fixed mode of life; and to this same cause is assigned the hermaphroditism to be found in such forms as the tunicata and the polyzoa.

Among the crustacea some interesting cases occur, showing the relation of hermaphroditism to peculiar conditions of life; with very few exceptions the members of this great group, and also of that of the tracheata, are bisexual. The cirrhipedes, however, are mostly hermaphrodite, and we have in them some interesting phenomena.[illegible] Two peculiar genera, *Cryptophialus* and *Alcippe*, which live in the calcareous shells of other cirrhipedes and mollusca, are bisexual, the males being exceedingly aberrant in structure, being in *Alcippe* dwarfed and without digestive organs, mouth, or feet. The fact of the occurrence of these dimorphous males is an indication of the original bisexuality of the ancestors of the cirrhipedes. This indication is further strengthened by what is found in the genera *Ibla* and *Scalpellum*. These forms are hermaphrodite (with a single exception in each genus), but are nevertheless furnished with minute dwarfed males termed by Darwin "complemental males." Consequently, we have in this group three conditions: (1) bisexual forms with dwarfed males; (2) hermaphrodite forms with dwarf complemental males; and (3) hermaphrodite forms. The interpretation of the occurrence of these stages is simple. Upon the renunciation of the free life which their ancestors led, and which is still retained by their larvæ, it became advantageous for the cirrhipedes that they should have increased facilities for insuring the fertilization of the ova, and they became hermaphrodite. The occurrence of complemental males shows an intermediate stage in the development of pure hermaphroditism.

Among the vertebrates bisexuality occurs almost invariably, hermaphroditism being among them usually a monstrosity. In two genera of fish, *Serranus* and *Chrysophrys*, hermaphroditism occurs, and it has been occasionally observed in the carp, and in frogs and toads among amphibia in a more or less perfect degree.

With regard to the last case Pflüger[illegible] has suggested that among young frogs there are three forms, males, females, and hermaphrodites, the last changing either into males or females as development progresses. In this way, he thinks, is to be explained the somewhat frequent occurrence of ova among the cells of the testes of these animals. Although this is merely a suggestion and the process of change from an hermaphrodite to a unisexual condition has not actually been observed, yet there is no doubt but that in the embryonic stages of the reproductive organs the cells which give rise to the reproductive elements are quite unspecialized, and it is impossible to say, from a microscopical inspection, whether they will in the future develop into ova or spermatozoa. This is well shown in Fig. 5032, representing the embryonic testis and ovary of the earthworm, in which, owing to the presence of hermaphroditism and the separation of the male and female organs in different regions of the body, it is possible to ascertain which of the similar structures really represents the ovary and which the testis.

It is probable that the same undifferentiation of the mother-cells of the reproductive elements, and therefore of the reproductive organs, exists in the early stages of all forms, and it is only later that the sex of the individual is determined. Düsing[21] has lately published the results of a very detailed study of the causation of sex, and as a result of his investigations, concludes that equality in numbers must be the normal and proper proportion for the sexes, and any abnormal proportion tends to be corrected by the birth of a greater proportion of the sex whose numbers are below the normal. In other words, there is a tendency in all animals, when there is a lack of individuals of one sex, to produce more individuals of that sex. Düsing brings forward many facts to substantiate the statement, such, for example, as the well-known increase of the number of male births after a disastrous war. Since conception, late in life, is equivalent to a numerical lack of males, the statistics of primiparous births, in the cases of women of a somewhat advanced age, show a great excess of males. Absence of proper nutrition has great influence in determining the sex of the progeny, such a condition being equivalent to a lack of males, and therefore causing an increase of male births.

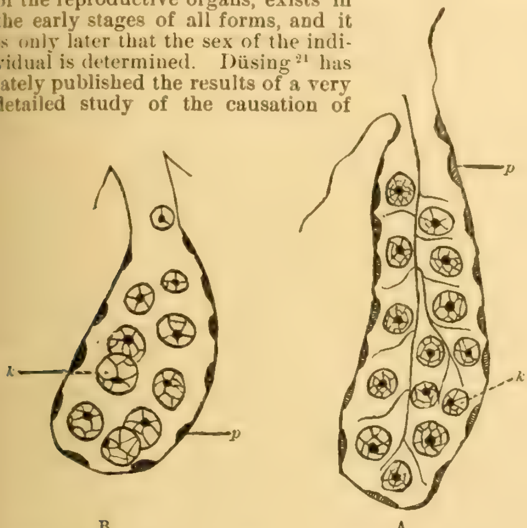

FIG. 5032.—A, Testis, and B, Ovary, of an Embryonic Lumbricus Turgidus. (After R. S. Bergh.) *p*, Peritoneum; *k*, reproductive cells.

Cross-fertilization.—There is no doubt that cross-fertilization, *i.e.*, the union of gametes from different individuals of the same species, the more remote their genetic relation the better, is of great advantage; and contrariwise, that self-fertilization and interbreeding, if carried to any extent, tend very markedly toward producing a deterioration and lessened fertility of the race. We are led to this conclusion partly by the experience of stock-breeders, and partly by the experiments on the subject which have been conducted by several careful investigators, especially by Charles Darwin.[22]

It may be of advantage to cite here some of the results obtained by Darwin. The first series of experiments recorded were upon a plant of *Ipomœa purpurea,* which is cultivated in gardens under the name of *Convolvulus major.* Ten flowers were fertilized by pollen from the same plant, and ten others by pollen from a distinct plant. The number of seeds produced by the crossed and self-fertilized flowers was very nearly the same. The seeds thus obtained were allowed to germinate in damp sand, and when germinated, a pair of seeds, one being crossed and the other self-fertilized, were planted on opposite sides of the same flower-pot, care being taken to place in contrast seeds which germinated at the same time. Three such contrasting pairs were placed in one pot and two in a second, while the remaining seeds, whether they had germinated or not, were placed in a third pot. Rods of the same thickness and material were supplied for each plant to cling to, and as soon as one of each pair had reached the top of the rod both were measured. In the third pot, the highest only on each side was measured. The results of growth in inches were as follows:

No. of Pot.	Seedlings from crossed plants.	Seedlings from self-fertilized plants.
	Inches.	Inches.
I	$87^4/_8$	69
	$87^4/_8$	66
	89	73
II	88	$68^3/_4$
	87	$60^4/_8$
III*	77	57
Total in inches	516	394

* Plants crowded; the tallest one measured on each side.

These plants were cultivated until they flowered, and the flowers on the crossed plants were crossed by pollen from other plants of the same generation, while the flowers on the plants from self-fertilized seeds were again self-fertilized. The same methods of germinating and growing were employed and the results noted; and so on through ten generations. The entire results are summed up by Darwin in the following table:

Number of the Generation.	Number of crossed plants.	Average height of crossed plants.	Number of self-fertilized plants	Average height of self-fertilized plants.	Ratio between average height of crossed and self fertilized plants.
First generation	6	86.00	6	65.66	as 100 to 76
Second generation	6	84.16	6	66.33	as 100 to 79
Third generation	6	77.41	6	52.83	as 100 to 68
Fourth generation	7	69.78	7	60.14	as 100 to 86
Fifth generation	6	82.54	6	62.33	as 100 to 75
Sixth generation	6	87.50	6	63.16	as 100 to 72
Seventh generation	9	83.94	9	68.25	as 100 to 81
Eighth generation	8	113.25	8	96.65	as 100 to 85
Ninth generation	14	81.39	14	64.07	as 100 to 79
Tenth generation	5	93.70	5	50.40	as 100 to 54
All the ten generations taken together.	73	85.84	73	66.02	as 100 to 77

It can be seen from this table that self-fertilization had a very decided effect upon the growth, the self-fertilized plants being on the average only a little more than three-fourths the size of the crossed plants. The plants of the fourth, seventh, and eighth generations, grown under unfavorable conditions, bring the average height of the self-fertilized plants a little higher, perhaps, than it should be, but, nevertheless, the difference is sufficiently striking.

It is not, however, only in height that the effect of inbreeding is shown. The general vigor of the crossed plants was evidently much greater than that of their self-fertilized companions. This was shown in various ways, as, for instance, by the greater hardiness of the crossed plants when subjected to low temperatures; by the greater strength of their stems, very evident in one case in the eighth generation, where the self-fertilized plant was higher than its crossed fellow; by their greater fertility; by the production of monstrous flowers on the self-fertilized plants of the ninth generation; and by the greater production of leaves by the crossed plants. This last difference was especially evident in the tenth generation, the weight of the leaves of the crossed plants being to that of the leaves of the self-fertilized plants as 100 to 44.

It is unnecessary to go into details with regard to other series of experiments conducted on plants belonging to a great many of the natural orders; those interested in the subject must be referred to Darwin's book, so full of suggestive facts relating to the whole subject of reproduction and heredity.

With regard to animals, facts similar to those just stated have likewise been noted, though no such comprehensive study has been given to the subject as has been done in plants. Darwin has given some facts on the subject which may be recounted here. He states that the white cattle of Chillingham Park, England, which have been inbred for a great many years, show lessened fertility. Wright paired a boar with daughter, granddaughter, etc., for several generations, with the result that finally the young were feeble, without inclination to suck, could not stand upright, and were mostly [illegible]. A relatively normal sow of the last generation would not pair with the original father, but did so willingly with a strange boar.

The disadvantageousness of self-fertilization being thus evident, it remains to be seen now just to what extent it is guarded against by plants and animals. We have already seen that hermaphroditism, and therefore the possibility of self-fertilization, is quite frequent among animals, and almost the rule among plants; nevertheless it is almost certain that in the immense majority of cases crossing of different individuals takes place. Thus in such hermaphrodite animals as the earthworm and snail, it is well known that pairing takes place, and the same would seem to be the case with many other similar forms. On the other hand, it is probable that in some degenerate parasitic forms, such as the trematodes and cestodes, self-fertilization is of by no means infrequent occurrence, crossing being wellnigh impossible in some cases, owing to the conditions of life. It would seem, too, that in certain cœlenterate forms self-fertilization is normal (ctenophores). But these last-named cases are exceptional, and one is justified in stating that cross-fertilization is the rule in the animal kingdom.

As regards plants, the researches of Kölreuter, Sprengel, Darwin, and Hermann Müller in particular have demonstrated that in flowering plants self-fertilization is certainly the exception, and many marvellous adaptations of form occur whose object is to insure crossing. Thus, in many cases, the stamens ripen before the pistils, or *vice versâ*; and in others the stamens become aborted in certain flowers, and the pistils in others; while in others, again, as the primrose, what is termed dichogamy occurs, consisting of the occurrence of stamens and pistils of different sizes in different plants of the same species, and so arranged that the long stamens are associated with the short pistils and *vice versâ*, fertilization occurring perfectly only between stamens and pistils of the same relative size. For a more detailed account of these and other wonderful arrangements, the reader must be referred to the special works upon the subject.

The conclusion which follows from the observed facts in cross-fertilization is that it is advantageous to the species, and that continued self-fertilization, on the other hand, is injurious. Instances can, however, be advanced which seem to indicate that self-fertilization does not in all cases necessarily prove disadvantageous. It seems that the value of cross-fertilization depends in reality on differences in the uniting gametes, which are the result of growth and development under different conditions. As the result of his observations, Darwin arrived at the following conclusions: "Firstly, that the advantages of cross-fertilization do not follow from some mysterious virtue in the mere union of two distinct individuals, but from such individuals having been subjected during previous generations to different conditions, or to their having varied in a manner commonly called spontaneous, so that in either case their sexual elements have been in some degree differentiated. And, secondly, that the injury from self-fertilization follows from the want of such differentiation in the sexual elements."

On this principle consanguineous marriages will prove disadvantageous only when the contracting parties have been brought up under the same or closely similar intellectual and physical conditions; and, on the other hand, cross-fertilization will lose its virtue to a very great extent in similar cases. These facts have been recognized by some breeders, who, when inbreeding is necessary for the preparation of some special variety, are accustomed to keep the individuals to be crossed on distant and diversely situated farms, by which arrangement the crossing, though between consanguineous animals, has nevertheless the advantages of a cross between forms possessing no close relationship.

As to the actual nature of the cause of the difference in the result produced by the union of similar and dissimilar gametes, we are at present in ignorance. Some have suggested a difference in chemical composition of the two gametes, and the inauguration by their union of a new series of chemical changes whereby added vigor is imparted to the progeny; but such a theory, however, needs substantiation. The same idea in a more general form might be expressed by saying that the benefit derived from cross-fertilization was due to the difference in the education of the gametes. Just as with mankind, a continuance of the same conditions tends to narrow or degrade the intellectual and moral natures, while the influence of new conditions of life, with the accompanying new ideas and new possibilities, is to educate and enlarge these natures, bestowing fresh vigor upon them; so new conditions may be considered to act upon the physique of the sexual elements. The mingling of gametes educated along different lines offers new possibilities and new vigor to the resulting individual; while a union of elements both educated to the same point, and along the same lines, cannot confer any advantages which the parent gametes did not possess, and if continued would naturally tend to a deterioration of the race.

There is a limit, however, to the degree to which the differentiation may be carried in order that good results may be obtained. Injurious results will follow from attempts to breed between forms too widely distinct. The best results are probably obtainable from forms of the same variety living in widely diverse regions, or in some cases between varieties of the same species. Crossing between decidedly distinct species is, as a rule, much less satisfactory, as may be seen in the case of the horse and the ass, where the progeny are almost invariably sterile, while attempts at crossing between members of different genera are usually unsuccessful. The education of the gametes in these cases has been along too diverse lines to yield good results. To take a simile from our own experience, again: Just as a Hollander and an Englishman, owing to the similarities of their respective languages, might succeed in understanding each other in conversation, so two gametes from forms belonging to different varieties of the same species might be able to harmonize and be mutually acceptable; whereas gametes from members of different genera would be able to understand each other as little as would an Englishman and a Chinese.

One other point of theoretical interest must be alluded to. This is the disinclination which exists toward union between consanguineous forms. This is to be seen in the case of the sow already referred to, which Wright found to be adverse to pairing with a closely related boar, while she did so willingly with a strange animal. Darwin has observed the same fact with regard to plants. He found that a plant's own pollen has a greater fertilizing power than, or, as he terms it, is prepotent over, that from a distinct species; while with regard to different individuals or varieties of the same species the reverse is the case. An illustrative instance may be given in Darwin's own words: "The pollen of Mimulus luteus regularly falls on the stigma of its own flower, for the plant is highly fertile when insects are excluded. Now, several flowers in a remarkably constant whitish variety were fertilized without being castrated with pollen from a yellowish variety; and of the twenty-eight seedlings thus raised, every one bore yellowish flowers, so that the pollen of the yellow variety completely overwhelmed that of the mother plant."

The most interesting case of this kind, however, has been already alluded to, viz., the disinclination which, according to Dodel-Port, exists in the zoospores of Ulothrix to unite with others from the same cell. It would seem that what might be termed a polarity existed in these lowly organized structures, the polarities in those from different cells differing, and there being thus an attraction between these; while those from the same cell, having a similar polarity, are mutually repellant. Some physical cause, no doubt, lies at the bottom of the phenomenon, but whether it is some force which we already know, or a form of energy as yet undiscovered, remains to be seen. *J. Playfair McMurrich.*

REPTILES, POISONOUS.—Under the head of Reptiles, Poisonous, in Vol. VI. of this HANDBOOK, care was taken to add to the article three notes, which read as follows:

NOTE 1.—"With regard to the very poisonous qualities of the *Heloderma* saliva, recent experiments by the writer would seem to indicate an extremely feeble toxic effect, at least so far as rabbits and fowls are concerned."

NOTE 2.—"It is to be regretted that a repetition of de Lacerda's experiments with the permanganate by the writer has not given the results claimed by the distinguished Brazilian."

NOTE 3.—"A series of experiments are now being tried to verify what appears to be decided antidotal effects of *Jaborandi* to *Crotalus* venom, the writer having succeeded in saving rabbits which had received fourfold lethal doses of the poison. It has no antidotal effect, however, upon fowls."

The writer is now prepared to demonstrate that good ground existed for the notes as appended to the article, as the following experiments will prove. The first experiments have a direct connection with Note 1.

Before giving notes of the experiments made at the National Museum, it may be well to describe the process by which Drs. Mitchell and Reichert obtained the saliva of the *Heloderma*, and our own method. The first consisted in "provoking the reptile to bite on a saucer edge, which it was not disposed to do. When once it had seized the saucer it was hard to pull it away, so powerful was the grip of the lizard's jaws. After a moment a thin, fluid-like saliva dripped in small quantities from the lower jaw; it was slightly tinted with blood, due to the violence of the bite, and it had a faint and not unpleasant aromatic odor. The secretion thus collected from the mouth was distinctly alkaline, in contrast to serpent venoms, which are all alike acid."

Our own method consisted in forcing the lizard to bite upon a piece of artist's gum, which being elastic and yielding, did no injury to the teeth and afforded a fair hold. So soon as the saliva appeared to be flowing it was carefully swabbed up with pledgets of absorbent cotton, which were washed out with glycerine, and in this way we had no difficulty in securing all of the fluid needed. It was preserved in glycerine in the same manner as our serpent venom was preserved.

The first experiment, November 8, 1887, was as follows:

November 8, 1887, 12.17 P.M.—Held left hind leg of rabbit to *Heloderma*, who grasped it with his teeth, and held on for three-fourths of a minute, biting fiercely.

1.30 P.M.—Rabbit a little lame, but enjoyed eating as much as before.

3 P.M.—No result so far.

November 9th.—Rabbit appears to be perfectly well, with the exception of a very slight lameness of the left hind leg, due to the lacerated wound made by the lizard's teeth.

12.30 P.M.—Held leg of another rabbit near mouth of a different *Heloderma* from the one used in the former experiment, and irritated the reptile until he took hold. In this case the rabbit's leg was seized several times and bitten to the bone, the reptile being unwilling to let go. There was a copious flow of saliva, which ran over the teeth wounds and was rubbed in by the experimenters, care having been taken to remove the hair from the rabbit's leg. In fact this was done in every case, as it was feared the thick fur might prevent the saliva from reaching the wounds.

3 P.M.—No result.

November 10th.—No result.

November 11th.—No result except slight lameness.

November 17th, 12.45 P.M.—Injected three minims of solution of *Heloderma* saliva in leg of hen (brown); respiration somewhat increased, but no other symptoms noticed.

2.30 P.M.—Fowl in about the same condition; respiration slightly increased and breathes with beak partly open.

November 18th.—Fowl appears to be entirely recovered.

November 20th.—Hen completely recovered.

In this case the increased respiration was probably due to the fact that the chicken, being a very noisy one, it became necessary to compress its throat during the experiment to avoid annoying other workers in the museum.

November 22d, 12.19 P.M.—Injected ten minims of solution of *Heloderma* saliva and ten minims of water into left breast of another hen. This chicken was very thin, but perfectly healthy, and had been used for two rattlesnake-venom experiments with ligature and recovered.

12.25 P.M.—Increase of respiration; wants to lie down; defecates; feathers ruffled.

12.30 P.M.—Panting heavily; peculiar outward and inward movement of anus; eyes closed and very drowsy.

November 28th.—Chicken entirely recovered, and has been well for several days.

12.35 P.M.—Injected twenty-five minims of solution of *Heloderma* saliva into left leg of another hen.

12.40 P.M.—Hen lying down; respiration quickened, and breathes with mouth open.

2.30 P.M.—Chicken still lying down and breathing fast.

November 29th, 11 A.M.—In same condition as yesterday; will not eat.

November 30th, 11 A.M.—Improving; eats a little.

December 1st, 11 A.M.—Appears to be all right; eats well.

December 2d, 11 A.M.—Chicken entirely recovered.

December 5th, 12.15 P.M.—Injected twenty-five minims of solution of *Heloderma* saliva into breast of chicken; same quantity into right leg; same quantity into left leg, making in all seventy-five minims. In a short time fowl had copious watery discharge per anum, with a peculiar oscillatory movement of that opening.

12.50 P.M.—Chicken lying down, with its feathers much ruffled.

December 6th.—Chicken found dead. This fowl had been used for previous experiments, and was very thin and weak, and it is by no means certain whether the copious diarrhœa, probably produced by the glycerine, did not cause its death.

December 5th.—Forced largest *Heloderma* to bite a chicken on the leg (from which feathers had been removed) several times. There was a copious flow of saliva and many lacerated wounds.

December 6th.—Chicken seems perfectly well; no swelling or local manifestations whatever.

December 7th.—Chicken perfectly recovered.

Fearing that possibly the glycerine solution of saliva (two drachms of saliva to six drachms of glycerine) was too weak, or had lost its strength through keeping, on December 8th, the following conclusive experiment was performed:

December 8th, 12.15 P.M.—Forced open the jaws of the largest and most savage *Heloderma* and collected upon a piece of absorbent cotton from ten to fifteen drops of fresh saliva. An incision was made in the breast of a chicken and the cotton placed in it and allowed to remain.

December 10th.—The chicken appears perfectly well; no sign of indisposition or local manifestations whatever; wound appears to be healing by first intention.

January 20, 1888.—Wound in breast has been healed for some time; the cotton remains where it was placed, and can be felt encysted under the skin and has produced no injury.

April 4th.—The chicken alive and healthy, with the cotton still in situ.

This experiment would seem to show that a large amount of the *Heloderma* saliva can be inserted into the tissues without producing any harm, and it is still a mystery to the writer how Drs. Mitchell and Reichert and himself obtained entirely different results. Both the "Gila monsters" used by us were good-sized, active specimens, full of vigor, secreting a considerable amount of saliva, and we can hardly suppose that the short captivity they had suffered could have so modified their saliva as to render it innocuous.

With regard to Note 2, the results of a few conclusive experiments are given to show that the statement was warranted by facts.

Permanganate of potassa was the first substance used in the course of experiments, and de Lacerda's directions were carefully followed, with the exception that chemically pure glycerine was used as a menstruum to preserve the venom, instead of distilled water. The writer is aware that de Lacerda claims that if glycerine is used to hold the venom in solution, the permanganate is rendered inert; but that is not the case, as in our experiments it has been found that a five per cent. solution of the salt, if added to the glycerine and venom solution, neutralizes its venomous effects. Moreover, if a ligature is placed around the leg of an animal, and a certain quantity of glycerine venom is injected below the ligature, followed by a solution of the permanganate, no venomous effect is produced by the venom. This effectually disproves de Lacerda's statement. It should be mentioned that in all the experiments tried with the various reputed antidotes, different quantities of these were always first injected into the animals on the day preceding the test with the venom, in order to ascertain if the remedy itself was capable of producing mischief or death.

In order to ascertain the amount of glycerine venom required to destroy a pigeon, the following experiment was made:

October 21, 1887, 11.45 A.M.—Injected pigeon in the lower part of left breast with three minims of glycerine venom solution.

11.48 A.M.—Pigeon commenced to tremble and had difficulty in opening the eyelids.

11.55 A.M.—All voluntary motion ceased.

12 M.—A good deal of tumefaction was noticed around the part injected.

12.05 P.M.—The pigeon has recovered partial muscular movement and the eyes appear brighter.

12.15 P.M.—The pigeon has again lost muscular power.

12.35 P.M.—The pigeon gave two slight flutters, a few gasps, and was dead. A *post mortem* was made before rigor mortis set in, and it was found that the whole of the left breast was ecchymosed and congested with dark blood, and the heart was filled with venous blood.

It was thus discovered that three minims of the venom solution was sufficient to destroy a large, healthy, blue rock pigeon in less than an hour, the strength of the solution being eight drachms of glycerine to one drachm of the *Crotalus* venom.

October 22d, 11.43 A.M.—Injected pigeon with five minims of venom solution in the left breast.

11.45 A.M.—Injected seventeen minims of one per cent. solution of potassa permanganate in left breast.

11.54 A.M.—Convulsive movements of the pigeon's head were noticed.

11.55 A.M.—Injected seventeen minims more of the permanganate solution, as the bird was getting very feeble. Opisthotonotic spasms took place.

12.15 P.M.—The pigeon died without a struggle.

In this experiment the permanganate solution was injected twice in the immediate vicinity of the venom injection. It should not be forgotten that the one per cent. solution of the permanganate is the one recommended by de Lacerda.

October 25th, 12.45 P.M.—Injected a large, healthy, English rabbit, in the left thigh, with five minims of the venom solution, followed at once, without withdrawing the hypodermic needle, with an injection of twenty-five minims of the one per cent. permanganate solution.

12.50 P.M.—Rabbit began to show the effects of the venom; respiration very much quickened; heart beats fast and is weak; animal indisposed to movement.

1 P.M.—Rabbit drank a little water, but was breathing short and fast.

1.10 P.M.—Part injected quite swollen and ecchymosed, but otherwise the animal seemed to be better.

1.40 P.M.—Rabbit was eating, and appeared to be doing very well.

3 P.M.—Rabbit seems perfectly well, with the exception of a stiffness of the leg injected.

October 26th, 12 M.—Rabbit appears perfectly well, with the exception of a slight lameness and some swelling of the injected limb.

October 27th.—Rabbit found dead in the cage. *Post mortem*: Heart contracted; lungs, liver, and kidneys congested; bladder full of urine; intestines full of fæces. In the vicinity of the point of injection was found a large abscess, and the surrounding tissue and whole limb was ecchymosed, and had sloughed deeply. The liver, lungs, and mesentery were studded with parasitic cyst worms still living. Decomposition was well advanced in the affected leg.

In the next experiment it was decided to use a smaller dose of the glycerine venom, the subject being a large, healthy English rabbit:

October 27th, 11.45 A.M.—Injected rabbit in left hind leg (thigh) with three minims of venom solution, to which was added ten minims of water. Without withdrawing the hypodermic needle this was followed at once with an injection of twenty-five minims of one per cent. permanganate solution.

11.50 A.M.—Respiration and heart's action much increased, with a curious backward movement of the animal.

11.55 A.M.—Complete loss of motion in leg, with considerable tumefaction of part injected. Animal averse to motion even when irritated.

12.30 P.M.—Animal moves more freely, and seems better, although there is much more swelling and discoloration in the vicinity of the point of injection.

3 P.M.—Animal appears to be doing very well.

October 28th, 12 M.—Great tumefaction of leg and thigh; œdema of anus. Punctured and let out a large amount of bloody serum. Animal has eaten, but is averse to movement.

3 P.M.—Animal very sick, unable to stand; all motion of hind legs lost; is very weak.

October 29th.—Rabbit was found dead in its box, excessive hæmorrhage having taken place from the wound. *Post-mortem:* Great infiltration of blood in leg and surrounding tissue; much decomposition and sloughing

It was now determined to try the effect of placing a ligature around the leg of a fowl before injecting the venom, with the following result:

November 2d, 12.40 P.M.—After a ligature had been placed around the upper part of the thigh of a large, healthy hen, an injection was given, two inches below the ligature, of three minims of venom solution, to which was added ten minims of water. Without withdrawing the hypodermic needle, twenty-five minims of one per cent. permanganate solution was injected.

12.50 P.M.—The ligature was removed.

1.15 P.M.—No effect.

1.25 P.M.—Hen draws up the leg injected and stands on the other.

November 3d.—Fowl apparently in fair condition, but there is much greenish discoloration of the leg and softening of the tissues contiguous to the joint where the venom was injected; abscess forming. Is quiet and stands upon both legs, but does not use the left leg.

November 4th.—Fowl in about the same condition as yesterday; greenish discoloration more marked, but not extending so far into the surrounding tissue. Part quite soft and feverish.

November 5th.—Fowl suffering no inconvenience from the injection; discoloration of the part subsiding; very little swelling.

November 7th.—Discoloration and swelling of part injected have entirely disappeared and the hen has entirely recovered from the effects of the venom.

It will be seen from this experiment that the permanganate had a decided antagonistic effect to the venom, doubtless because the ligature confined the latter to a limited area, and prevented it being carried into the general circulation.

With a view to still further determining the beneficial effect of the ligature, the following experiment was tried with a large dose of the venom and of the permanganate solution:

November 10th, 12.45 P.M.—Injected ten minims of venom solution into right leg of hen below ligature, followed at once by twenty-five minims of two per cent. permanganate solution. Ligature was allowed to remain on three minutes. The tissues near puncture were well kneaded. (This chicken was injected before with three minims of venom, and one per cent. permanganate solution, and had entirely recovered).

2.30 P.M.—Fowl inclined to stand still, otherwise no other symptoms noticed.

November 11th, 11 A.M.—Fowl not inclined to move around, but sits down; not much swelling or inflammation of the part injected, but a little darker in color; eats well.

2.30 P.M.—Fowl appears to be much better than she was this morning; eats and drinks as usual.

November 12th, 11 A.M.—Hen slightly lame in the leg injected; part swollen, with greenish discoloration; eats and drinks well.

2.30 P.M.—Fowl in same condition.

November 14th.—Fowl entirely recovered.

It was thought advisable to try the antidotal effect of a much stronger solution of the permanganate, giving a small dose of venom solution, and not using the ligature, the result being as follows:

November 21st, 12.18 P.M.—Injected three minims of venom solution into left leg of a large, healthy hen, followed at once by twenty-five minims of a five per cent. permanganate solution through same puncture without removing the hypodermic needle.

12.22 P.M.—Leg drawn up and trembling; respiration quickened, and chicken lying down; can hardly be made to stand up, and oscillates backward and forward; feathers ruffled.

3 P.M.—Chicken will not stand; loss of motion of leg injected.

November 22d, 11 A.M.—Fowl somewhat better, can use the leg injected a little, but still inclined to lie down. Much swelling and greenish discoloration of the leg.

November 23d.—Hen in about the same condition as yesterday. Will not stand up.

November 25th.—Hen found dead; probably died yesterday (Sunday); much swelling and sloughing of the leg injected.

This same experiment was repeated upon other fowls and upon rabbits, the result being death.

It should be remembered in this connection that de Lacerda claims that, in nearly every case in which he used a one per cent. solution of the permanganate, the animal recovered, and moreover, he claims that the antidotal effect is produced even if a considerable period of time has elapsed after the injection of the venom. In our experiments we have shown that even a five per cent. solution is of no value, and the reputed antidote was used immediately after the injection—in fact, so soon as the venom was injected the barrel of the hypodermic syringe was immediately unscrewed from the needle, which was allowed to remain imbedded in the tissues, the syringe was rapidly filled with the permanganate, and the injection was then made. Sometimes less than half a minute was consumed in the whole operation.

In regard to Note 3, while it is as yet impossible to state that *jaborandi* has a positive antidotal effect to *crotalus* venom, the experiments seem to support such a view, and the writer has proof in his possession that a valuable dog was saved in Florida by this drug.

Dr. Robert Fletcher, in his valuable paper entitled "A Study of Some Recent Experiments in Serpent Venom," in the *American Journal of the Medical Sciences*, new series, lxxxvi., 144, 1883, mentions a case reported by a French physician, of a person bitten by a viper, in which the very grave symptoms developed had been cured by the administration of jaborandi, which produced copious salivation and perspiration, the dangerous effects of the venom gradually disappearing.

This case was looked up and was found in the *Gazette Hebdomadaire de Médecine et Chirurgie*, Paris, xix., 835, 1882, the reporter being Dr. Josso. He states that the patient was bitten by a viper between the thumb and index-finger, and that, when called to see her, all the characteristic dangerous symptoms of poisoning from snake venom were present, notwithstanding that phenic acid had been freely used as a supposed antidote. Having seen an account of the use of jaborandi by the South Americans in snake bite, he determined to give it a trial, and four grammes (about sixty grains) of the leaves were infused in a glass of water and given at 2 P.M. of the 13th inst., and on the 14th the patient was well, with the exception of pain in the arm and some swelling, which lasted for three weeks after the accident. As already stated, copious salivation and perspiration were produced, but no mention is made of any action upon the kidneys. As no other cases had been reported, and the writer being aware that jaborandi was supposed to be contraindicated by the state of the kidneys, he determined to examine the subject thoroughly.

As some non-professional readers may care to know what jaborandi is, and what effect is produced by it, the following short summary is given:

Jaborandi is an extract made from the dry leaves of *Pilocarpus pennatifolius*, a South American plant, its properties being due to a volatile oil and two alkaloids, pilocarpine and jaborine. The preparations and doses are:

	Dose.
Extract jaborandi	[illegible]
Infusum jaborandi	[illegible]
Pilocarpine nitrate	[illegible]
Fluid extract, U. S. Ph.	[illegible]
Tincture jaborandi	[illegible]

"**Pilocarpine stimulates the peripheral terminations** of efferent nerves going to glands, and first stimulates and then paralyzes the efferent nerves going to structures composed of involuntary muscular fibre. In large doses it lessens but does not quite destroy the irritability of voluntary muscles and motive nerves" (Lauder Brunton). "It increases flow of saliva enormously, the secretion of sweat, and excites the secretion of tears, certainly in cats, mucus from nose and from bronchial mucous **membrane, of gastric juice, intestinal juice, and** urine from the kidneys. Upon the circulation: vessels become **dilated at first, pulse rapid, feeling of heat** over the body. Blood pressure falls a little at first with **quicker pulse, and rises with a slower pulse. Respiration** is increased, with dyspnœa. It is used as a cardiac **stimulant when digitalis fails.**"

Now, as will be seen from these statements, this South American plant really seems to possess all those **properties which might be supposed necessary to constitute** a true physiological antidote to serpent venom, and so far as our limited experiments go, there appears to be good warrant for such a belief, as in all of our experiments the so-called antidote was first tried on healthy animals without producing any ill effects. The first experiment was as follows:

November 28th, 12.20 A.M.—Injected five minims of **solution of rattlesnake venom into left hind leg** of strong, healthy rabbit, followed immediately by ten drops of fluid extract jaborandi in ten drops of water; and ten drops of jaborandi and half an ounce of water was forced into the animal's stomach with a syringe.

2.30 P.M.—Animal slightly lame in the injected leg, holds it up when walking; eats well.

November 29th, 11 A.M.—Animal still a little lame, slight swelling and tenderness of the injected leg, otherwise seems to be in good condition.

November 30th, 11 A.M.—Rabbit in about the same condition as yesterday, but improving.

December 1st, 11 A.M.—Animal still slightly lame; a hard **tumor formed at seat of injection.**

December 2d, 11 A.M.—Rabbit in same condition as yesterday; appetite **normal.**

December 5th.—Swelling entirely gone; animal perfectly well.

It was noticed in this case that the animal urinated freely and very frequently, and that the mouth and nostrils were very moist. Chickens and pigeons being peculiarly susceptible to venom, it was determined to try the effect of the jaborandi **on them:**

December 3d, 12.30 P.M.—Injected five minims of *crotalus* venom solution into leg of chicken, followed by ten minims of fluid extract jaborandi, in water, by the stomach.

1 P.M.—Chicken appears not so well, lying down. Gave ten minims more of jaborandi, in water, per stomach.

3 P.M.—Chicken standing up, and feathers drooping; does not seem very sick.

December 5th.—Chicken found dead; probably died during the night, as it was alive yesterday (Sunday) at 1 P.M.

In this case it may have been that not enough of the jaborandi was given to overcome the double lethal dose of the venom, and also that none was given hypodermically; however, the experiment shows that life was prolonged after a dose of venom which, if allowed to act without hindrance, would have destroyed life in about two hours. Another experiment was tried upon a fowl, a smaller dose of venom and a larger amount of jaborandi being given, but the chicken only lived two days. These two experiments would seem to show that in the case of fowls poisoned by serpent venom, jaborandi has **only the effect of prolonging life. To verify the former** experiment upon a rabbit, it was resolved to again try the antidotal effect of the drug with the following result:

December 5th, 12.05 P.M.—Injected ten minims of *crotalus* venom solution into right hind leg of large, healthy rabbit, followed by fifteen minims of fluid extract **of jaborandi**; also gave fifteen minims of jaborandi, in water, per stomach.

12.15 P.M.—Rabbit sluggish, and indisposed to move. Respiration hurried, and animal seems very sick.

12.30 P.M.—Gave fifteen minims more of jaborandi hy**podermically.**

December 6th.—Rabbit appears perfectly well and is eating. Copious discharge of serum from wounds made by hypodermic needle, and a good deal of **urination.**

December 8th.—Rabbit appears perfectly well, but has a healthy looking raw surface near point of injection on leg, which is healing.

December 10th.—Rabbit well excepting ulcer, which is healing nicely.

December **12th.—Animal perfectly well.**

One more experiment was tried upon another rabbit, in which a fourfold lethal dose of the venom was injected, viz., twenty minims of venom solution, followed by sixty minims of jaborandi at intervals, hypodermically, with sixty minims, in water, by the stomach, the animal recovering perfectly. From the foregoing experiments with the fluid extract of jaborandi, it will be seen that while this substance appears to have antidotal effects upon rabbits, in fowls it fails, as has already been stated; **but it is intended to pursue this line** of experimentation **still further, especially with the active princip**le known as *pilocarpine*. It may be mentioned that a medical man of Washington City is so convinced of the efficacy of the **jaborandi, that he has offered himself for the purp**ose of **an experiment with venom, and in** addition to this offer **the writer has received a communication from** a person in Ohio, also proposing to submit to the test. Until we **have experimented further, however, the scientific** devotion of these gentlemen will not be tried.

The writer would like to acknowledge the aid rendered him by his able assistant, Mr. E. S. Rheem, in the preparation of this and the previous article in Volume VI.

Henry Crécy Yarrow.

RIVIERA. There is probably no region of country in all the civilized world of to-day that seems by nature so specially adapted to the purposes of a winter health-resort as is the strip of coast which extends in a northeasterly **direction along the shore of the Mediterranean** between Nice and Genoa, and, although in less degree, the continuation of this strip in a southeasterly direction beyond Genoa, and as far as Spezzia. The Italian name of this coast strip, "la Riviera," indicates that it is by them regarded as in some sense the *coast* land *par excellence*, and the name of the great post road between Nice and Genoa, "il Cornice," the "Cornice," is in itself almost enough to show the extreme narrowness of the comparatively level space intervening between the main chain and foot-hills of the Maritime Alps and the waters of the Mediterranean Sea. Moreover, when we come to consider the great depth of the sea at but a short distance from the shore-line ("two thousand feet a few yards from the land at Nice," Bennet tells us), and the very considerable height of the mountain chain lying thus close to the shore, it is evident that the small areas of level or gently sloping country which, intervening between the shore-line and foot-hills, are hemmed in on either side by the buttressing cross-ridges that run down to the very water-line itself, and that divide the whole coast line into a series of shallow bays, are in themselves no more than a series of shelf-like or cornice-like interruptions in the steep slope from mountain crest to sea-bottom. The conformation of the whole country is little else than a long shelf, or rather a series of shelves, on the south side of a very high mountain-wall, which wall, up to the level of these shelves, is submerged in the waters of the sea. This peculiar conformation, while in a great degree characteristic of the entire Riviera from Nice to Spezzia, is especially characteristic of that portion of the western Riviera which lies to the east of the Tête du Chien, a promontory jutting into the sea immediately to the west of Monaco, and about eight or ten miles to the east of Nice. West of this point the main chain of the Maritime Alps recedes much farther from the shore, and a much larger share in the production of shelter from northerly winds devolves upon their foot-hills. Such is the case at Nice, although even there the backbone of the Alps lies but thirty miles distant from the shore: such is still more the case at Cannes, which lies about eighteen miles southwest of Nice, and where the higher mountains stand nearly forty miles back from the coast. Yet both these places share in great degree the climatic characteristics of the better-sheltered portion of the coast, and may properly be considered as belonging among the Riviera resorts.

The latitude of the Riviera plays but a small part in the production of its mild winter climate, while the chief factor in determining the climate of this region undoubtedly is its extraordinary protection against northerly winds. The warm water of the Mediterranean Sea helps to maintain the relatively high winter temperature, and the prevalence of clear skies, allowing the sun's rays to strike with full power upon the rocky southern slope of the sheltering mountain-wall, has also a powerful influence in the same direction, especially during the day hours. "It has been calculated," says Dr. Yeo, in his work on "Climate and Health-Resorts," "that the temperature of the Mediterranean off this coast is twenty degrees higher than that of the Atlantic at the same depth and in the same latitude; and that the temperature of the surface of the sea (off the coast of Cannes), has a mean excess of about 12° Fahr. over the minimum temperature of the air, and a mean excess of 9° over that of the sea on our own southern coast (Falmouth)."

The mountain-wall that shelters the western Riviera varies in height from about nine or ten thousand feet behind Nice, where the main chain lies some thirty miles from the coast, and where many ranges of foot-hills intervene, down to four thousand five hundred feet behind Albenga, Noli, etc., where the crest of the chief ridge itself approaches to within seven miles of the shore, and where there is no longer any space left for the intervention of secondary ridges or foot-hills.

The climate of the Riviera is a moderately dry one, mild rather than warm during the winter months, and especially characterized by the general prevalence of bright sunshiny weather, by great heat of the sun's rays, and, above all, by its relative immunity from cold winds.

The most typical example of the climate of the true Riviera is to be found at Mentone, and it is purposed in the present article to avoid any attempt at lengthy discussion of this type, such information as may be desired on this subject having been already presented in the article entitled Mentone. Brief mention of other less celebrated Riviera resorts, as well as of Cannes and Nice, is all that the reader will find in this general article, a long array of figures and detailed discussion of meteorology or topography being avoided, and in their stead but a few words being said regarding the alleged special peculiarities of these other Riviera stations, and respecting their differentiation from Mentone, the Riviera type.

CANNES.—The town of Cannes lies on the French coast, twenty-eight miles southwest of Mentone. It is the least sheltered from northerly winds of any of the resorts mentioned in this article, being especially exposed to that curse of the Riviera, the mistral. Close to the town the dust is very annoying, at least it was so when Dr. Sparks wrote his work on the Riviera some ten years ago. The town is abundantly supplied with good water, and its drainage (in 1879) was in fair condition. Living accommodations are many and good, although by reason of the popularity of Cannes among the English, not yet abundant. The cost of living is especially high. The surrounding country is very attractive, and being far more open than that about the true Riviera resorts, which in fact hardly have any surrounding country, affords exceptional facilities for riding and driving. There are also good boating facilities. In regard to the opportunities for driving, Dr. Sparks tells us that Cannes "has a decided superiority to Mentone, and still more to San Remo;" for "not only can one go farther to the east and west of the town without encountering steep hills, but there are many more carriage excursions to be made inland." The immediate neighborhood of Cannes is "not so well off for walks as drives," he says, by reason of the building operations involved in the constant growth of the town. At the close of January, 1878, there were no fewer than seven hundred and fifty English families at Cannes. The many social gatherings and entertainments are an objectionable feature of life at this place, so far as the invalid is concerned. The subject of the winds at Cannes is very carefully considered by Dr. Sparks, and he sums up his conclusions by saying that he thinks there is little doubt but that it is a very windy place, and that like Hyères, the wind to which it is especially exposed is the "mistral," or dry, and often cold, northwest wind. Of the little village of Le Cannet, two miles and a half north of Cannes, he tells us that it is well sheltered under the hills; that the natives say it "feels no wind," and that "it is easy to believe that they are right." Out of a goodly number of statistics regarding the temperature, rainfall, etc., given in Dr. Sparks's work, I select for quotation only those for average temperature and relative humidity, presented on the authority of Dr. Marcet, and covering the years 1874–77, those of mean maximum temperature for three years, and of mean minimum temperature for two years. They are as follows:

	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.
Average temperature........	53.6	48.2	50.23	48.5	50.7	55.7
Mean maximum temperature.	66.06	54.3	55.76	54.26	57.23	61.8
Mean minimum temperature.	46.9	39.7	44.5	41.0	44.6	49.2
Relative humidity..........	70.64	69.99	60.99	71.6	70.73	74.16

At Cannes, as at Nice and at Hyères, olive-trees are abundant, and Dr. Sparks tells us (op. cit., p. 36) that this tree "appears to be unable to support a temperature below 21° or 22° Fahr." The olives at Cannes are smaller, he says, than they are east of Nice; while lemon-trees, which are abundant about Mentone and San Remo, at Cannes are scarcely ever seen. Orange-trees, on the other hand, are to be found at Cannes in abundance, but of these two varieties of the genus Citrus he tells us that, "roughly speaking, two to four degrees of frost, Fahrenheit, kill the lemon, whereas we only hear of orange-trees being killed by relatively severe frosts, such as occurred in 1709, 1788–89, and 1829." *

Respecting the special climatotherapy of Cannes, Dr. Sparks pronounces it to be "distinctly a bracing place;

---

* A. J. C. Hare, in his book, "A Winter at Mentone," says that oranges bear seven degrees of frost, i.e., a temperature of 24° F.; while lemons bear only four or five degrees of frost, viz., a temperature of 27° or 26° F.

[illegible] In fact, sometimes," although, he adds, that [illegible] "suits many people better than Mentone or San Remo, especially as the spring advances and the days get warm;" and he thinks "invalids who have wintered in one of these places often benefit by a change to Cannes at the end of March or in the middle of April."

Nice.—Proceeding along the coast from Cannes, in an easterly, or rather northeasterly direction, the next health resort of the Riviera series met with is the city of Nice, the largest town of the coast between Toulon and Genoa, having a population of 53,880 on the occasion of the last census preceding the publication of Dr. Sparks's book, and a transient population of winter visitors, according to this author, of from 10,000 to 15,000 more. The town itself stands directly on the sea-shore, but is backed by a sloping area of country intervening between the foot-hills proper and the shore, which is some four miles wide from east to west, and a trifle deeper or longer from north to south (Sparks). "It is only in the immediate neighborhood of the town," says the author just quoted, "and for a short distance from the coast, along the edge of the bay, that there is any level ground; the remainder of the area consisting of low ridges and shallow valleys with a general direction from north to south." The highest of the foot-hills back of Nice is the Mont Chauve, with an elevation of 2,824 feet, and standing seven miles back from the coast. The elevation of the main chain of the Maritime Alps behind Nice, offset by its very considerable distance from the coast at this point, has been already mentioned. The foot-hills north of the Nice amphitheatre are, as pointed out by Dr. Sparks, too far distant and too much intersected by valleys to afford very good protection against winds coming from that direction; in fact, they appear to be much like the "multis interessit vallibus colles" described in the "Bellum Alexandrinum" as surrounding the town of Zela in Pontus; and as to the more distant mountains he says that "they can scarcely benefit Nice as much as is generally supposed, owing to the cold currents which descend from the snow-fields on their southern face." The writer recalls a view of distant snow-covered peaks, seen from the top of the Observatory Hill at Nice early in March, 1866, yet at the same time in Nice roses were blooming in the open air.

Like Cannes, Nice is one of the windiest of the Riviera resorts. "The mistral blows about nine times in the year, chiefly in February and March, and it is accompanied by clouds of dust whose density has been compared to that of a London fog; while at the same time the amount of moisture in the atmosphere is reduced to a minimum" (Sparks). The average number of days of complete calm during the nine autumn, winter, and spring months, as quoted by Sparks from Teysseire, is 18.6, while the average number of days of gentle wind is 200.8, and that of strong wind days is 69.4, out of which 29.4 occur during the three spring months.

Teysseire's figures for mean relative humidity (1869–76), for mean temperature, and for *absolute* (not average) maximum and minimum temperatures during the twenty-eight years 1849–76, are given below, and are all the meteorological data we shall attempt to quote out of the many provided by Dr. Sparks.

	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.
Mean temperature	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

Mean relative humidity*	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

Hotels and pensions abound at Nice, and villas, many of them handsome and surrounded by large gardens, are not only numerous in the city itself, but are also thickly scattered all over the hill-sides behind the town.

For cases of pulmonary phthisis the climate of Nice is by no means so well adapted as is that of the Riviera proper, east of the Tête du Chien promontory, although for that particular class of phthisical cases known as the "torpid," in whom open-air life alone is the chief consideration, and who have no febrile reaction and no marked susceptibility to taking cold, Nice is a good place of winter resort, provided they are careful to live away from the sea and to select a residence either in the relatively sheltered northern portion of the town, or, better still, at the suburb of Cimiez ("the Civitas Cimeliensis of the Romans," A. J. C. Hare), lying two miles from the sea, or at some other sheltered spot among the hills. For the chronic bronchitis of elderly people, for delicate women, strumous children, and dyspeptics, and for nervous diseases—excluding those accompanied by symptoms of excitement and also excluding all neuralgic cases—the climate of Nice appears to be a good one. The objections to the climate in the case of cardiac disease, and, above all, pulmonary disease, are such that Dr. Sparks very wisely remarks that "no invalid should ever think of settling down at Nice for the first time without consulting one of the local medical men." The closing paragraph of his seventh chapter deserves quotation in full, and its lesson should be impressed upon the mind of every physician who thinks of recommending this celebrated resort, which is to-day rather a pleasure resort than a refuge for invalids.

"As to amusements," says Dr. Sparks, "what with theatres, operas, balls, soirées, etc., there is only too much even for healthy people. The society is extremely mixed, as Nice is more uniformly frequented by the nations of Europe and the world than any of the other southern health-resorts; but the larger number of winter visitors come not for health, but for pleasure, which, in other words, means gambling at Monte Carlo, or playing baccarat at the clubs on the Promenade des Anglais. Certainly some of the social aspects of life in that city might well be dispensed with, and to search for [illegible] in any sense of the word we must not go to Nice."

Mentone.—This celebrated, and very justly celebrated, health resort not only lies within the true Riviera district, but by reason of its exceptional shelter against cold winds, as well as for other reasons, may be regarded as the type of all Riviera resorts. It has been elsewhere fully described (see article Mentone, Vol. IV., pp. 780–785). The accompanying illustrations give a very good idea of the appearance of the town as viewed both from the east and west, and are properly introduced in the present article as typically representative of the scenery of the entire Riviera. Fig. 5033 is a view taken from a terraced olive orchard on the Cap St. Martin, the headland separating the bays of Mentone and Monaco. The other view, shown in Fig. 5034, is taken from the shoulder of the Monte Bellinda, which, running out as a buttress into the sea, constitutes the Punta della Murtola. Both wood-cuts are copied from Dean Alford's interesting book on the Riviera, a work that cannot be too highly commended to such of my readers as may desire to get a fair idea of the scenery of this most beautiful region without visiting it in person.

Bordighera.—The little town of Bordighera (population in 1876 about 2,500), lying at the extremity of a promontory about ten miles east of Mentone, is peculiar among Riviera resorts in possessing (by reason of this very situation upon a promontory) a more distinctively maritime climate than is to be found at any other point along this whole coast. Mr. Frederick Hamilton, quoted by Sparks, describes the situation of the town, and its consequent climatic peculiarities as follows: "All the other health-resorts," he says, "Cannes, Nice, Mentone, San Remo, and even Alassio, . . . are more or less at the bottom of bays. The situation of Bordighera is quite the reverse. It stands on a promontory which projects into the sea more than any other headland in Liguria. Hence it gets more sea air than any of the places already mentioned. The winds from north of east, round by south, to a little north of west, all necessarily blow from the sea. Live where you will in the neighborhood, even seven or eight hundred yards from the shore and on the hills, you will still find yourself under the influence of the sea air, just as you would along the beach in the other health-resorts. . . . The result in a medical point of view is, obviously, that the climate of Bordighera should be advised only to those who may expect benefit from sea air. Such patients will have the advantage there of breathing the sea air *inland* (*i.e.*) without the inconvenience of the high winds, and the noise of the waves, which they would suffer from in other localities." Dr. Sparks adds that obviously in the latter part of this quoted passage Mr. Hamilton was speaking rather of the "Bordighera of the future," than of the town as it existed at the time his (Dr. Sparks's) book was written: for at that time all that had been built of the suburb of New Bordighera (the only portion of the town suited to the residence of invalids), lay close down by the shore on the west side of the promontory, exception made only of a few scattered villas standing among the olive groves between the main road, close to the beach, and the old Roman road, the Via Aurelia, a road which, running close under the base of the foot-hills a quarter of a mile back from the sea, was then (1879, October) being "partly resuscitated and converted into a boulevard." These foot-hills, covered with olives and pines, attain an elevation, according to Dr. Sparks, of from four hundred to (at most) one thousand feet. The old and compactly built town of Bordighera, standing at the very tip end of the promontory, is decidedly picturesque, as are all these Riviera towns, but is not suited to the residence of invalids, and the east side of the promontory, though "occupied by a charming valley, rocky and sandy, full of palms and lemons, abundantly watered and prettily closed in by towering hills," does not seem to be popular as a place of residence, probably, according to the writer just quoted (Mr. Hamilton), "because the cemetery stands in the centre of it, which is a drawback in most people's eyes." So that the narrow strip of olive-covered, nearly level country to the west of the promontory is evidently destined to be the chosen site for the growth of the new town. This strip, although flat, is

---

* The contrast between these humidity data and those of Dr. Vincent at Cannes is very striking, and the writer cannot help suspecting that Dr. Teysseire's table for Cannes, which was quoted by Dr. [illegible] [illegible] when compared with those of [illegible] [illegible] with those of Nice. For Dr. Sparks is [illegible] [illegible] [illegible] [illegible].

[illegible] of the foot-hills, a point of exceedingly great importance in the Riviera, where the [illegible] [illegible] [illegible] [illegible] different portions of one and the same town may be said to possess entirely different climates.

FIG. 5033.

FIG. 5034.—Mentone from the East.

well drained, having a soil which consists of a mixture of sand and clay resting upon a loose bed of shingle. The desirable portion of this narrow strip is that which lies within a distance of a mile from the cape, and which contains, according to Mr. Hamilton, "over two hundred acres of building land," while "the hills behind offer double the extent." New Bordighera, and in fact all this western strip of country, is to a good degree sheltered against easterly and northeasterly winds by the Cape of Bordighera itself.

On the north, Bordighera is "almost completely protected" against winds, and "the outlines of the Alpes Maritimes to the northwest and west break the force of winds from these quarters" (Sparks). Against the southwest wind—a warm and moist one—it is, of course, not sheltered at all, and this wind "sometimes blows with considerable force." The westerly winds at Bordighera are "generally light breezes accompanying fine weather," according to Mr. Hamilton. Dr. J. Burney Yeo says that at Bordighera "the mistral is a west wind, being turned completely in that direction by the mountains behind Monaco," but that "from being forced to blow over the sea it loses somewhat of its dry and cold character." As to the local sea breezes, "which are not strong winds," he says that Bordighera naturally feels them more than do the neighboring resorts.

The following table, condensed from one given by Dr. Sparks, and containing data for temperature based on Mr. Hamilton's observations, will suffice to show the mildness of the climate and its very great similarity in this respect to that of all the other Riviera resorts:

	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.	May.
Mean temperature	64.5	56.4	50.8	49.6	49.1	52.5	57.1	63.6

The observations were taken at a height of more than sixty feet above the ground. Mr. Hamilton's maximum and minimum readings for the same period, and his data for rainfall may be found in Dr. Sparks's book. "Snow and hail are of extremely rare occurrence, and as at Mentone, the former melts almost immediately after it falls" (op. cit.).

When Dr. Sparks wrote his book, the only really good drive at Bordighera was along the shore road (the Cornice). But, as at other points along the coast, the resident who is able to drive over rough and steep roads, or to ride on a donkey, has a choice of excursions to many exceedingly picturesque places in the back country; while for invalids the walking facilities in the immediate neighborhood are exceptionally good. "Leaving their hotel or villa," says Sparks, "they at once find a shady and level retreat under the olives; or, if able to ascend the hills, they can do so without having to encounter any very steep ascents." The extensive palm groves of Bordighera are famous. "I have been told," says Dean Alford, in the beautifully illustrated chapter of his book devoted to this peculiar feature of the place, "that there are probably more palms at Bordighera alone than in the whole of the Holy Land."

In regard to the climatotherapy of Bordighera, Dr. J. Burney Yeo says: "It is especially suited to invalids who want sea air; to cases of scrofulous phthisis in its early stages and other cases of early phthisis without any tendency to hemorrhage; to cases of throat and bronchial catarrh; to cases of chronic gout; of convalescence from acute diseases, cases of anæmia, and many other conditions of constitutional feebleness. Its climate is too exciting for the very nervous and sensitive."

SAN REMO.—The town of San Remo lies seven and a half miles east of Bordighera, at the bottom of a small bay, closed in by the two promontories known as Capo Verde and Capo Nero. The town itself, closely and compactly built, like other Riviera towns, is triangular in shape, and extends up the slope of a steep hillside, somewhat like the city of Algiers in miniature. Its population in 1881 was [illegible]. Owing to the narrowness of its bay and its relation to the general trend of the coast line, there is no extensive view (excepting, of course, that straight out to sea) to be had at San Remo, a point urged against it by Dean Alford and quoted by Dr. Sparks and Dr. Yeo.* The scenery generally is less bold and picturesque than it is at many other points on the coast: "the higher hills recede somewhat from the coast, and the nearer ones are wooded to their summits and present nothing particularly striking in form or colouring" (Yeo). The winds to which San Remo is chiefly exposed are those blowing from the east and southeast, according to Sparks; while Weber * states the comparative frequency of the different winds during the five months, November to March, as follows: N.E. and E., 115; N.W. and N., 154; S.W. and W., 101; S.E. and S., 25.

The mistral appears to be felt at San Remo as much as, or even a little more than, at Mentone. The soil is largely clay, and less readily percolable by water than at Mentone and at Bordighera.

The water supply is good. In point of temperature the climate is almost an exact counterpart of that of the West Bay of Mentone. It is considered less stimulating than the latter. There are many hotels in the newer outlying districts of the town, both on the west and east sides of its older portion; many villas, too, have lately been built, San Remo having grown greatly in popularity as a health station during the past ten or fifteen years. Many of the winter residents are Germans—fully half of them in 1879, when Dr. Sparks wrote.

In the matter of drives and walks, what was said of Bordighera may be repeated as applicable to San Remo, but Dr. Sparks says that there is no good sea walk close to the town. The market is good. The cost of living is about the same as at Nice and Cannes. Many data of temperature, humidity, etc., may be found in Dr. Sparks's book and in Dr. Weber's account already cited. The rainfall and number of rainy days appear to be less than at other Riviera resorts. The afternoon heat after the middle of April is less than at Mentone.

ALASSIO.—The town of Alassio, twenty-eight miles east of San Remo, "is situated in a lovely bay, having a southern aspect, well protected between two headlands, . . . is probably not so warm as San Remo, as it is more open to the northeast winds, and, the northern hills not being so high, the north wind (Tramontana) reaches a portion of the district close to the shore" (Yeo, op. cit.). The water supply is abundant and good, according to Dr. Sparks. Alassio, as regards the beauty of its scenery and in the way of picturesqueness, is one of the most attractive points in the eastern portion of the Western Riviera, and of late years has acquired some reputation as a health resort. Of meteorological data there is as yet a dearth, and such as are given by Dr. Sparks are by him subjected to much critical comment as regards reliability and practical usefulness. I shall therefore spare the reader these quotations.

No other resorts along the Western Riviera call for special mention in this article, although several others exist. As regards the Eastern Riviera, a good, and perhaps the best, type of such resorts as exist along this part of the Ligurian coast has been already presented in the article describing Nervi (Vol. V. of the REFERENCE HANDBOOK, pp. 151 and 152).

GENERAL CLIMATOTHERAPY.—The climate of the Western Riviera has been properly classified by Dr. Hermann Weber among the "dry, warm coast climates"—a classification justified by such data for temperature and humidity as have been presented in the course of this general article and in the special article on Mentone. The Eastern Riviera is less dry, consequently less stimulating, and, as a whole, rather less warm.

As has been already stated in the general article on Health Resorts (Vol. III., pp. 529-530), the Riviera climate is suited to the treatment of cases of bronchial catarrh, chronic bronchitis, laryngeal catarrh, and pulmonary phthisis in its earlier stages, and when not accompanied by very marked febrile movement or by a special tendency to hæmoptysis. In cases of general progressing phthisis, with formation of cavities—a class of cases where least benefit is to be expected from any climatic treatment—even Dr. Weber, a strong advocate of "high-altitude" resorts, gives the preference to Mentone and like resorts, and pronounces against what may be called the "high-and-dry" sanatoria that are so much in vogue to-day. For diabetes, chronic renal disease, and chlorosis the entire Riviera is well suited, as it is to cases of anæmia and of "threatened phthisis" in strumous children. Such of the Western Riviera resorts as are most sunny and sheltered, and least "fashionable" as regards the matter of social entertainments are well suited to cases of rheumatism and gout. For the functional ailments characteristic of old age the Riviera is also a good place of resort; but persons having a tendency to apoplexy are by some writers loudly warned against taking up a residence in this region.

---

* Dr. [illegible] says of San Remo that, "though beautiful and [illegible], it [illegible] and scenery which made Mentone so attractive."

Dr. Weber's statistics, showing the result of one hundred and twenty-four winters passed on the Riviera by 63 patients suffering from pulmonary phthisis certainly speak well for the climate. Of these patients 36 were in the first, 15 in the second, and 12 in the third stage of the disease. I give his results below in tabular form:

	Cases.	Improved.	Unimproved.	Worse.
First stage	36	22	3	11
Second stage	15	6	3	6
Third stage	12	2	5	5

As summed up by Dr. Weber himself these figures showed 47.6 per cent. of improved cases, 17.5 per cent. unchanged, and 34.9 per cent. of patients who grew worse.

He quotes also the statistics of the two Doctors Williams, based upon their observation of one hundred and fifty-two phthisical patients who had passed two hundred and twenty-nine winters in the Riviera. These observers found 62.5 per cent. of improved, 20.39 per cent. of unimproved, and only 17.10 per cent. of retrograde cases; and Dr. Weber very justly remarks that even better results could be obtained were patients only more prudent in regard to avoiding the special climatic risks peculiar to the Riviera (*e.g.*, the great contrast between sun and shade temperatures and between the temperature immediately before and immediately after sunset, and a foolish exposure to the sea-breeze such as is spoken of and warned against by Dr. Bennet—vide article "Mentone"), and were they only more careful in matters of diet, more disposed to keep away from the social gatherings of such places as Cannes and Nice, and more ready to consult the local physicians.

A very similar climate to that of the Genoese Riviera is to be found in Southern California; indeed, so far as climate *alone* is concerned, the Southern California resorts are probably superior to those of the Riviera. For patients, however, who are not imperatively called upon to select the very best possible climate for their disease, and particularly for those—and they are many—in whom a distraction of the mind, such as is effected by beautiful and picturesque scenery and by objects of historical interest, is an important element in cure, there can be no comparison between the much more varied and infinitely more picturesque scenery of the Riviera and that of California; nor between the historical interest of a country where the towns to-day look much as they did in the middle ages, where there are occasional remains dating from the classical period, (*e.g.*, the Via Aurelia, the Roman ruins at Turbia, Veilles, Carnolles, Cimiez, and Ventimiglia), and where, as in the celebrated bone caves of Mentone, not only implements belonging to, but actual skeletons of, prehistoric men have been discovered, and the historical interest of a country whose scanty remains are those merely of a remote Spanish colony not over three hundred years old.

BIBLIOGRAPHY.

For further and more detailed information regarding the Riviera, the reader is advised to consult Dr. J. H. Bennet's Winter and Spring on the Shores of the Mediterranean. Dr. Edward L. Sparks's Riviera; Dr. J. Burney Yeo's Climate and Health Resorts; the Rev. Dean Alford's The Riviera: Pen and Pencil Sketches from Cannes to Genoa; and also Augustus J. C. Hare's A Winter at Mentone.

[1] Climate and Health Resorts, by Dr. J. B. Yeo.

[2] Klimatotherapie, in Ziemssen's Handbuch der Allegemeinen Therapie.

RUMINATION IN MAN. Synonyms: Merycism (from Gr. *μηρυκισμός*); Fr., Mérycisme; Ger., Merycismus, Wiederkauen; Lat., Ruminatio. Medical literature, especially that of recent years, contains numerous instances of rumination, or "chewing the cud," occurring in the human subject. At a period usually of from ten minutes to half an hour after the ingestion of food, though sometimes during the progress of the meal, the subject of this peculiar complaint suddenly feels the presence in the pharynx of a bolus of food, which has been regurgitated from the stomach without any conscious effort on his part. This regurgitation is usually unaccompanied by any subjective symptoms, either pain or nausea, though, if for any reason it do not occur, the patient commonly experiences a feeling of discomfort and weight in the stomach until the process of digestion is completed. In most cases the rejected bolus of food is neither bitter nor acid, unless the regurgitation has been delayed beyond the usual time, and the subjects of the malady not infrequently describe the process as a pleasant one, expressing their dissatisfaction at anything which may happen to prevent its recurrence at the usual time. M. Blanchard, who is himself a mérycole, as the human ruminator is called, testifies to the pleasurable sensations experienced in the act, and even confesses to having occasionally selected by preference certain articles of food which his previous experience had taught him would most promptly cause rumination, or which would have a specially agreeable taste when masticated a second time.

The condition is sometimes congenital, or at least the subject cannot remember the time when he did not ruminate, and there are many people doubtless who are mérycoles without knowing that they differ in this respect from their fellows. Blanchard learned that his rumination was abnormal only when he began to study physiology. It may even be hereditary, several cases being on record in which father and son were both ruminators. It occurs usually in persons who are large eaters, and in those who bolt their food without properly masticating it. Occasionally the habit is an acquired one, coming on without any apparent reason, or being referred to various and dissimilar causes. Brown-Séquard is said to have suffered for a time from merycism, brought on by some experiments made upon himself to determine the time required for the digestion of various alimentary substances. In conducting these experiments he enclosed the articles of food in a sponge to which a string was attached, and after a certain period of time he brought up the sponge by pulling on the string. After this had gone on for a while he found that the sponge was returned spontaneously, and then whatever was swallowed was returned in the same way. In another case, reported by Dehio, of Dorpat, the habit of ruminating was attributed to a violent and long-continued attack of whooping-cough, the paroxysms of which were always terminated by vomiting. Goldenhorn, of Odessa, relates a case occurring in a young man, which was associated with neurasthenic symptoms brought on by excessive sexual indulgence. Another case, reported by Boas, of Berlin, occurred in the person of a merchant who had travelled extensively, and had indulged for a long time in excesses of eating and drinking. Jürgensen, of Copenhagen, saw a case in a young girl, in whom rumination began without any apparent cause when she was ten years of age. Both the father and the grandfather of the patient were mérycoles. This case is exceptional by reason of the sex of the patient, most of the recorded instances having been in male subjects. In a few of the reported cases a distinct neuropathic family history was present, epilepsy in some of the immediate relatives being noted, but in other cases no such history was found. Among the exceptional and accidental causes of merycism may be mentioned oesophageal diverticulum. The act in such a case is, however, not properly merycism, but is simply a regurgitation of food which has become lodged in the diverticulum.

In the absence of any other explanation, merycism was formerly regarded as a pure neurosis; but recently Alt, Boas, and Jürgensen have published cases in which there was found an alteration in the amount of free hydrochloric acid present in the stomach during digestion. It is somewhat singular, however, that this change was not the same in the different cases, for in one case there was hyperacidity, in another the amount of free acid present was less than normal, and in two there was complete absence of this element of the gastric secretion. In some cases a moderate amount of dilatation of the stomach was noted, while in others no change of this sort could be detected.

Usually the merycole is healthy in every other respect, and the process is doubtless often beneficial, since, as in the ruminants, it provides for a remastication of food which has been hastily swallowed without having been properly chewed and mixed with the saliva. Dr. Hubbard, of [illegible], N. Y., reports a case in illustration of this. A previously healthy man consulted him in the hope of getting back his "lost cud." He stated that he had always been a ruminator, but that the habit had suddenly left him a short time before. He was a very large eater, and was accustomed to swallow his food without sufficient mastication, but had never suffered from dyspeptic symptoms, as the food was invariably regurgitated a short time after the termination of the meal, and was chewed leisurely. Since the cessation of the habit, however, he had been a martyr to indigestion.

An alarming suggestion has been made by Martel, to the effect that man is destined in time to become a ruminant animal. The habit of rumination, he says, quoting Blanchard, was acquired by certain animals at the time that the carnivora appeared upon the earth. Fearful of attack, the ruminants grazed rapidly, ready for flight at the first intimation of danger. Then, having reached a place of safety, their food was regurgitated and masticated thoroughly. A similar condition is obtaining in man, he asserts, in this age of hurry; and unless we learn to be more deliberate in our eating, and to masticate our food in the first instance more carefully, the necessities of digestion will compel a regurgitation and rechewing of the food, which has been so imperfectly prepared for the action upon it of the gastric and intestinal secretions; and in time this process, which is now exceptional in man, will become habitual.

In the present state of our knowledge concerning the nature and cause of merycism, it is difficult to discuss satisfactorily the subject of treatment. It is, of course, necessary to study the individual case with care, since the causes of acquired rumination are so varied. In a case of so-called congenital merycism, in which no cause can be found either in the mode of eating or in the state of the gastric secretions, it is probable that but little can be done in the way of ameliorating the condition. In such a case, indeed, the physician ought to proceed with some caution, since, were he successful in breaking off the habit, it might well be that more harm than good would result from his efforts, the patient, who was before a merycole suffering only from the comparatively slight annoyance of his habit, becoming merely a confirmed dyspeptic.

In the case of a voracious eater, a certain measure of self-restraint and greater care in the mastication of food may, by removing the occasion of rumination, abolish the habit. The character of the gastric secretion should be examined into, and if hyperacidity be found to exist it should be corrected by the administration of acids before eating, or of alkalies after the ingestion of food. Alt has reported a case of this nature in which a cure was obtained. The patient was a rapid eater and used to swallow his food very imperfectly masticated. There was a slight degree of dilatation of the stomach, some patency of the cardiac orifice, and examination showed an excess of free hydrochloric acid. The digestion of albumen was very rapid, while that of starchy matters was imperfect. It was only after these had been returned to the mouth and again chewed and mixed with saliva that they could be digested. The treatment consisted in lavage of the stomach, galvanism of the oesophagus, an albuminous diet, and the exhibition of large doses of alkalies. A complete cure was obtained in a fortnight. The use of the stomach-tube alone has in certain cases been found productive of benefit, although no cure by this means has been reported. Jürgensen relates an instance of this kind in which the smallest amount of food swallowed in the usual way was always rejected, while a much greater quantity introduced through a tube was retained without the slightest trouble. Boas believes that the mechanical effect of the sound upon the nerves of the stomach is of service, and thinks that the therapeutical value of this procedure in gastric affections is not sufficiently appreciated. In cases such as those reported by Jürgensen and Boas, in which there was a deficiency of acid, the administration of acids in connection with hygienic and dietetic measures would be indicated.

The following is not offered as a complete bibliography of the subject of merycism, but the reader will find in it references to some of the more important articles on the subject, most of which have been consulted in the preparation of this brief sketch of the disease.

Thomas L. Stedman.

SKIN AND ITS APPENDAGES, THE ANATOMY OF THE.

The skin, or integumentum commune, of the body acts as a covering and a protection for the deeper portions, besides being an organ of excretion and absorption and the seat of the sense of touch. Embryologically, it is developed from those two primitive layers of the blastoderm, the ectoderm and the mesoderm, which are formed by the cellular division of the impregnated ovule. The epidermis, or most external layer of the skin, is formed from the ectoderm, while a superficial portion of the mesoderm furnishes the remaining constituent parts, the corium or cutis vera, and the subcutaneous or fatty tissue.

GENERAL CHARACTERISTICS.—When fully formed the skin can be regarded as a completely closed sac, which moulds itself so closely upon the portions of the body which lie immediately below it that it allows their shape and configuration to be more or less accurately distinguished. This, naturally and to a great extent, will depend upon the amount of intervening fatty tissue, which, when in excessive amount, entirely destroys that symmetry and roundness of form dependent upon its presence in moderate quantity.

The skin does not stop abruptly at all the natural openings of the body. It is continuous at these points with the mucous membrane which clothes the cavities. At the nares, on the labia majora and minora, and on the external surface of the anus, the same skin is present as on the rest of the body, and it goes gradually over into the mucous membrane. At the mouth, however, on the eyelids, and at the meatus urinarius, the transition is abrupt.

The integument is very variable in thickness. In general it varies between $\frac{1}{2}$ and 4 mm. ($\frac{1}{50}$ to $\frac{1}{6}$ inch), exclusive of the subcutaneous tissue. It is thinnest on the eyelids, and thickest on those portions which are subjected more especially to pressure, as on the palms and soles, or which serve as points of insertion for muscles, as on the upper lip, alæ nasi, etc.

Density and Elasticity.—It has been found that the skin possesses considerable solidity and very perfect elasticity. Sappey concluded from his experiments that a strip of skin 3 mm. long and 10 mm. broad was able to support a maximum weight of 12 kilos (26$\frac{1}{2}$ lbs.). The solidity was also in direct ratio to the thickness of the piece of skin used in the experiment. As mentioned, the elasticity is very perfect, but slight; a considerable amount of stretching may result from the application of a small weight, but complete rectification takes place after its removal. The skin is not of uniform texture; but consists of bundles of fibres arranged like a net, between which are spaces of various sizes which are rhombic in shape. In these spaces there is found a cementing substance, and it is due to it that the former are able to regain their natural shape after having been stretched. Rollet observed, that when this cementing substance had been destroyed the elasticity of the skin was lost; consequently, he concluded that the elastic property of the skin must be ascribed to its presence.

Cleavage.—The cleavage lines of the skin were discovered by Langer. He pierced the skin with small, round awls, and, after removal of the instruments, observed that the wound which was made was a linear one. He then made series of them in rows and close together, and from the uniformity in the direction of the long axes of a more or less greater number of the small wounds, he was able to conclude that the skin possessed complete linear cleavage over the greater part of the surface of the body. Not on all, however, for in some places, as on the forehead, on many points on the scalp, etc., the wound made was a triangular one, and he found that these occurred where two spaces met together which possess linear cleavage in opposite directions.

The explanation of the fact that the skin is, to a great extent, cleavable linearly, is to be found in the arrangement of the spaces between the bundles of fibres. These spaces are of various sizes and shapes, and in many places are so stretched longitudinally and so narrowed that the fibre-bundles run almost parallel to each other. The course of the cleavage lines of the skin can be well understood by consulting the accompanying figure.

Tension.—Except upon the scalp, the palms of the hands, and the soles of the feet, the skin is, more or less, in a state of tension. When a portion is excised, it will be seen that it diminishes in size to such an extent that it will no longer cover the surface which has been laid bare. This cannot be ascribed entirely to the retraction of the borders of the wound, but is also due to the diminution in size of the excised piece, which is then no longer subjected to its former tension. Where the skin possesses linear cleavage, the tension is in the direction of these lines, but where this condition does not exist, it occurs uniformly in every direction in the plane of the surface. The tension likewise depends upon the movements of the joints and muscles, the amount of fat deposited in the subcutaneous tissue, and also upon morbid conditions, such as œdema, or upon the existence of pregnancy. In this latter condition the degree of tension may be so great that a permanent change may result in the direction in which the bundles of fibres run.

Color.—The color of the skin differs according to the individual, the race, and the age, and it also varies upon different portions of the body. It cannot be ascribed in certain races to climatic influences alone, since in the same zones people of different color are found, as in Africa negroes, and in a corresponding portion of America the much lighter-colored Indians. The difference in color depends entirely upon the amount of pigment present in the epidermis, where, under the form of granules, it is found especially in the lowest layer of the epithelial cells forming it. This is easily demonstrable in the skin of the negro two or three days after death, and before decomposition has set in. If the skin is, under such conditions, sharply rubbed, the epidermis is detached and rolls up under the finger, and the corium or true skin being exposed is seen to be of a dull white color.

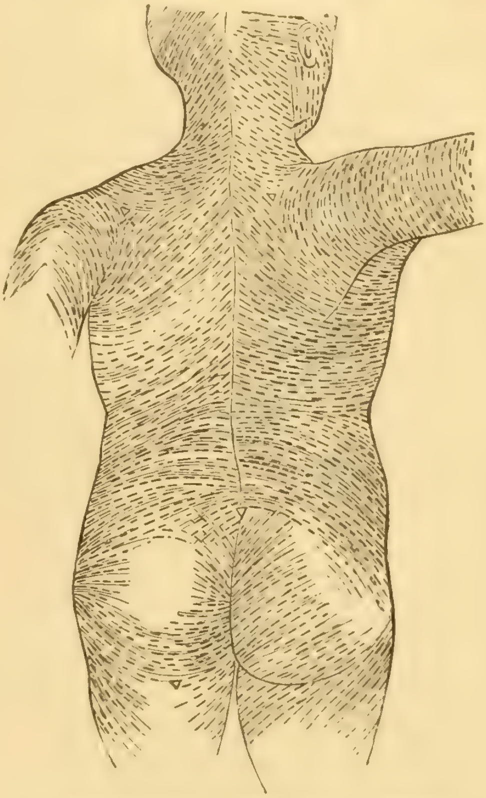

FIG. 5035.—Cleavage Lines of the Skin. (Langer.)

In the white race the color changes, within certain limits, in the various seasons of the year. When exposed to the heat and the sun in summer, there is an increase in pigment deposit and it appears darker, but this disappears and the whiter color returns in winter.

Under certain physiological conditions, such as pregnancy, there is likewise an increase in the amount of pigment in particular portions of the skin—the areola around the nipple, the linea alba, etc.—and this may in some instances be to an exaggerated extent. A large portion of this increase often disappears after the birth of the child, but a considerable amount usually remains. In the male the scrotum and penis, and in the female the vulva, are of a darker color than the rest of the skin. The pink or red color seen on certain portions of the body, as the cheeks, or induced by certain temporary causes, as those which produce flushing, is due to the blood in the vessels of the cutis. These latter becoming filled with blood its color is conveyed to the eye through the epidermic covering. When venous congestion is present the color to more or less of a brown tinge, as can be seen when certain portions of the skin with natural sluggish circulation, the nose, etc., have been subjected to cold. In old age the skin acquires a more or less yellow color, which is due to the atrophic changes that take place in it, and also to the lessened amount of blood supplied to it.

The Folds and the Furrows of the Skin.—There are many furrows which are seen on the skin. Some of them are long and deep, others are short and shallow. The former are present to a great extent from birth, and are seen running in a transverse direction across the extensor and flexor surfaces of joints. The latter are represented by the wrinkles on the face which develop with age. These latter are due partly to the diminished elasticity and turgescence of the skin, but they are induced more often by muscular contraction and stretching of the cutis.

The furrows around the joints are produced by the movements of flexion and extension. They are not able to overcome directly the tension of the bundles of fibres which, in this situation, run transversely or obliquely across the joints, and, in consequence, the fibre bundles are not stretched by the ordinary movements, but the interstitial spaces between them are. On one side of the joint their tension is in the direction of their breadth, while on the opposite side of the joint the fibre bundles are brought closer together. In this way the constant furrows around the joints are caused. Those which are due to muscular action, as the wrinkles on the forehead, etc., are produced in the same manner, the constant repetition of the movements finally effecting a permanent change in the arrangement of the fibre bundles and of the spaces between them.

The folds seen in very emaciated persons are likewise caused by the diminution in the size of the interstitial spaces. This is brought about by the loss of fat and the consequent change in the arrangement of the fibrous structure of the skin. Coarser furrows are also seen on the palms of the hands and on the soles of the feet, and in these places the skin is not movable. These furrows are always permanent, being caused by the firm union of the skin to the tissues below by means of short bundles of connective-tissue fibres. Dimples, where they occur, are due to the same cause; that is, the skin is at that point attached to the underlying tissues and does not move together with the rest of the skin of which it forms a portion.

THE STRUCTURE OF THE SKIN.—The integument of the body is composed of several layers. The most external of these consists of epithelium and is termed the epidermis. It clothes the outer surface of the corium, or cutis propria, the line of division between the two being very sharply defined owing to the great morphological difference between the elements composing each. The corium is a closely knit tissue, which consists of connective tissue, elastic fibres, and unstriped muscle. It contains the glands of the skin and the hair, and is rich in blood-vessels and in nerves. It is not sharply limited on its under surface, but goes over here gradually into the subcutaneous or fatty layer of the skin. This layer, the panniculus adiposus, is in reality the deeper portion of the cutis, and consists of connective-tissue fibres loosely put together, which contain in their cells and in the spaces between them a more or less large amount of fat.

The epidermis and the corium are the most important portions of the skin, and vary in many particulars on different portions of the body. The various appendages of the skin—the hair, the nails, and the glands—grow from and are attached to them. The complexity of all these separate constituents of the skin is, however, so great that each one requires special consideration.

EPIDERMIS. *Embryology.*—The epidermis, the most external layer of the skin, is formed from the ectoderm, and in the first month of life and the beginning of the second consists of only a single, or in its thicker portions of two or three rows of polygonal cells. Beneath these is a layer of very small cells, which represent the origin of the stratum mucosum or rete Malpighii. This increases in the course of development by proliferation to several rows of cells, the layer becoming more and more distinct and thicker. In the meantime the outermost cells have also become flatter, and thus represent the primitive horny layer, which, however, remains during fetal life of a low grade. It is subjected to constant desquamation, and the scales from its surface are mixed with the secretions from the skin to form the vernix caseosa. As early as the eighth month (Unna) granular cells begin to appear between the horny and mucous layer, and the cornification of the epidermis cells becomes more marked. Nevertheless, and before this, the horny layer has become strong enough to oppose sufficient force to the epithelial growth and to the proliferation of its cells, so that the increase in thickness of the rete Malpighii can no longer take place in the direction of the external surface, but is compelled to proceed downward toward the cutis propria. It penetrates, in its further development, into the spaces between the rudimentary papillæ which spring from the surface of the cutis, and thus forms the interpapillary prolongations of the epidermis. It is by virtue of these ingrowths of the epidermis that, when fully formed, it lies upon the derma as an accurately fitting coat, which follows closely the outlines and inequalities of the true skin.

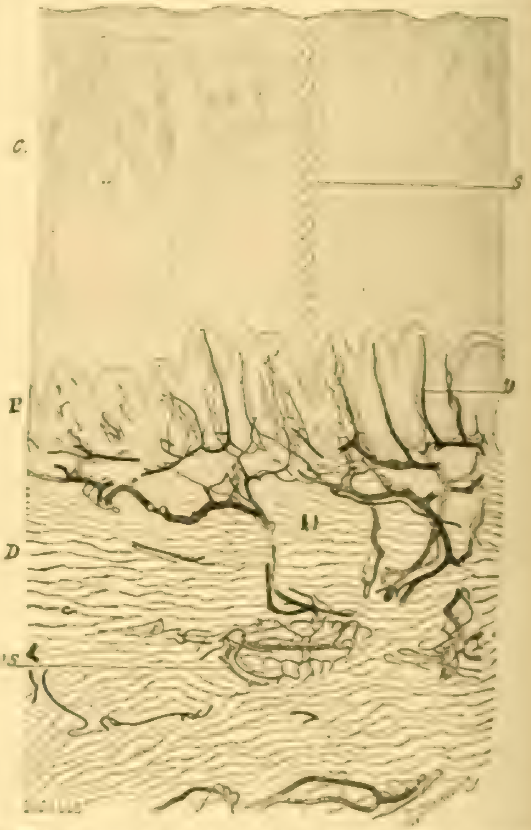

FIG. 5006.—Transverse Section of the Skin on the Palmar Surface of the Third Finger. C, epidermis; P, papillæ; D, dermis; S, sweat pore; v, vessels of the papillæ; vs, capillary net-work of a glomerulus of a sweat gland. (Toldt.)

Thickness of the Epidermis.—The depth of the epidermis, as a whole, varies from birth to old age, and also on different parts of the body. It is also influenced by external causes, as pressure, rubbing, etc. At birth it is from 0.15 mm. to 0.25 mm. in thickness, but in adult life from 0.75 mm. to 1.66 mm. The differences are due, for the most part, to the thickness of the horny layer, which in some situations, as on the palms and soles, or on any surface subjected to constant pressure, may attain a very considerable increase in thickness.

Layers of the Epidermis.—The epidermis is divided into two major layers, the division being due to the different consistency of the cells constituting each. The most external and superficial one, which consists of horny cells and is firm and resistant, is termed the stratum corneum, while the one immediately below it, which lies in contact with the derma, is called the stratum mucosum, or rete Malpighii. This latter consists of soft epithelial cells, and is sharply defined from the stratum corneum. Both of these major layers are still further subdivided according to the appearance of its cells, or to the reaction of their various portions to certain coloring substances.

Rete Malpighii.—The most deeply situated cells of the stratum mucosum, those which are in immediate contact with the derma, are cylindrical in shape and form the basic layer of the rete. Its importance can be estimated from the fact that it represents the productive part of the stratum mucosum. In normal skin they are the only cells which show the karyokinetic cell-figures, and indirect division of the nucleus occurring in epithelial growths. Their long axes are directed perpendicularly to the corium, and if the layer is carefully examined, small basic cells, resulting from the cell-division, are seen pushing their way in between the older ones. In this way the constant regeneration of the rete is provided for.

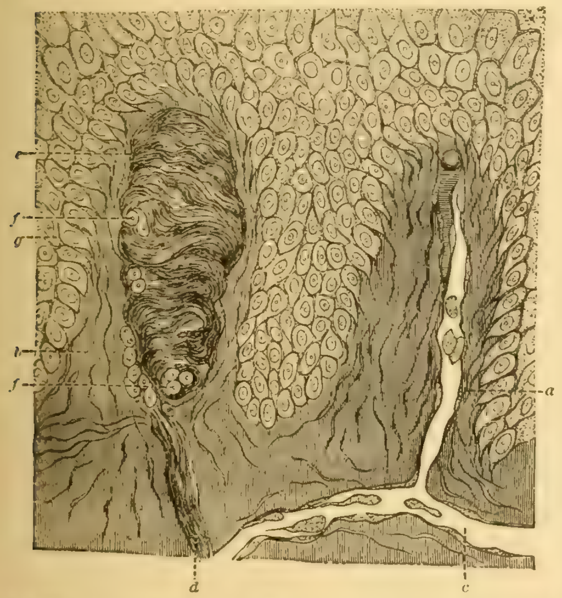

FIG. 5037.—*a*, Capillary ; *b*, papilla containing tactile corpuscle ; *d*, nerve-fibre which goes to the tactile corpuscle ; *e*, *f*, cross-section of a nerve-fibre ; *g*, cells of the rete Malpighii. (Kaposi.)

The cylindrical cells send out into the corium more or less long prolongations, but the spines, which characterize the entire rete, are seen clearly only upon their upper contours. It is in these cells, especially, that a more or less large amount of pigment granules are deposited, which give the various shades of color to the skin of different individuals and races.

Above the basic layer cells of various shapes and sizes are found. Over the papillæ, and in the interpapillary portions of the rete, round and cuboid and polygonal cells are seen. In the interpapillary prolongations, however, round cells predominate. As the external surface is approached the cells become larger, and have their long axes more parallel to the surface of the skin. The cells themselves have a body consisting of finely granulated protoplasm, which contains a clearly defined nucleus, in which are several nucleoli. According to the position of the cells in the rete, the shape of the nucleus varies. In the uppermost portions it is oval, in the middle, round, and in the cylindrical layer, rod-like, thus agreeing more or less accurately with the shape of the cell. The varying form of all of these cells is due in general to the degree of mechanical pressure to which they are subjected by the individual growth of each, and by other causes, such as atmospheric pressure. The cells composing this portion of the rete Malpighii do not lie in close contact with each other, but are held in apposition by protoplasmic prolongations from their surfaces, which are continuous with the protoplasm of the cell-body. They have been termed spines. It is due to this characteristic that the entire layer has been named the stratum spinosum.

The spines, which characterize these epithelial cells, were first observed by Schrön, and the function of binding the cells together has been attributed to them. The manner in which this occurs has, however, always been a subject of controversy. Max Schultze was of the opinion that they were arranged as in a pinion and ratchet ; Bizzozero, that their ends were united together ; and Ranvier, that their ends were fused together, forming a peculiar elastic organ which allowed considerable movement. These spines can be studied best in rapidly proliferating growths of the rete, as in condylomata acuminata ; but in the normal skin it is very difficult to form any opinion in regard to their natural arrangement. Whether the spines are active or passive in their nature is likewise a disputed point. Still, as Unna has pointed out, they are in all probability the result of active protoplasmic movement, since they are purely prolongations of the cell-body and consist of the same protoplasm.

Intercellular Spaces.—The arrangement of the spines springing from the surface of the cells of the rete is such that small spaces are left between them. These, the intercellular spaces of the stratum mucosum, are of great importance, inasmuch as they serve as channels for the passage of the nutrient fluids from the corium to the epithelium. The communication existing between the blood- and lymph-vessels and spaces and these intercellular spaces was clearly demonstrated by Nalepa, who succeeded in injecting them from the subepithelial blood-vessels. The wandering cells coming from the vessels of the cutis and seen in the rete are also enabled to wander along by means of these spaces, and they are the source of the pigment sometimes seen in these situations. When they break down they are taken up by the spiny cells.

Stratum Granulosum.—Situated above the stratum spinosum, but yet in close contact with it, is a layer of cells characterized by the possession of certain peculiarities. This layer consists of one or two rows of cells, seldom of more, upon whose surfaces shortened spines may still be seen, and they also contain granules of various sizes and shapes. It is owing to the presence of these that it has received the name of stratum granulosum. These granules react toward certain coloring substances in a marked manner, and stain very deeply. Unna, who has studied this layer very carefully, states that it makes its appearance in the epidermis toward the end of fœtal life, but that it can be seen much earlier in the inner root-sheath of the embryonic hair.

The stratum granulosum is present over the entire skin, except on the vermilion border of the lips and in the nail bed. The granules appear white by direct light, and for this reason Unna asserts that they are the cause of the white color of the Caucasian race. Such an explanation is, however, scarcely a reasonable one, owing to the fact that this same stratum granulosum is present in the skin of the negro as well as of the other dark races ; and besides, when it is found pathologically or even under natural conditions greatly increased in depth, it does not seem to cause the color of the portions where it is situated to be whiter than the remainder of the skin. The stratum granulosum is very marked in condylomata acuminata and on the palmar surface of the hands, and yet the former are far from being white in color, and the latter are not especially so.

The granules which are present in these cells have been the subject of so much discussion that they are worthy of extended consideration. They were observed long ago by Kölliker in the medulla of the hair, and by Aufhammer in the epidermis. Langerhans, however, was the first to describe them carefully, while Unna pointed out that they stood in intimate relationship to the process of cornification, and he claimed that they represented the intermediate steps which occurred in this process transforming the soft epithelial cells into horny tissue. Ranvier regarded them as drops of a fluid substance, which existed in a free state in the lowest layers of the stratum corneum, and to which he had given the name of eleidin. Waldeyer, however, has furnished the most satisfactory and correct information in regard to them. He proved that they could not be drops of fluid, because they swelled up on the addition of alkalies and also changed their shape on pressure, but not in the manner that fluids do. They were likewise insoluble in ether, alcohol, or water, and possessed a very great affinity for the nuclei-staining dyes, as hæmatoxylin, picrocarmin, etc. The supposition that they were fatty in character was also excluded by their want of reaction to osmic acid. Waldeyer found, on the other hand, that they agreed chemically very closely with the hyalin of Recklinghausen, a product of degeneration, and for this reason he suggested the name of keratohyalin for the substance.

Keratohyalin, according to Unna, is found to a small extent around the nucleus of the cells in the middle portion of the stratum spinosum, but it exists to a considerable extent only in the stratum granulosum. The granules here are small, and though the cells are filled with them, yet a small peripheral zone always remains free from encroachment. The cells in this layer have atrophied nuclei, which, however, still stain well, and the intercellular spaces are narrowed to such an extent as to be almost entirely absent.

The significance of keratohyalin and its relation to the process of cornification has received much attention. The general opinion at present is in favor of regarding these granules not as the cause of the cornification of the cells, but as a phenomenon accompanying that process, and as one which is produced by the act of cornification taking place in the periphery of the cells.

Stratum Corneum.—The layer of the epidermis lying above the stratum granulosum is the stratum corneum. It is the one which is most external and is in contact with the air. It varies greatly in thickness on different portions of the body, being, however, usually most marked on the palms of the hands and on the soles of the feet, and also being always much increased on any portion of the skin which is subjected to constant pressure. On these surfaces especially—that is, on the palms and the soles—it is noticeable that its lowest portion, that which is immediately next to the stratum granulosum, possesses great transparency. This stratum is narrow, sharply defined, and is known as the *stratum lucidum* of Oehl, but its existence has never been satisfactorily explained. The cells forming the stratum corneum are clear and transparent, showing neither granules nor nuclei. Unna claims to have found traces of the spines seen on the cells of the stratum spinosum even here, and asserts that the coherence of the cells forming the horny layer is due to their persistence.

By means of artificial digestion with pepsin and trypsin, it has also been found that the entire cell does not become cornified, but only the peripheral portions. After employment of this method it is clearly seen that it is the contents of the cells which are destroyed, while the peripheral portions remain and have the appearance of horny shells.

The reaction of the epidermis to certain staining materials allows furthermore a recognition of several layers constituting it, and shows successive changes not only in the cell substance, but also in the intercellular spaces. We owe to Unna the following table showing the reaction of the several layers of the epidermis to various dyes:

Layers of the Epidermis.		Consistence.	Osmic acid.		Picrocarmine.	Hæmatoxylin, alum, and acid.	Gentian violet (Gram-Weigert).	Safranin and [illegible] H. Hebra.
			Without removal of fatty matter.	After removal of fatty matter.				
A. Stratum Corneum.	1. Superficial.	Firm.	Black.	Clear.	Yellow.	Bluish white.	Blue.	Brown.
	2. Middle.	Looser texture.	Clear.	Dark brown.	Red.	Violet.		Clear.
	3. Suprabasal.	Firm.	Black.	Clear.	Dark red.	Bluish white.	Clear.	Light brown.
	In Basal, stratum lucidum of Oehl.	Very firm.			Yellow.		Blue.	Not constant.
			Clear.	Dark brown.				
B. Stratum Granulosum.		Soft.	Transparent.		Granules dark red.	Granules dark violet.		Brown.
C. Stratum Spinosum.	Rete Malpighii, stratum of Purkinje.		Greenish grey.		Nuclei colored red.	Nuclei colored blue.	Nuclei and [illegible] blue.	Light brown.

The several layers which have just been described as entering into the formation of the epidermis should be carefully considered in the study of the anatomy of the skin. It is from the epidermis that the appendages of the skin, the hair, the nails, and the glands originate and derive their most important parts. We shall refer to this again when describing these various constituent portions of the skin.

THE CORIUM, DERMA, OR CUTIS PROPRIA. *Embryology.*—The corium, or true skin, is that portion which lies between the epidermis and the subcutaneous or fatty layer. It is derived from a superficial portion of the mesoderm, consisting at first of only round cells. In the second month of fœtal life, however, spindle-shaped cells begin to appear, but only very little intercellular substance is present. Very shortly after this it is noticed that the cells in the upper portion of this primitive corium become more closely aggregated together than in the lower portion, and at the same time the formation of fibrillated tissue begins in this latter. The fibres increase greatly in number, and by the fourth month the presence of fat is detected. It is in this way that the subcutaneous or fatty layer is developed, and it is to be considered as, in reality, a part of the derma, since it has the same embryological source, and not as a separate and distinct layer of the skin. The transformations which take place among the closely aggregated cells in the upper portion are shown by the penetration of fibres between them and by the deposition of collagenous material. The individual cells are thereby more and more widely separated from each other, and the corium attains a considerable degree of thickness. Gradually blood-vessels and nerves pass into it, and upon its superficial surface the papillæ begin to form. These latter appear about the sixth month of fœtal life as small eminences upon the surface of the cutis. They are formed by the growth of the epidermis, which pushes before it the weaker and more yielding portions of the cutis. They are first seen on the palms of the hands and the soles of the feet, but are quite general toward the end of fœtal life. The development of the papillæ is not fully completed until after birth.

Histology of the Cutis.—The major part of the cutis consists of fibrous connective tissue, which is poor in cells and which is arranged in the form of bundles. The texture of the cutis is closely knit in that portion next to the epidermis, but is much looser in the parts below this. In this situation, the fibre-bundles crossing each other form the rhombic spaces, which have been mentioned as the cause of the linear cleavage of the skin. On account of the difference in the texture of the cutis, it has been divided into two layers: the one in immediate contact with the epidermis being termed the pars papillaris, that below it, the pars reticularis.

Pars Reticularis.—The pars reticularis of the corium is composed of bundles of fibres of various sizes and length. They are continuous with the connective tissue of the inner portions of the body—the fasciæ, etc.—and pass upward perpendicularly, or slightly inclined to the surface of the skin, until they arrive at the cutis. Here they run obliquely, crossing each other at various angles, and serve as boundaries for spaces, which are formed by their intersection. These spaces are, in general, rhomboidal in shape, but oftentimes polygonal, their regularity depending upon the length and uniformity of course of the fibre-bundles forming them. The length of the fibre-bundles and the absence of their firm adhesion to the underlying tissues is a very important factor. It is owing to such an arrangement that the skin is freely movable over the greater portion of the body. On the scalp, the palms of the hands, and the soles of the feet, where these bundles of fibres are short and intimately united to the underlying fascia, the skin is only very slightly movable. These places of intimate union, however, serve as fixed points from which the skin is stretched over the body. The movability of the skin is also limited on the circumscribed portions, where it is in immediate contact with bone, cartilage, or tendons, as over the tibia, etc.

The bundles so frequently mentioned are composed of fibres, which correspond in structure to those of fibrous connective tissue. Under normal conditions they are in a state of tension, and are for the most part straight, but under the microscope they are found presenting a wavy appearance. Chemical examination has shown that they consist, to a great extent, of collagenous material. The fibres themselves are bound together in bundles by an albuminous semifluid cementing substance, which Rollet has found to be similar to mucin. According to Fleming, this cementing substance exists not alone between the fibres, but also surrounds the bundles, and Tomsa claims that it binds together all the constituents of the cutis.

The fibres possess cells, but they are numerous only in the vicinity of the large blood-vessels. These cells are the usual connective-tissue cells; they are large and contain nuclei and nucleoli. They lie upon the bundles in the same manner as endothelial cells do in the situations where these are found, and for this reason have at times been considered as forming an endothelial lining for the rhombic spaces between the bundles. It has, however, been demonstrated that they differ from the cells of endothelium in that their edges do not lie in contact with each other, and they do not form a continuous covering for the bundles (Ranvier).

Elastic tissue. According to the latest investigations made in regard to the elastic fibres of the skin—a most thorough study of which has been made by Unna—they are exceedingly abundant in the reticular portion of the cutis. By the use of special methods of staining and of preparation, Unna found that, under the form of broad bundles, elastic fibres spring from the fascia below the skin, and, passing up between the fat masses, penetrate into the cutis. In their course they divide continually in a more or less forked manner. These bundles may be traced upward to just below the epidermis. The muscles of the cutis also serve as points of origin for bundles of elastic fibres, and Unna claims that they can be seen attached to the muscles at their points of origin and insertion, having a tendon-like appearance.

Another relatively fixed point of the elastic basework of the cutis is seen in an extensive net-work of fibres, which follows with the greatest regularity the outline of the epidermis, where this latter is in contact with the corium. This net-work, which Unna terms the subepithelial elastic net, is situated just below the surface of the cutis, being separated from the epidermis by a narrow homogeneous strip of the derma, in which there are very few blood-vessels. From this net-work fine fibres are given off, which proceed upward perpendicularly and are lost sight of here and there between two of the basic epithelial cells of the epidermis.

There is, also, in the papillary portion of the skin an extensive net-work of elastic fibres. It is formed by the repeated division of fibres which originate from the subepithelial net-work. All of these elastic fibres do not exist independently of the rest of the cutis, but are more or less closely connected with the fibre-bundles of connective tissue which have already been treated of.

The relationship of these elastic net-works to the appendages of the skin, such as the hairs and glands, has not yet been thoroughly studied. Still Unna claims that there is some special connection between them and the sweat ducts and glands. The elastic fibres are found to be entirely absent around the coils, but quite abundant about the ducts, along which they run in a parallel direction. He consequently is of the opinion that the contraction of the elastic net-work of the skin, acting with the fibre-bundles with which it is in close union, produces a pressure on the ducts, and shortens them by diminishing the thickness of the skin. In this way the passage of the secretion of the glands through the ducts to the outer surface is favored.

Unstriped muscle. With the exception of the palms of the hands and the soles of the feet, the skin of the entire body contains a more or less large number of unstriped muscular fibres and bundles. They are found to attain their highest development in the skin of the scrotum, in the penis, the nipple, and its areola. The vermicular movements of the scrotum are due to these involuntary muscles, as is also the erection of the nipple. They are situated in the cutis propria, and lie perpendicular to the plane of cleavage of the skin. On the penis they are arranged in a circular manner, and they follow a similar course in the nipple and in its areola.

Besides these, there are other muscles in the cutis which, owing to the connection existing between them and the hairs, are termed the arrectores pili. They are formed by the union of several small muscular bundles, which, originating in the pars papillaris, run an oblique course through the reticular portion of the cutis, and are attached to the hair-follicle. The point of their attachment is not uniform—sometimes to the middle portion of the hair-sheath, sometimes low down in the lower third. It will usually be observed that, in their course to their point of attachment, they curve around the sebaceous gland attached to the hair-follicle and are in quite intimate connection with it. According to Tomsa, the fixed point of the arrector muscles is the hair-follicle, while the point of movement is the pars papillaris of the cutis.

The arrangement of the involuntary muscular fibres in many places in the derma, as in the cutis of the forehead, cheeks, back, is in the form of a net-work. This net originates in the pars papillaris and is distributed throughout the upper two-thirds of the pars reticularis. By the action of these muscles the skin is kept more or less in a condition of tension. According to the direction in which they exert their action, the muscles have been divided into horizontal and oblique tensors. The elastic bundles and fibres connected with the muscles play here an important part, inasmuch as Tomsa has shown that they stand in the same relationship to them as do the tendons to the voluntary muscles, and serve as fixed points from which the contraction of the cutis tensors takes place. The action of these muscles also regulates to a great extent the circulation of the lymph in the cutis, while the contraction of the arrectores elevates the hair, compresses the sebaceous glands, and facilitates the propulsion of their secretion into the hair-follicle.

The Pars Papillaris Cutis.—The papillary portion of the true skin is constituted by a series of small eminumber of papillæ which spring from its upper or free surface. It is in direct contact with the epidermis, which, as has already been described, sends down prolongations of epithelial cells between the papillæ; but the line of demarcation between them is most distinct, owing to the difference between the elements composing each.

The papillæ of the skin are found most fully developed on the palms of the hands and on the soles of the feet. They are arranged here in long double rows, which form the curvilinear ridges seen in these situations. Between these rows there is a narrow path in which are the external orifices of the sweat-ducts. On other portions of the body the papillæ are arranged more or less in groups or in short rows, and the surface of the cutis seems to be divided into rhomboidal spaces of various sizes by the deeper penetration of the interpapillary prolongations of the epidermis. The long diameters of these spaces agree with the lines of cleavage of the skin where they are situated, and their shape is dependent upon the arrangement of the connective-tissue bundles in the reticular portion of the cutis.

The papillæ are more or less conical in shape, sometimes simple, or again cleft into two or more points, forming a compound papilla. They differ greatly in shape, size, and distribution on the various portions of the body, and also vary according to the age of the person (Unna), becoming in old age almost flat. They are very numerous on the penis, the nipple, the labia minora, and the clitoris, appearing in these places as low hills. The largest papillæ are found in the cutis of the nipple and of the corona glandis. Those distributed generally over the surface of the body are very small, about 0.05 mm. in height. On the ends of the fingers, under the free borders of the nail, they attain a size of 0.5 mm.; but their height varies in general between 0.05 mm. and 0.2 mm.

The papillary portion of the cutis consists of a closely woven network of fibres, which are derived directly from those forming the pars reticularis. The papillæ are very rich in elastic fibres, and contain blood-vessels, lymphatics, nerves, and, in certain situations, tactile corpuscles. The manner in which the papillary body and the epidermis are joined together, must be studied on specimens which have been macerated, and from which the epidermis has been removed *in toto*. When this has been done it is seen that the entire surface of a papilla has a finely ribbed aspect. On sections made horizontally through them, they look as though their contour was toothed. The ribs have a slightly wavy course and are at times arranged in a concentric manner, having much the same appearance as may be observed on the palmar surfaces of the ends of the fingers. These ribs on the papillæ have been found to correspond to minute furrows on the cells forming the basal or cylindrical epithelial layer of the epidermis, and to fit into them, each cell requiring usually three or four ribs. From the fibrillated appearance it might be thought that these ribs were connective-tissue fibres, but such has not been found to be the case. They consist in reality of a transparent homogeneous substance, which covers thinly the surface of the papillæ. The proof that it is a distinct membrane has never been satisfactorily made, and it seems better to accept Unna's view, that it stands in intimate connection with the cementing substance of the cutis in general, since it has been found that when the cutis is subjected to the action of trypsin, this homogeneous substance covering the papillæ disappears in the same way as the cementing substance in other portions of the derma. The blood-vessels, etc., in the papillæ will be treated of in their appropriate place.

THE SUBCUTANEOUS CONNECTIVE TISSUE OR FATTY LAYER.—It was mentioned, in speaking of the embryological origin of the skin as a whole, that the subcutaneous or fatty tissue was derived from the mesoderm. It is that portion which attains its full development the earliest of all the layers of the skin, and in which the deposition of fat between the fibres constituting it takes place very early in fœtal life. The subcutaneous connective tissue, or panniculus adiposus, though in reality the lower portion of the corium, is regarded as forming the third layer of the skin, and it is characterized by the presence of a greater or less amount of fat deposited within its meshes.

It is composed of bundles of connective-tissue fibres, a network of elastic fibres, and fat, and is very rich in large cells. These have long poles and are situated either in or between the fibre-bundles, occurring in the form of spindle-shaped cells. According to Flemming, the masses of fat can be divided into three classes, each of which is characterized by its blood-supply: the fat-clusters with their own blood-vessels; the strands of fat which lie around the large vessels and receive only a meagre supply of blood from capillaries; and the fat-islands which have no blood-supply of their own. We have to thank the same investigator for our knowledge of the histology of fatty tissue. He found that the fat-cells were derived from ordinary branching connective-tissue cells. They took up fat in small drops, and in proportion as the fat increased in quantity the protoplasm of the cells also increased, and they became round in shape. The protoplasm containing the nucleus is forced to the periphery by the accumulation of fat, and appears as a membrane; but these fat-cells have no true enclosing membranes, except when they are old, and when the protoplasm has become thickened into a membrane-like covering. The contents of the cells do not consist of pure fat, but of a mixture of fat and of some product from the protoplasm. At the time of birth the panniculus adiposus is very greatly and uniformly developed over the entire body. As the child grows, however, it diminishes in quantity and remains of considerable extent only on certain portions. Its function is protection to the underlying tissues, and it serves to give roundness to the outline of the body. Those portions of the body which are firmly bound down to the fascia by short bundles of fibres, as the scalp, the skin of the palms and of the soles, etc., possess only a small fatty layer. Where great mobility is necessary, as in the eyelids, or where there is a great amount of muscular tissue, as in the scrotum, the panniculus adiposus is also absent. Over the joints, where the skin lies in close contact with the bones and by their movements is continually subjected to pressure and tension, bursæ develop in the subcutaneous tissue after birth. In this layer the large arterial and nerve trunks going to the cutis are found, and also the veins and lymphatics which come from the derma and unite to form large efferent branches. In certain localities the Pacinian bodies are also present.

THE GLANDS OF THE SKIN.—There are two sets of glands which are found in the skin, the sweat glands and the sebaceous glands. They differ from each other to a most marked degree, and if considered from the stand-point of their relative importance the former claim priority and more extended study. We shall, therefore, begin with the sweat glands.

THE SWEAT GLANDS. *Embryology.*—The primary evidences of the development of these glands of the skin are seen in the fifth month of fœtal life. They appear first on the palms and on the soles under the form of rows of epithelial prolongations from the inferior border of the epidermis into the cutis. At this stage they are solid, club-shaped, and surrounded by a homogeneous membrane. Their further development consists in the elongation of these epithelial ingrowths downward, and in the formation, by the seventh month, of a cavity along its axis, which is later further extended through the epidermis to the external surface. In the meantime the gland tube at the end in the cutis has become coiled up, forming a ball, and the excretory duct in its course through the skin is twisted upon itself. The development of these glands is very rapid, and by the end of fœtal life they have already attained their full development. In certain situations, however, they enlarge even after birth, and in their structure differ somewhat from the ordinary and smaller ones distributed generally over the body. These larger glands are found in the axillæ, the inguinal regions, around the anus, the nipple, and in the auditory canal (ceruminous glands).

The sweat-glands are present everywhere in the integument of the body, with the exception of the glans penis, the under-surface of the prepuce, and the vermilion border of the lip. They are small bodies, consisting of a convoluted tube and an efferent duct which leads to the external surface, and they are situated in the corium or even in the subcutaneous connective tissue. They vary greatly in size. The coils of the large ones situated in the axilla are from 1 mm. to 2 mm. in diameter; the smaller ones on the general surface are from 0.2 mm. to 0.3 mm. They are most numerous on the palms of the hands, Krause estimating that there were 2,800 orifices in a square inch on those surfaces.

The sweat-glands, as a whole, are composed of two distinct portions, a secretory and an excretory. The former is represented by the coils, the latter by the duct which leads to the external surface of the skin. The histological anatomy of the smaller glands differs somewhat from that of the larger ones, and will be considered first.

Histological Anatomy.—The coils, or secretory portions of the sweat-glands, consist of a single layer of columnar epithelium, arranged around a rather irregularly shaped lumen. The cells are cloudy throughout, with the exception of a narrow portion along their free margin, which is clear. They are bounded externally by a layer of involuntary muscular fibres, which run spirally around the mass of cells, and which are so arranged that small spaces are left between them. The secreting-cells send out processes into those spaces, and these form a union with the limiting membrane or membrana propria of the glands, which is composed of connective tissue. The excretory portion of the gland, or duct, consists of a connective-tissue coat, a structureless membrane, and bounding its lumen are two rows of epithelial cells, the free margins of which are covered by a cuticula. There are no muscle-fibres in the coats of the sweat-ducts. These latter begin in the inner portion of the coils, and rise to the surface in an oblique direction having a more or less spiral course, and they always reach the epidermis at an interpapillary prolongation. The duct here loses its membrana externa, which goes over into the tissue of the papilla, and also its cuticula, so that the lumen is bounded for a short distance in the stratum spinosum by the spiny cells alone. The cells which limit the lumen in its course through the epidermis, show granules of keratohyalin very early, and considerably below the level of the stratum granulosum; and it can further be seen that all the layers of the epidermis become interested and aid in forming the boundaries of this spiral canal in its course to the external surface. The views which are held by Unna, in regard to this portion of the duct, have so much in their favor as to claim general recognition. He does not consider that the spiral portion in the epidermis belongs entirely and alone to the duct of the sweat-gland, of which it seems to be a continuation, but thinks that it is a canal which is also in connection with the system which conveys the juices throughout the epidermis. According to him, the sweat-duct ends in the basic layer of the stratum spinosum, and he would, consequently, separate the two portions very sharply. He very rightly points out in support of this, that we have no reason for concluding that the fluid which passes through it comes entirely from the same source, inasmuch as there are no grounds for asserting that the sweat is derived from the coils alone. All that we do know is, that it appears upon the external surface at the openings of these canals, but more than that has not been proved.

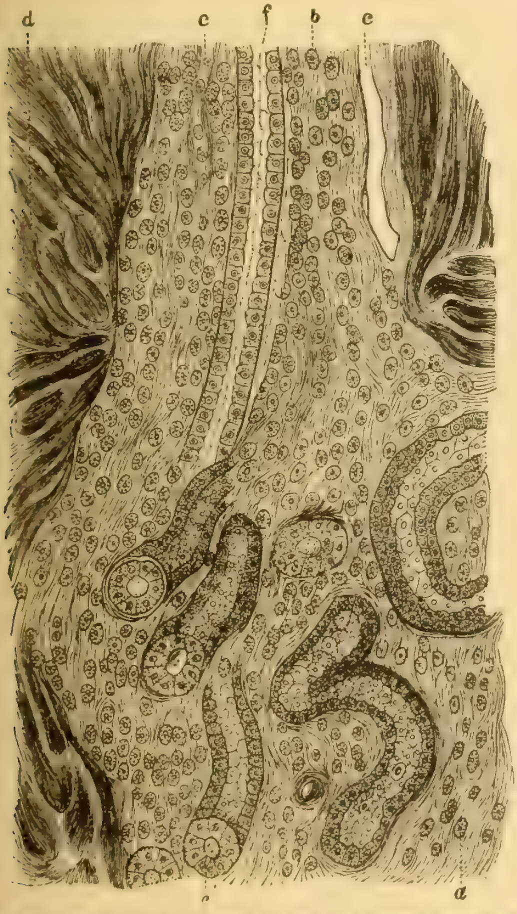

FIG. 5038.—Sweat Gland and Duct, as seen in a Section Perpendicular to the Cutis. *e*, Cross-section of a coil; *f*, lumen of duct; *c*, *c*, blood-vessel accompanying the duct; *d*, connective-tissue bundles; *a*, *b*, cellular infiltration of the cutis (pathological). (Kaposi.)

The histological anatomy of the larger sweat-glands, as has been already mentioned, differs somewhat from that of those just described. The differences are shown both in the coils and in the duct, by a dilatation and a narrowing of the canal in places. Where the lumen is larger there is only a single layer of epithelial cells; but in the narrower portions there are several. It is also claimed that muscle-fibres are present in the former situations, but they are always absent from the latter.

THE SEBACEOUS GLANDS. *Embryology.*—The sebaceous glands of the skin make their appearance from the beginning of the fourth to the fifth month of pregnancy (Gegenbauer). Those glands, which open directly upon the external surface of the skin, are formed from ingrowths of the rete Malpighii, which penetrate into the cutis. These epithelial prolongations are at first solid, but a canal soon forms in them by the fatty degeneration of the central cells. In its further development it is found that, by a process of cell proliferation, solid buds are given off from the original epithelial ingrowths, canals form in the axes of these, and the gland, finally consisting of several lobules, has become racemose. The origin of the sebaceous glands attached to the hairs is the same, except that the epithelial ingrowths proceed from the external root-sheath of the hair. They appear very soon after the formation of the hair-follicle by the prolongation of the rete into the cutis.

Distribution and Size.—The sebaceous glands are distributed very generally over the body, and are found everywhere in the skin, except upon the palms of the hands, the soles of the feet, and the last phalanges of the fingers and of the toes. They are particularly numerous upon the face and the scalp, where they are set very closely together. On the rest of the body they are found to be fewer in number and more widely separated. The glands vary very greatly in size. Of those connected with the hairs, the smallest are the ones on the scalp, 0.1 mm. to 0.16 mm. in diameter, but larger ones are attached to the hairs of the beard and axilla, from 0.16 mm. to 0.24 mm.; but the largest are on the mons veneris, the labia majora, and the scrotum. The sebaceous glands which are in connection with the lanugo hairs are from

0.25 mm. to 1 mm. in diameter. The length of the glands is from [illegible], but the large ones on the nose measure even as much as 1 mm.

In shape there is also considerable variation. The simplest ones resemble small pouches, but the glands are usually found to be racemose or acinous, that is, composed of several lobules which possess one duct in common.

These glandular bodies are situated for the most part in the upper portion of the corium above the level of the coils of the sweat glands. Some extend, however, through almost the entire thickness of the cutis.

They are found either directly attached to the hair-follicles, into which their ducts open at a variable distance from the orifice on the cutaneous surface and empty the fatty matter secreted by them, or the external opening of their ducts is situated on the surface of the skin. These latter are the glands with which the lanugo hairs are associated. Besides these two forms there are others which are entirely unconnected with hairs and which also open directly upon the outer surface of the skin.

The sebaceous glands which open into the cavity of the hair-follicles are the most numerous. They are seen wherever fully developed hairs exist, as on the scalp, the beard, etc. There is sometimes only one gland, but more often two, situated on opposite sides of the follicles, of different sizes, and at different heights. Their excretory ducts are short and pass obliquely upward to enter the follicles, the larger glands opening more superficially, the smaller ones more deeply, but the common location is at the junction of the upper and middle thirds.

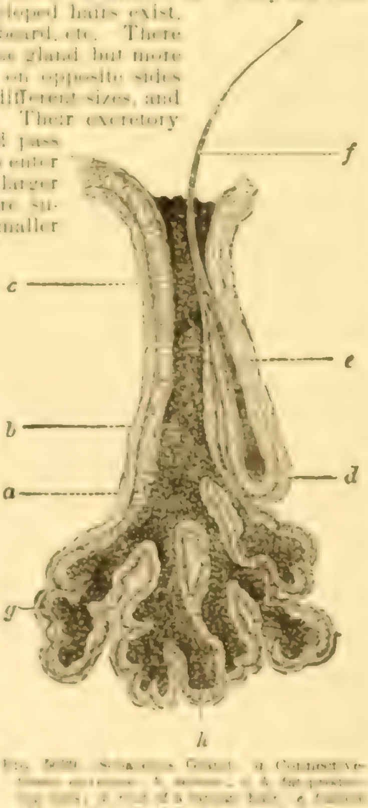

Fig. [illegible].—Sebaceous Gland. a, Connective-tissue envelope; [illegible] hair; f, shaft of hair; g, [illegible] of the gland. ([illegible].)

The sebaceous glands which are associated with the lanugo hairs and which open directly upon the external surface are distributed over the forehead, cheeks, sides of the nose, and alæ especially. They occur also more or less scattered over the trunk, the extremities, and the genitals. These glands are the largest and also the most complicated in their structure. The duct is usually broad and its orifice dilated. The hair attached to it is really an appendage and passes through the duct to reach the outer surface of the skin. It has no follicle of its own, except at its deepest portion.

The glands which are in no way associated with hairs, and which open directly upon the external surface, are rather seen situated in special localities. They have received distinguishing names, and are known as the Meibomian glands in the eyelids, and the glands of Tyson on the glans penis and prepuce. To this class also belong the large glands of the labia minora, and those of the vermilion border of the lip.

Histological Anatomy.—A sebaceous gland may be considered as composed of an outer wall and an inner mass of cells. The wall is formed of connective tissue, which is derived from the external sheath of the hair-follicles; but in those glands associated with the rudimentary or lanugo hairs, and in those unconnected in any way with hairs, the fibrous envelope is obtained from the corium. The wall acts as a support [illegible] for a basement or membrana propria, which bears upon its inner surface a layer of cylindrical epithelial cells, and it also contains the nerves, blood-vessels, and lymphatics supplied to the glands. The membrana propria is exceedingly thin and amorphous. The single row of cells which are in connection with it is a continuation of the basic layer of the epidermis, the spiny cells stopping at the neck of the glands. The cavity of the glands is filled with large oval and polyhedral cells having large nuclei, but in the central portions there is a semifluid homogeneous mass, the sebum. The source of the sebum seen in the sebaceous glands are the cells, which are found presenting all stages of fatty degeneration. The most external ones are granular, the succeeding ones contain small drops of fat, which gradually increase in size as the central portion of the cavity is reached, until there is no trace of protoplasm remaining, the cell being completely filled with fat.

THE BLOOD-VESSELS OF THE SKIN.—The vessels which supply the skin with blood are branches from the larger arteries which lie below the subcutaneous fatty tissue. They pass up through this latter and form at its junction with the corium a more or less horizontal net-work. From this net-work further branches are given off, some to supply certain portions of the skin, others to ascend obliquely and perpendicularly through the cutis, having only few branches, until they reach the subpapillary layer of the corium. Here they again form a more or less horizontal net-work, which also gives off many branches.

The plexus of arteries at the junction of the cutis and subcutaneous tissue is very rich. It supplies the papillæ of the hair, the coils of the sweat glands, and also sends off branches which break up into capillaries in the panniculus adiposus. The subpapillary net-work of arteries supplies vessels to the external root-sheath of the hair, the sebaceous glands, the unstriped muscles, and the ducts of the sweat-glands. In addition, this plexus gives off branches which break up into capillaries just below the papillæ, and into each of these a tortuous arterial capillary ascends almost to its upper end, where it forms a loop and goes over into a venous capillary. These latter unite to form venules in the same plane as the arteries, and course along them. When they arrive at the subcutaneous layer they, together with the veins from the other portions of the cutis, unite to form large venous trunks in the same plane as the large arteries. Between the two horizontal plexuses of arteries there is a portion of the cutis which has a very poor blood supply, and here even the bundles of fibres which go to form the pars reticularis do not receive any vessels.

There are considerable differences in the distribution of the blood-vessels of the skin, and the area supplied by any one branch. These areas are very small on the palms of the hands, the soles of the feet, and the face, also at the sulcus coronarius and the corona glandis; in which places each branch from the subpapillary arterial plexus, when it breaks up into capillaries, supplies only a few papillæ. The areas which are furnished with blood by one arterial branch are much larger in the greatest part of the skin—the vessels breaking up into a number of capillaries—and it is in general observed that they are more extensive on the extensor than on the flexor surfaces of the extremities.

Peculiar circulatory conditions are found in certain portions of the skin. On the ear, the alæ nasi, and in the region of the lips, large lacunæ are seen into which the venous capillaries empty from above, while from below the venules are given off. On the ends of the fingers there is likewise a special arrangement of the vessels. It has been found that here some branches of the digital arteries empty directly into the large veins of the bed of the nails, without there being any intervening capillaries. And also it is observed that, after the vessels for the panniculus adiposus and sweat-glands had been given off, but before the upper horizontal plexus for the supply of the papillæ had been formed, small arterial branches divided and broke up into many small coils. In the inner portion of these they emptied directly into venules.

The lumen of the arteries of the skin is narrow, but the veins are large and wide. Their coats are slightly marked in the cutis, and they show only near the subcutaneous connective tissue an adventitia and a media. But even there these are poorly developed. All the vessels of the papillary layer of the corium are capillary in character, that is, simple endothelial tubes.

THE LYMPHATICS.—There are in the integument of the body two forms of channels which contain the lymphatic fluid, and through which it flows, viz., the lymphatic vessels proper, those which possess an endothelial lining, and the numerous spaces which occur between the elements composing the various layers of the skin.

In regard to the latter, it has been proved that they are the origin of the lymphatic system of the skin, through the successful injection of the intercellular spaces in the spiny layer of the rete Malpighii from the lymphatics of the subcutaneous connective tissue (Retzius, Axel Key, et alii). Other lymph-spaces exist between the membrana propria and the secreting cells of the coils of the sweat-glands, and between the epithelial cells of the sweat-ducts. The intercellular spaces in the stratum spinosum of the hair-follicles and in the sebaceous glands are also points of origin for the lymphatics. The bundles of unstriped muscle-fibres and the coils of the sweat-glands also are situated in large lymph-spaces. In the same way, the bundles of connective-tissue fibres forming the cutis are sheathed by lymph-spaces, as are also the fat-clusters. According to Klein, very fine channels proceeding from these lymph sheaths penetrate into the latter and ramify between all the fat-cells of which they are composed.

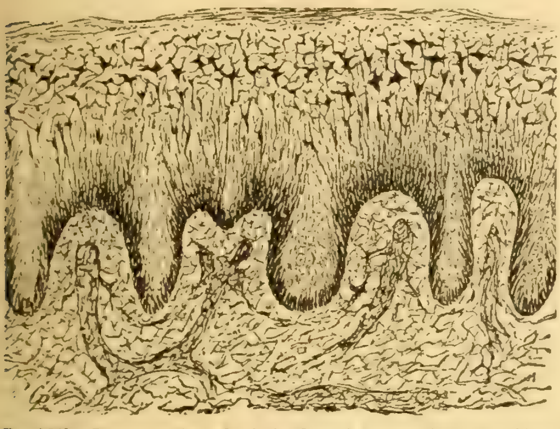

FIG. 5040.—Demonstration of all the Lymph-spaces of the Papillary Body and of the Epidermis. (Ziemssen.)

The papillæ are also extensively traversed by lymph-spaces, which empty into the lymphatic vessels proper. These vessels are lined with endothelium, and begin in the upper third of the papilla (the Hoggans) by means of a cul-de-sac. They course downward in the form of a plexus through the cutis, and at its junction with the subcutaneous connective tissue unite to form a few large vessels, which, according to Heming, have a muscular coat.

THE NERVES OF THE SKIN.—The nerves which are supplied to the skin are derived from branches of the cerebro-spinal system. They pass up through the subcutaneous connective tissue, in the same manner as the blood-vessels, from the larger trunks situated below. In the upper part of the panniculus adiposus the course of the nerves is a horizontal one, and they give off a large number of small branches for its innervation. They penetrate the cutis together with the arterial vessels, and accompany them more or less in their distribution. In their course they give off branches to supply the various constituent portions of the cutis. Those which supply the hair-follicles pass to them in the neighborhood of the sebaceous glands, to which they send fibres. They penetrate the hair-sheath and are distributed between the cells of the root sheaths. The sweat-glands and their ducts are also furnished with nerves which lie in close contact with the latter. Unna claims to have seen nerve-endings between the secretory epithelial cells of the coils.

When the nerves arrive at the upper portion of the cutis they take a horizontal course and form a rich plexus just below the epidermis, which gives off a great number of branches. These break up into fine fibrillæ, and are distributed in every direction. These fibrillæ terminate either in the endothelium of the papillary blood-vessels, or free in the connective tissue of the papillary body, or penetrate into the interepithelial spaces of the stratum spinosum. Longer branches from this plexus ascend into the papillæ, and in certain portions of the integument end in the tactile corpuscles.

The nerve-fibres which, it is claimed, have been traced between the cells of the epidermis are non-medullated. They are said to be distributed generally throughout the rete Malpighii, as far up as the stratum granulosum, and to end in the intercellular spaces, either tapering to a point or with a small rounded extremity. Unna claimed that they terminated in small disks upon the cells, but his view has not received recognition.

Besides the above-mentioned ways in which the nerves end in the skin, there are special forms of termination. These are represented by the tactile corpuscles, the tactile disks of Ranvier, the Pacinian bodies, and the end bulbs of Krause.

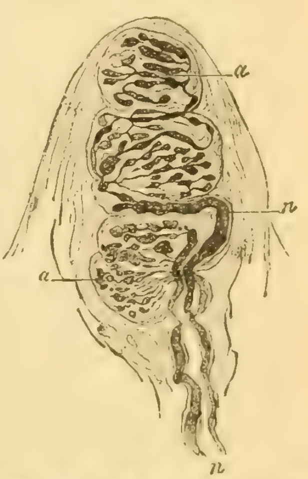

FIG. 5041.—Tactile Corpuscle. *a*, *a*, Glomeruli; *n*, *n*, afferent nerve-fibres. (Ranvier.)

Tactile Corpuscles.—The tactile corpuscles are very small, oblong bodies from 40 to 200 μ in length, and from 30 to 60 μ in breadth. They are situated in the upper portion of a broad papilla, and are found especially on the fingers and toes, and in the palm. They have a distinctly striated appearance, and are directly connected with one or two medullated nerve-fibres which wind around the corpuscle, and, on entering it, lose their medullary sheath, the perineurium becoming continuous with the capsule of the corpuscle. The nerves split up into branches, which end in flattened knobs between the connective-tissue cells of which the corpuscle is composed. They often consist of two or three sections lying close together, each one being supplied with a nerve.

Ranvier's Tactile Disks.—These disks are small cup-shaped bodies, the concave side of which is always directed toward the free surface of the epidermis. At several points on the convexity of the disk the termination of a non-medullated nerve-fibre is seen. Ranvier claims that this nerve ends only on the surface of these disks, but according to others this takes place in the cell between the nucleus and the external membrane. This form of nerve-ending has been found in the deeper portions of the epidermis, near the sweat-duct, and in the corium just below the rete.

The Pacinian Bodies.—The Pacinian bodies were first thoroughly described by Pacinius, though they had already been mentioned by Vater over a hundred years ago. They are small, oval, transparent bodies from 2 to 4 mm. long and 1 to 2 mm. broad, and are situated in the subcutaneous connective tissue, almost exclusively upon the branches of the nerves which supply the skin of the palms of the hands and of the soles of the feet, but also upon the dorsal nerves of the penis and of the clitoris. They are likewise found in other places, as around the joints, where they are deeply situated, and also in the mesentery, etc. The major part of the Pacinian body is formed by the capsule. This capsule is derived from the perineurium of the nerve which ends in the corpuscle and is in reality composed of a large number of concentrically arranged lamellæ, which are separated one from the other by a layer of flat endothelial cells. Between each of these there is a more or less large quantity of an albuminous fluid, and connective-tissue fibres forming septa are also seen. This laminated and concentrically arranged capsule surrounds a narrow cylindrical space, which contains a granular substance in which a few cells are seen, and the termination of the nerve fibre. At its entrance into the cavity of the Pacinian body, the nerve loses its medullated character and the axis cylinder alone passes in. It appears as a pale, finely granular, narrow band, which ends in a single small knob or in a series of them. The nerve has also been observed to pass entirely through one of these bodies and end in another. A small artery penetrates the capsule of the Pacinian bodies along with the nerve and forms a capillary plexus between the peripheral lamellæ.

End-bulbs of Krause.—The end-bulbs of Krause are minute oval or cylindrical bodies, which are regarded as being more or less related to the tactile corpuscles. They consist of a connective-tissue capsule containing a large number of cells which form a core. Between these, one or more nerve fibres end. They are found in the conjunctiva and the mucous membranes of the mouth, the glans penis, clitoris, and vagina, where they are termed genital corpuscles. The capsule of these end-bulbs is derived from the perineurium, but the nature of the core which it contains is still a mooted point. The axis cylinder alone penetrates into this core, having lost its medulla, and it ends in the upper portions either free, or as a small button-like protuberance.

THE APPENDAGES OF THE SKIN. THE NAILS.—*Embryology.*—The first steps in the development of the appendages of the skin, which are called the nails, and which are found on the last phalanges of the fingers and of the toes, occur in the third month of fœtal life and consist in the marking out of the nail bed and furrow. This is covered by the ordinary stratum corneum of that period of life, and it represents the eponychium of Unna; underneath the eponychium the embryonic nail remains up to the fifth month. According to Kölliker, there appears in the fourth month, between the eponychium and the stratum mucosum, a layer of large, pale-colored, horny plates, which cover the bed of the nail and represent its primary form. The nail in its further growth increases in thickness quite rapidly, possesses a free border in the sixth month, and by the seventh month is fully formed. Kölliker also claims that the development of the nail takes place from the entire nail bed, but Unna insists that he has observed the formation of a germinal spot in the matrix, from which the embryonic nail grows and pushes itself forward beneath the eponychium.

General Characteristics.—The nails of human beings are elastic structures of a horny texture which occupy the dorsum of the last phalanges of the fingers and of the toes. Each one is convex upon its external surface, concave upon its internal, and moulded upon the cutis to which it is firmly adherent. The exposed portion of the nail is called its body, the anterior extremity, the free edge; the semilunar portion posteriorly, which is of a white opaque color, the lunula. The portion of the cutis upon which the nail is situated is the nail-bed. It is bounded laterally by two folds of the skin, which are known as the walls of the nail. Around the nail-bed is a groove which is covered by the nail wall, and in this lie the lateral edges of the nail, while the posterior portion, the nail-root, is implanted in a similar though much deeper groove; this latter represents the matrix, and it is from here that the growth of the nail takes place.

Histological Anatomy.—The bed of the nail consists of the corium and the stratum mucosum. The connective-tissue bundles of the cutis run here partly longitudinally and parallel to the axis of the fingers, partly in a perpendicular direction from the periosteum to the external surface. The epithelium covering the corium is composed of cells identical with those in the stratum mucosum of the epidermis, and is sharply defined from the nail, except at the matrix.

The corium at the matrix of the nail shows a well-developed papillary body, and is very vascular, each papilla receiving a blood-vessel. In front of this and beneath the lunula the papillæ are very small, and still more so anteriorly; the cutis forming the nail-bed has no papillæ but fine longitudinal ridges in which run the blood-vessels, which give off capillary branches at regular intervals. These ridges of the corium are covered by the epithelial cells of the stratum mucosum, which also dips down between them.

The nail itself consists of horny lamellæ, which are closely bound together, and which are composed of cells similar to those of the epidermis, except that they contain nuclei.

In the formation of the nail the matrix plays the important part, and it is from this portion that regeneration of the nail is continually going on.

THE HAIRS. *Embryology.*—The hairs show the first steps in their development at the end of the third or the beginning of the fourth month of fœtal life. These are manifested by the formation of small, solid prolongations of the rete Malpighii, which penetrate into the cutis and which are increased in length by the proliferation of the cells composing them. Arriving in the deeper portions of the cutis, the lower end of the prolongations is very soon surrounded by an aggregation of round and spindle cells, which partly form the papilla of the hair and partly grow around the epithelial ingrowth in order to form the sheath of the hair follicle (Unna). During this time changes also take place in the epithelial column. In its inner portion a conical-shaped mass of cells, with its apex directed externally, becomes differentiated from the remainder, and this represents the primitive hair-body. From it the hair and its inner root-sheath are formed. The primitive hair-body having grown around the newly formed papilla, it increases in length upward, and keratinization begins and proceeds from above downward. The external root-sheath is constituted by the portions of the epithelial ingrowth of the rete Malpighii which remain after the differentiation of the primitive hair-body and then surround the entire hair.

From the sixth to the eighth month of life the fœtus has become covered with hair, which, however, falls out and is replaced by new hair. This regeneration of the hair on the fœtus is continuous as in adults, but the rapidity of the change ceases a few weeks after birth. The embryonic or lanugo hairs, which have a much shorter length of life than those which grow after birth, give place to more permanent ones, and on certain portions of the body acquire a much greater development than they do on others. The new hairs originate from the epithelium forming the external root-sheath of the lanugo hairs, which sends out solid buds from which the hair develops in exactly the same way as has just been described, and grows up alongside of the embryonic hair to the external opening of the follicle. The old hair has, in the meantime, been separated from the papilla and become completely horny, owing to its loss of nourishment, and being pushed upward by the new-formed hair falls out when the external surface is reached. In this way the temporary hairs are replaced by the permanent ones, and an entirely similar procedure is furthermore constantly seen repeating itself, even in adults.

General Characteristics.—The hairs, which are modifications of the epidermis, are found in greater or less amount over the entire body, with the exception of the palms of the hands, the soles of the feet, the vermilion border of the lips, the glans penis, the labia minora, and inner surface of the labia majora. Over the majority of the surface they are short, rather colorless, having the character of the embryonic hairs, and hence are termed the lanugo hairs; but on the head, the eyebrows and the eyelids, in the axillæ, on the pubes, and in the male sex on the cheek and upper lip, they attain a much higher grade of development.

The hairs which are present upon the scalp, eyebrows, and eyelids become gradually more marked, thicker, and longer after birth, but at the age of puberty the hairs on the pubes and in the axilla, and the beard in the male, begin to develop and to increase rapidly. Hair also is found around the anus in the male. It is not unusual to see, in certain races, that in women, as they approach and pass the climacteric, a stronger growth of hair appears on the upper lip and face.

The hairs, both the lanugo and the fully developed ones, are for the most part placed obliquely in the skin and are situated in follicles termed the hair-follicles. These latter are sometimes short, the papilla lying high up, or, again, of considerable length, and deep down in the subcutaneous connective tissue. The portion of the hair situated in the follicle is the root, that above the level of the skin, the shaft. At the lower extremity of the root there is a whitish, soft, bulbous enlargement, the hair-bulb, which has a concave end that fits upon the conical vascular eminence already mentioned as being the hair-papilla.

The hair-follicle itself may be divided into three parts, according to its form. From its upper extremity, where it opens out upon the surface of the skin, it descends, shaped like a funnel, as far down as the opening of the duct of the sebaceous gland. It then becomes narrowed for a short distance, but broadens again near the papilla to receive the hair-bulb.

The hair-shaft varies considerably in shape, being in some cases round, in others much flattened, or again angular.

On cross-section the hairs are either round, or oval, or triangular, or square, having convex or concave sides. The angular and flattened hairs are found in those localities where the hair is curly, the round ones where it is smooth.

At its free external end the hair is pointed when in its natural state, but owing to the fact that it is continually subjected to mechanical influences, such as rubbing, etc., it is usually found to have a more or less rounded extremity.

Histology of the Hair and of its Follicle.—Hair-follicle. The hair-follicle is represented by a sac-shaped cavity composed of connective tissue. At its lower end, which is more or less deeply situated in the cutis, an eminence is seen, analogous to the papillæ in the upper portion of the corium, which is known as the hair-papilla. This body, upon which the concave extremity of the hair-root is accurately fitted, is oval in shape, and at its base is a distinctly marked constriction—the neck of the papilla. It is composed of connective tissue, similar to that of the cutis, of which it is a part, and contains blood-vessels.

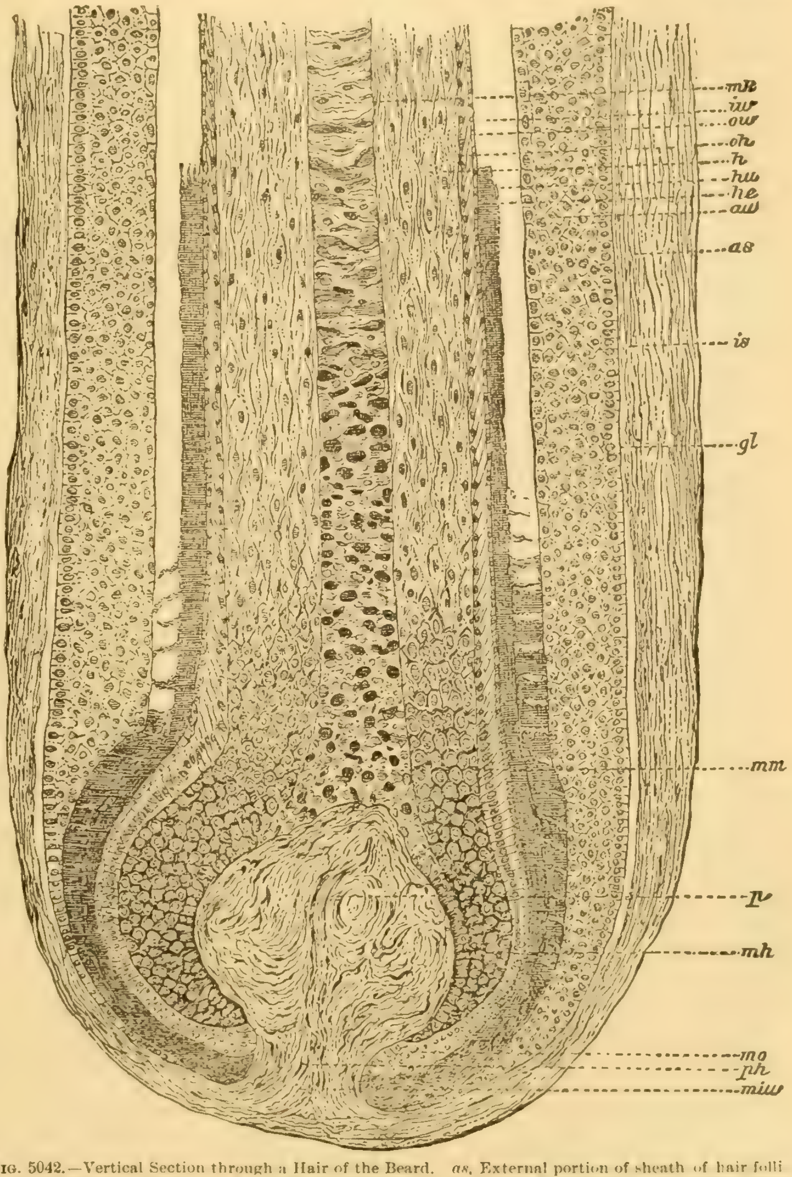

FIG. 5042.—Vertical Section through a Hair of the Beard. *as*, External portion of sheath of hair follicle; *is*, internal portion; *gl*, homogeneous membrane; *aw*, external root sheath; *iw*, internal root sheath; *he*, Henle's layer; *hu*, Huxley's layer; *ow*, cuticula of root sheath, *oh*, cuticula of hair; *h*, cortex of hair; *mk*, medulla; *p*, papilla; *miw*, *mo*, *mh*, *mm*, matrices of *iw*, *ow* and *oh*, *h*, and *mk*; *ph*, neck of papilla. (Ziemssen.)

The hair-follicle envelops the lower two-thirds of the hair and of its sheaths, but above the openings of the ducts of the sebaceous follicles it is not demonstrable as a separate formation, becoming lost in the tissue composing the papillary body. It consists of three coats. The most external of these is a portion of the cutis proper, and is composed of connective-tissue fibres, which are closely bound together, and run longitudinally in the axis of the hair, and is quite rich in connective-tissue cells. In it are distributed the blood-vessels and nerves supplied to the hair. The next innermost coat is composed of similar elements as are found in the most external, but they are arranged, however, in a circular manner running around the hair follicle. There are many nuclei found in this coat, the long axes of which are directed parallel with the course of the fibres, and they resemble very strongly the nuclei seen in unstriped muscles; but this resemblance is in all probability due to the tension to which the fibres are subjected.

The innermost of the coats of the hair follicle is a hyaline basement membrane, which has a glassy, transparent appearance. It is in immediate contact with the cylindrical layer of epithelial cells belonging to the external root-sheath of the hair. It is not always demonstrable, varying greatly in thickness, and is most clearly marked in the lower third of strongly developed hairs. In the lanugo hairs the connective-tissue envelope of the hair is absent, the root-sheaths being derived from the epidermis forming the hair follicle.

The Hair-sheaths.—The root of the hair proper is in the greater portion of its extent covered by an envelope, which consists of several layers of cells very adherent to it. It constitutes the inner root-sheath of the hair, and lies in contact with the external root-sheath, by which it is separated from the connective-tissue envelope of the hair follicle.

The Hair Proper.—When a fully developed hair is examined under the microscope, it can be seen that it is composed of three tissues, which differ from each other in appearance. These three portions are termed the cuticula, the cortex, and the medulla. Each of these can be easily recognized in the shaft of the hair, but not so readily at the bulb. Still, if the hair is treated with picrocarmin, the cuticula can be traced here, and it can be seen that it starts from the neck of the hair papilla (Unna). By the same method, it is also found that the cortex develops from the lateral portions of the papilla, and the medulla from the apex.

The Cortex.—The most voluminous portion of the shaft of the hair is constituted by the cortex, a transparent fibrillar mass of varying color. In it are seen dark spots and longitudinal streaks, which are situated between the horny elements of the hair, and are caused by the presence of air. Pigment granules are also present in greater or lesser quantities.

When the hair is treated with sulphuric acid the cortex breaks up into the fibres of which it is composed, and, if the action of the acid has been long continued, it may even separate into long, narrow, spindle-shaped plates. In the centres of these latter an indistinct linear figure is oftentimes traceable. It represents the remains of the nucleus of the cell from which the plate was derived.

The development of the hair from cells is very distinct as seen at the papilla. The portion of the hair in immediate contact with this body is hollowed out or concave in shape, and it is composed of a row of cylindrical epithelial cells entirely similar to those forming the basic layer of the epidermis. This layer of cells is termed the matrix of the hair, and it is upon it that the growth of the hair depends. Starting from this point it can also be seen how the cells and their nuclei grow longer, become finely fibrillated and granular, and finally, when entirely horny, appear as small plates. These successive changes should be studied on hairs which are little pigmented, for in them they can be seen much more easily than when the opposite is the case. The cells of which the cortex of the hair root is formed have been found by Waldeyer to be composed of small fibres. Each cell is united to the contiguous ones by short spines, in a manner analogous to the cells composing the epidermis.

The pigment which gives the hair its various shades of color is an important constituent of the cortex. It varies greatly in quantity, and in proportion to its abundance or comparative absence the hair is dark or light in color. It occurs both in a diffuse form and also in granules. The elements of the cortex are diffusely pigmented by the former, but the pigment granules are distributed here and there, and are situated in and between the cells composing the cortex (Waldeyer). This deposition of the pigment granules in the cells is most clearly seen in the root of the hair. The source of the pigment is not yet fully established, though Riehl, in his investigations has thrown some light on the subject. He found in the tissue of the papilla of the hair irregular-shaped, branched cells, the protoplasm of which contained a considerable amount of pigment. They were present as far up as the matrix of the hair, between the cells of which they sent long prolongations, and they could also be traced higher up as fine intercellular pigment deposits. Riehl also observed that the cells of this portion of the hair root, which were not yet horny, contained granules of pigment around their nuclei, and also that the cells of the matrix were quite closely connected with the prolongations of the wandering pigment cells of the hair papilla, from which their protoplasm took up pigment granules. In regard to the source of these granules, Riehl argued that, inasmuch as wandering pigment cells were regularly met with in the papilla of the hair and following the course of the blood-vessels, the blood must be the source of the pigment, and this latter must be carried by the cells to the hair.

The Medulla.—The medulla is situated in the axis of the hair throughout almost its entire length, but it narrows and terminates at some distance from the free end. It is marked in the stronger hairs, but is usually absent in the lanugo hairs, and often also in those of the scalp. The presence of the medulla is shown by a more or less broad, longitudinal band of a dark color, which is due to the air situated between its composing elements. These latter are cells which are shrunken into irregular shapes, possess no nuclei, and are furnished with spines and prongs (Waldeyer).

At the base of the hair, the medulla differs very slightly from the cortex. Over the apex of the papilla and above the cylindrical cells situated there, and which represent the matrix of the medulla, large nucleated cells are seen, and in their protoplasm are large drops of keratohyalin. In proportion as the shaft is ascended, these cells become shrunken, harder, lose their nuclei, and the keratohyalin disappears. They are bound together by means of the spines and prongs on their surface, between which are left spaces—intercellular spaces. Below the external surface these spaces serve as channels through which nourishment is furnished to the young cells of the medulla, but where the hair is exposed to the external atmosphere this fluid evaporates, and the spaces become filled with air.

The Cuticula.—The hair is also furnished with a cuticula which surrounds the majority of that portion of the hair which lies in the follicle. It is formed by a layer of horny plates, arranged like tiles on a roof, and they are closely bound together. The cuticula originates from the neck of the papilla of the hair between the matrix of the cortex and that of the inner root-sheath. At this point it consists of several rows of cylindrical nucleated cells, which divide soon after leaving the matrix into two layers. One of these goes to form the cuticula of the hair, the other the cuticula of the inner root-sheath. The cells of the former are, at the neck of the hair papilla, directed perpendicularly to the circumference of the hair, but gradually become more and more inclined toward it. At the upper portion of the hair-follicle the cuticula is no longer distinguishable, and becomes a constituent portion of the cortex. At the matrix the cells are epithelial in character, but they become transformed into solid transparent horn plates without nuclei.

The Root-sheaths.—The hair root is further enveloped by two coats—the root-sheaths—which are closely adherent to it. They are known, individually, as the inner and the outer root-sheath. The former is immediately around, and in contact with, the hair, and ends within the hair follicle; the latter, more external, passes up to the orifice of the follicle, where it becomes continuous with the spiny layer of the epidermis.

The Inner Root-sheath.—The inner root-sheath is composed of three layers—the cuticula, the one nearest the hair, Henle's layer, the most external, and between these two Huxley's layer.

The cuticula of the inner root-sheath arises from the same matrix at the neck of the hair papilla as the cuticula of the hair. The cells composing it are so arranged that their long axes are parallel to the circumference of the hair, that is, in an opposite direction to those forming the cuticula of the cortex. They undergo transformation in a manner entirely analogous to the one which has been already described for the cuticula of the cortex. The cuticula of the inner root-sheath is lost sight of within the follicle, becoming a part of the sheath.

The Layers of Huxley and of Henle.—The portion of the inner root-sheath which is situated between the cuticula just described and the external root-sheath is composed of the two layers known as those of Huxley and of Henle. They also take their origin from the neck of the papilla, and at that point appear as a layer of three or more cylindrical epithelial cells. Drops of keratohyalin, however, appear very soon in these cells, and this substance increases rapidly in quantity. The change in their appearance due to the presence of the keratohyalin is very marked on a level with the apex of the papilla, and the cells are seen here to have attained a much larger size. The cells forming the layer of Henle—the most external—contain, however, a greater amount of keratohyalin, and undergo hornification much more rapidly than they do in the layer of Huxley. Consequently, Henle's layer is found represented by horny, polygonal, non-nucleated elements at a much lower level than Huxley's layer. This latter, the inner portion of the inner root-sheath of the hair, is composed at the papilla of cells which contain a smaller amount of keratohyalin. Keratofication in them is not so rapid as in the cells of Henle's layer, the nuclei do not disappear so early, and the complete transformation of the elements of Huxley's layer into horny masses occurs at a higher level than is seen in the former one. The inner root-sheath ends in the hair-follicle.

The External Root-sheath.—In describing the embryology of the hair, it was stated that the first changes observed consisted in a proliferation and prolongation downward into the cutis of a portion of the cells forming the stratum spinosum of the epidermis. The further steps which occurred in the evolution of the hair, and which took place in the central portion alone of this prolongation, it has also been seen, resulted in the formation of the shaft of the hair, but the remaining portion also serves an important purpose. It represents the external root-sheath, or envelope, of the hair, and is separated by it from the connective tissue composing the follicle.

The outer root-sheath is not uniform throughout its entire extent, but is lined on the surface next to the hair-shaft, and as far down as the opening of the duct of the sebaceous gland, by the stratum corneum and stratum granulosum. From here to the level of the hair-papilla the stratum spinosum descends in its entirety, but then narrows, and at the neck of the papilla is reduced to a layer of two or three cylindrical cells. It lies at this point in close contact with the cells from which the inner root-sheath is formed.

The appendages of the hairs are the sebaceous glands, and bundles of unstriped muscular fibres are also attached to them. They have been, however, already described, and do not demand any further notice.

George T. Elliot.

SPINA BIFIDA. *Definition.*—Spina bifida is the name applied to a congenital hernia of the membranes of the spinal cord through a cleft in the walls of the spinal canal. It commonly presents itself as a rounded fluctuating tumor of varying size at the junction of the lumbar and sacral regions of the vertebral column.

Frequency.—It is by no means a very uncommon affection, as shown by the statistics of Demme[1] and Chaussier; the former found 57 cases in 36,148 births, while the latter recorded 22 cases in 22,293 births at the Paris Maternité. In 1882 there died from spina bifida in England and Wales, according to the report of the Registrar-General, 647 children (296 males and 351 females), 89 deaths occurring in London alone. Spina bifida is always congenital, and belongs to the class of congenital malformations due to an arrest of development; but three well-authenticated cases are reported where the tumor seems to have appeared some time after birth.[2] Its etiology is no more clear than that of the kindred affections, harelip, cleft palate, persistent branchial clefts, and the like. Heredity undoubtedly plays a certain part, cases being recorded where several members of the same family have been affected.

Cause.—It is, however, easy to see in what way it comes about that there may be a defect in the laminæ of the vertebræ. The vertebral canal is formed in the embryo by a furrow in the mesoblast, the sides of which furrow grow up and join over the top, enclosing, of course, a part of the epiblast. From the proto-vertebral plate grow up two processes, one on each side, which arch over the future spinal canal, and, joining in the median line above, become cartilaginous and finally ossify by three centres, one for the body and one for each lamina. A defect in this joining or ossification would cause a cleft in the median line of the vertebral canal on the posterior surface. The primary defect, then, is an absence of the laminæ and spinal processes. Sometimes, though rarely, this condition extends through the length of the vertebral column,[3] and then life is impossible. Sometimes it is confined to a defect in one vertebra, but commonly it includes two or three vertebræ, causing an oval tumor whose longest axis is in the line of the spinal column. Bryant has reported a case where the defective ossification was in the bodies of the vertebræ, and the tumor consequently occupied an anterior position.[4]

Associated Deformities.—It is often associated with talipes equinovarus, hydrocephalus, and the like. In some 300 children the following complications were noted, though they are probably of more frequent occurrence than the table would seem to indicate.

	Clinical Society table.	Demme's table.
Paralysis	53	Not stated
Talipes	42	13
Hydrocephalus	30	17
Idiocy	2	Not stated
Cretinism	1	"
Curvature of the spine	2	"
Absence of the cerebellum	1	"
Harelip and cleft palate	1	3
Imperforate anus, etc	2	1

Location.—Its location is, in about six-sevenths of all cases, sacral and lumbar, for here the vertebral laminæ are last solidified. Of the 236 cases analyzed by the London Clinical Society, 194 were lumbar or sacral, 8 dorso-lumbar, 14 dorsal, 13 cervical or cervico-dorsal, and 7 coccygeal. In general, the mid-dorsal region is the least likely to be affected.[5]

Formation of the Tumor.—There have always been two theories as to the primary cause of the deformity—one, that an early dropsy of the membranes of the spinal cord takes place and prevents the ossification of the laminæ; the other, that defective ossification of the laminæ is the sole cause; and this latter, the Dareste-Koch theory, meets to-day with acceptance to the exclusion of the other. It is chiefly the investigations of Recklinghausen[6] that have brought this about, and, in exact language, the cause of the deformity is found to be a local aplasia of the mesoblast, the cord remaining in the stage of the medullary plate. The investigation of thirty-one specimens established the facts (and the conclusion rests on such facts as these) that: 1, In myelo-meningocele the external wall of the sac consists not of dura mater but of pia mater turned inside out; and, 2, the remnant of the cord often corresponds with the persistence of the medullary groove in being itself bifid. And in the whole series no warrant was found for the old theory that the cause lay in dropsy of the membranes; also, when the latter occurred it was seen to be a result of the defective development instead of its cause.

Physical Characters.—Spina bifida presents itself as a tumor strictly in the median line, varying in size from that of a walnut to that of an infant's head (Fig. 5042). It is fluctuating and ordinarily partly reducible, and it can be seen to communicate with the spinal canal, usually by the following signs. The tumor becomes tense when the child cries, and it becomes less tense when the pelvis is raised and the fluid allowed to run into the vertebral canal. When hydrocephalus is also present, pressure on the sac causes the anterior fontanelle to bulge, and pressure on the fontanelle makes the sac tense; and ordinarily the opening in the vertebral canal can be felt by drawing the tumor to one side and making rather deep pressure with the fingers, and at the same time the sac will be felt adherent around the edges of the opening.

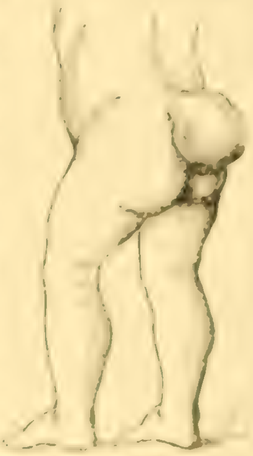

FIG. 5042.—Spina Bifida. (Treves.)

The tumors are either sessile or pedunculated; in the latter case the opening into the canal is smaller and communication less free, and an inflammation of the neck of the sac, and obliteration of the communication, is far more likely to happen. A case is reported where there was a pedicle a foot in length.[1]

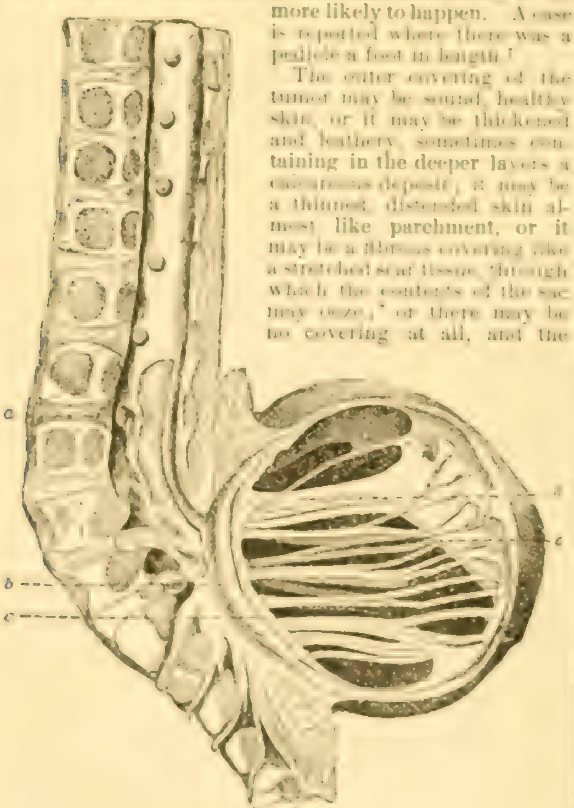

FIG. 5043.—Diagram of the Parts involved in a Lumbo-sacral Spina Bifida [illegible]

The outer covering of the tumor may be sound, healthy skin, or it may be thickened and leathery, sometimes containing in the deeper layers a calcareous deposit; it may be a thinned, distended skin almost like parchment, or it may be a fibrous covering like a stretched scar tissue, through which the contents of the sac may ooze;[2] or there may be no covering at all, and the bluish-red dura mater is seen protruding without protection. Whatever the character of the sac, its tendency is to ulcerate under the continued and increasing pressure, and herein lies the danger. Sudden evacuation of the contents of the tumor, and the consequent communication with the air, is very apt to lead to immediate death from violent convulsions, or an extensive destructive meningitis and myelitis.

Pathological Varieties.—Under the skin and adherent to it is found the sac, the walls of which are formed by the membranes of the spinal canal. Three varieties of little practical importance are made according to the contents of this sac: (1) When the membranes alone protrude it is spinal meningocele; (2) when the membranes, together with the spinal cord and nerves, protrude, it is meningo-myelocele (Fig. 5044). In both these cases the collection of fluid is between the cord and membranes (hydrorrhachis externa). When, however, the collection of fluid is in the central canal of the spinal cord (hydrorrhachis interna), the inner lining of the sac cavity is formed by the thinned and spread-out substance of the cord, and the condition (3) is known as syringo-myelocele. These varieties are the ones adopted in the classical report of the London Clinical Society already referred to.

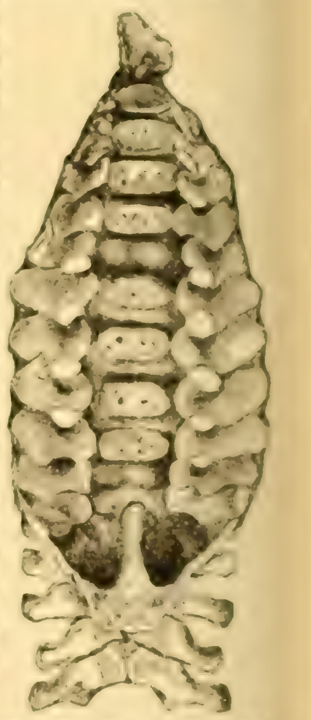

FIG. 5045.—Part of a Spinal Column [illegible] (The Clinical Society's Transactions, vol. xviii.)

The condition most commonly found is the second one, where some of the nerves, and probably part of the cord, enter into the contents of the sac; and on the point whether or no the cord is present in the sac must depend the advisability of active treatment. Follin and Duplay found the cord or nerves forming part of the sac in five per cent. of all cases; and Prescott Hewett, in twenty, found only one free from nerve structures in the sac.[3] The Clinical Society's Committee examined one hundred and twenty-five specimens, leaving out cases of syringo-myelocele, and found that the cord entered the sac in seventy-nine, or 63.2 per cent. It may be only a few nerves running irregularly along the inner surface, or it may be a complete cauda equina that one finds; sometimes the cord runs into the sac and again returns to the spinal canal lower down; and, lastly, one finds the condition described above where the atrophied cord is spread out over the inner surface, and, when the cord is consequently found fatal. In general the nerve-structures are adherent to the sac in the posterior median line, and it is said that a depression in the external surface of the tumor signifies the presence of the spinal cord in the sac; but it is no reliable test. As a rule the larger the opening in the vertebral canal the more likelihood there is that the cord is present in the sac.[4] Certain symptoms indicate the presence of the cord in the tumor. If tapping or manipulation of the sac cause convulsions or nervous symptoms, if the tumor increases in size, and with the increase in size convulsions begin, and if paralysis of the legs and sphincters is present, the chances are very strong that the cord is in the sac.

The fluid contained in the tumor is merely cerebro-spinal fluid, numerous analyses of which have been made.[11]

Sometimes one finds in the sac small masses of connective tissue and fat, but these are not common. Cases have been reported in which two or more sacs were present,[12] but these, too, are mere pathological curiosities.

Symptoms.—Children affected with spina bifida are often the subjects of other malformations, as, for example, in a case lately reported by Sutton, in addition to spina bifida there were also present lateral curvature, talipes equinus, atresia ani, imperforate pharynx, and only one kidney.[13] As a rule, the children are feeble and badly nourished. Associated very often with the tumor (and probably always when the fluid distends the internal canal of the cord) are paralyses, more or less complete, of the sphincter and muscles of the lower limbs, due to the implication of the nerves in the sac. Paralysis of motion predominates in the limbs, but complete paralysis of sensation is often associated with it. The distribution of the paralysis may rarely be unilateral.[14]

Convulsions occur with greater or less frequency, and are apt to be excited by pressure on the tumor.

Prognosis.—The affection is one of great gravity, and its course when untreated is of the greatest importance in regard to the advisability of treatment. Speaking generally, the tendency of these tumors is to increase in size from birth, and the distention causes the skin or other covering to ulcerate and thus the contents of the tumor are evacuated. This means death in most cases, but sometimes a spontaneous cure results; even a fistula may remain, and the child may live. A spontaneous cure is, of course, most apt to happen in cases where the tumor is pedunculated and the opening into the spinal canal is small.

Still more rarely there are cases where the tumor, after being stationary or increasing in size for some time, undergoes a retrograde change and shrivels without bursting; but such cases are uncommon.[15]

The general tendency in untreated cases is then to a fatal issue. Demme observed 57 cases, and in 32 no operation was done, and at the end of two years not one was alive. The Clinical Society collected 60 cases where no operative treatment was attempted, and found 14 cases where a spontaneous cure is said to have resulted; but the committee says: "These figures do not, however, represent the real mortality of the deformity when allowed to run its natural course," because only favorable cases are put on record in the journals.

Patients, however, occasionally reach adult life with the spina bifida still persisting. The Clinical Society recorded six patients between twenty-five and forty-three years of age; Behrend reported one case, fifty years of age, who still had the tumor unchanged;[16] and Callender one seventy-four years of age. The prognosis after the various operations will be considered in speaking of the treatment.

Diagnosis.—The diagnosis of spina bifida rarely presents any difficulty. The presence of a fluctuating, elastic, rounded tumor communicating with the vertebral canal by a defect in the posterior surface of the vertebral column is perfectly characteristic. Certain other congenital tumors, however, present a superficial resemblance to the affection under consideration.

1. False spina bifida is a term which has been applied loosely to all sorts of tumors in the lumbar and sacral regions, but, as Treves suggests, the term "should be applied to one tumor only, namely, to a spina bifida whose communication with the spinal membranes, and perhaps with the spinal canal itself, has been cut off." Such a tumor will be found in the ordinary location for spina bifida, strictly in the median line; it will not communicate with the spinal canal, and it will almost always be pedunculated, and very likely an examination of the history of the case will show that at one time it presented all the symptoms of a true spina bifida.

Certain congenital cystic tumors may be confused with false spina bifida, but the diagnosis between them is of no practical value, as the treatment is the same. These cystic tumors are generally multilocular, and therefore irregular in outline, not pedunculated, and often containing solid masses; these points will ordinarily establish the diagnosis.

Other congenital tumors of the sacro-coccygeal region need only to be named: 1, attached fœtuses,[17] sometimes with the remains in a cystic cavity or hanging from the back; 2, caudal excrescences, either supplementary coccygeal vertebræ or fibro-cellular masses; 3, congenital tumors, either cystic, as described above, or fatty, or fibrous. They present no difficulty in diagnosis.

Treatment.—The great obstacle to the successful treatment of spina bifida is the very frequent presence of the nerves and spinal cord in the tumor. The rarity of spontaneous cure, on the other hand, makes one inclined to adopt operative measures if they offer any likelihood of relief. In general, small tumors with pedicles, which communicate with the spinal canal by a small opening, are the most favorable ones for operations, and also, as we have seen, the ones most likely to undergo spontaneous cure.

Certain cases, all admit, should be let alone, especially those where hydrocephalus, marasmus, or intercurrent diseases are present. Certain other cases are not likely to be successfully treated, even by the mildest and safest operative procedures; these are cases where there is reason to suspect that the cord is present in the sac, such belief being based upon a depression in the skin, the size of the tumor and its communication with the canal, or the presence of paralysis, club-foot, or the other symptoms noted above. Very early operation is now discountenanced by nearly everyone; unless some very strong indication is present, treatment should be deferred until the child is two or three months of age. The palliative method should be adopted for a while, and if the case is kept under observation, such a course is attended by no risk. It can then be easily determined, in the course of a few weeks or months, what the course of the tumor will be. If it increases, operation must be considered; if it remains stationary, it will be safe to wait longer; and if it should diminish in size, nothing should be done. Certain means of protection are necessary to support the mass and prevent the clothes from chafing the skin, and at the same time to exercise a mild compression. The best dressing consists of cotton-wool, smeared with vaseline, lightly bandaged on. Another and much recommended application is painting the whole tumor with collodion, or collodion and castor-oil; but this tends to irritate the skin, and is especially unsuitable where a tendency to ulceration is present. When it is decided to continue the expectant treatment over a long period of time, or indefinitely, an accurately moulded leather or gutta-percha cap should be worn over the tumor, held in place by a belt around the waist.

If, however, the tumor increases in size, or, for any other reason, operation seems advisable, one of three operative proceedings has to be chosen: 1, puncture; 2, injection; 3, extirpation of the tumor.

1. *Puncture* has deservedly gone out of favor with the introduction of more intelligent methods. The evacuation of the entire contents of the sac at once, by this method, is, of course, risky in the extreme and not to be thought of. The only rational application would be a puncture to one side of the median line, made under every possible antiseptic precaution, and the evacuation of small amounts of fluid at different times. The Clinical Society's committee found on record 46 cases treated in this way; 30 of these died, 12 recovered, 2 were not relieved, and 2 were unaccounted for. Fourteen cases died of meningitis, and 8 of "convulsions" (probably meningitis also). The committee concluded that "this method of treatment is an imitation of that local change in the tumor (rupture) which most often ends fatally, and its disastrous results are, therefore, by no means surprising. . . . It should not be undertaken even as a palliative measure."

2. *Injection.*—It is generally accepted that the presence of the cord in the sac, when it can be definitely established, though not a positive contra-indication to

treatment by injection renders its utility somewhat questionable and adds to its danger. Paralysis has resulted directly from the employment of an iodine injection, and death has come on in half an hour after careful injection of Morton's solution in an apparently suitable case, so that the proceeding cannot be considered free from risk. Velpeau used a similar method, withdrawing the fluid and substituting iodinated water, just as one would in a hydrocele. Brainard, of Chicago, withdrew six ounces from the tumor, then injected half an ounce of a solution of iodine and iodide of potassium (5 grains and 15 grains to the ounce of water), let that run out after a moment, and then put back two ounces of the cerebro-spinal fluid originally withdrawn, and sealed the puncture. Morton, however, in a slight modification of the method, has produced the most successful injection of all. The advantage of his method seems to lie in the glycerine, which serves as a vehicle for the iodine, and which by its great specific gravity sinks to the bottom of the sac when the child lies on its back, and so does not enter the spinal canal as other injections probably do. A solution is used containing ten grains of iodine and thirty of iodide of potassium in an ounce of glycerine. A drachm or so of the fluid contents of the sac is withdrawn in order that the addition of the injection may not make the sac too tense, and then half a drachm or a drachm of the iodo-glycerine solution is slowly injected and the puncture sealed with collodion. A little inflammation results in all cases, but it soon subsides, and after from ten to fourteen days the proceeding should be repeated. The puncture should always be made to one side of the median line and obliquely through the sound skin, and a hypodermic syringe best serves the purpose. If a good result follows the use of this method the sac shrinks, and the process imitates the most favorable method of natural cure.

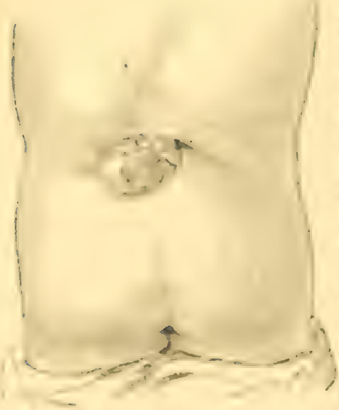

FIG. [illegible].—Spina Bifida. Appearance of the Tumor after [illegible]

So great was the reported success of Morton's method that the London Clinical Society appointed a committee to investigate the real value of that means of treatment, and they reported 71 cases—35 recovered, 27 died, 5 were unrelieved, and 4 were relieved. Meningitis caused only 7 of the deaths, and convulsions only 2, while 5 died of shock. A number of these cases were quite hopeless—cases in which other methods of treatment would not have been entertained. Morton's own report of the operation is still more favorable. In the edition of his book in 1887, he reports 65 cases treated, with 55 recoveries and 10 deaths. In his own experience he has operated 29 times, with 6 deaths. These percentages of recovery of course show a very different state of affairs from what one gets from any other treatment. The method is daily coming into greater use, and except for very unusual cases is the proceeding to be recommended. Successful cases are constantly being reported in the journals.

3. *Extirpation of the Tumor.*—In considering operative procedures for the removal of the tumor one fact is self-evident, that such operations are only applicable in cases where it is definitely determined that the cord is not present in the sac, and that, of course, restricts the field very much. Ligature and excision are the two methods. Ligature is best done by gradual compression between splints to excite adhesive inflammation at the neck of the sac, and a number of successes by this method are found-ed. Mosher cured three cases out of six with an elastic ligature. Sometimes a ligature is put around and drawn tight, or the mass is crushed off with the écraseur, and then death results with certainty if the cord is present.

Excision is practised in all sorts of ways, and the literature is full of modifications and new methods of it. The fact remains that when the sac is free from cord and large nerves, excision is the simplest of operations, and when the cord is present no operative skill will be likely to avert a fatal result (Lebrecht). One author proposes to open the sac and see if the cord is present, and if so to abandon further treatment. Mayo Robson recently has reported two successes out of four cases operated on by simple excision. He advises rather a wide application of the method, and would even cut out pieces of the sac between nerves, when they were present, and reduce the collapsed sac into the canal. A really useful modification of this operation has been recently proposed and has been successfully carried out, namely, fracturing the laminæ on both sides of the vertebral cleft and suturing them in the median line after the extirpation of the sac. Robson and Hayes, of Rochester, have brought about the same closure of the cleft by implanting a strip of periosteum from a rabbit. It is well to shut off communication with the vertebral canal by a ligature before opening the sac, as a sudden evacuation of the contents may produce serious results on the cerebrum and cord. A full account of the various useless modifications of excision can be found in Holmes' "Surgery."

But excision is not without its successes. Of 23 cases 16 recovered and 7 died (but the cases were probably very carefully selected), 5 of them from meningitis. Commenting on these results the committee says: "We are compelled to regard excision of the tumor as an inappropriate treatment of spina bifida."

In conclusion, it may not be inappropriate to call attention again to the fact that the cord is present in the sac in sixty to seventy per cent. of all cases. Having this fact in mind, the treatment of an average case would be summarized as follows: For the first months palliative measures alone should be used, in the hope that spontaneous shrinking may take place. If at the age of two months the tumor has increased in size, Morton's injection should be tried; if the tumor is stationary, it should be let alone for two months more. In either case, if Morton's injection fails and it seems reasonably sure that the cord is not present in the sac (and on this it all depends), a simple excision of the tumor should be done. If there is reason to suspect the presence of the cord in the sac, excision is, of course, out of the question, and the case must be left to itself.

Robert W. Lovett.

SPINAL CORD. The spinal cord (myelon) is an imperfectly cylindrical column of nerve substance extending from the brain, which appears to be attached to it as an enlarged outgrowth, to a variable point in the spinal canal. In man this point is stated as lying between the altitude of the first and second lumbar vertebræ. In reality it does not terminate, it merely becomes attenuated here into the so-called *filum terminale*, a structure which has all the morphological features of the more voluminous region of the cord, though physiologically it plays no important part in the human organism.

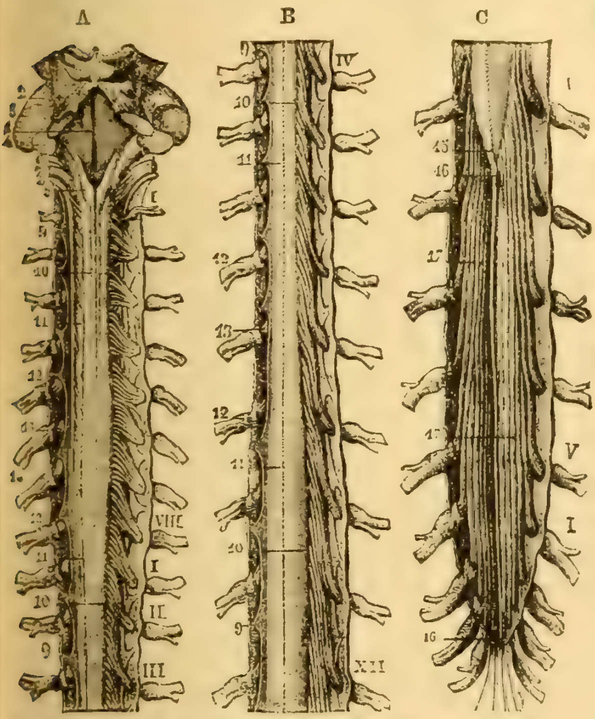

FIG. 5047.—The Cord seen from its Dorsal Face. (After Sappey.) A, The uppermost (cephalic) segment, including the cerebral attachment and extending to the origin of the third dorsal pair of nerves; B, the next following segment, including the origins of the remaining dorsal nerves and the beginning lumbar enlargement; C, the lowest (caudal) segment, including the end of the lumbar enlargement and filum terminale. The Roman numerals indicate the respective nerve-roots. At A, from I to VIII, the cervical; I to III, the upper dorsal. At B, the remaining dorsal from IV to XII. At C, the lumbar from I; V, the sacral from I to V; the lowest unnumbered are the coccygeal, and are not accurately represented in the figure. 1, Sulcus ventriculi quarti; 2, prepedunculus (processus e cerebelli ad cerebrum); 3, medipedunculus (processus ad pontem); 4. postpedunculus (restiform body, etc.); 5, clavæ or oblongata enlargement of column of Goll; 6, glossopharyngeal nerve; 7. vagus nerve; 8, spinal accessory nerve; 9, 9, 9, attachments of ligamentum denticulatum; 10, 10, 10, origins of dorsal (posterior or sensory spinal nerve-roots); 11, 11, 11, dorsal longitudinal septum (incorrectly termed the dorsal or posterior fissure); 12, 12, 12, spinal or intervertebral ganglia of the sensory roots; 13, 13, the sensory roots being divided on the left side, the motor (ventral or anterior) roots can be seen for a slight extent as they are about to join; 14, the division of a full spinal nerve into its ventral and dorsal peripheral branches; 15, conus medullaris; 16, filum (terminale); 17, 17, cauda equina.

The cord is essentially a segmental organ. In the typical vertebrate it may be regarded as made up of a series of nerve-centres, fused into a column; each centre corresponds to a somatic segment with which it is connected symmetrically by a pair of spinal nerves. In such a vertebrate, as well as in the embryos of higher vertebrata (see Embryology of the Brain, this HANDBOOK, Vol. I., p. 633), the spinal segment corresponds in its topographical situation with the somatic segment which its nerves supply, and these nerves take a direct transverse course, leaving the cord at right angles to traverse the intervertebral foramina and thus reach their somatic destination. But owing to the atrophy of the caudal segments of the body in higher animals, particularly in man, this topographical correspondence becomes lost. While both the vertebral column and the spinal cord continue growing in the fœtus and child, yet the growth-rate of the vertebral column is so much greater that the cord appears to shrink upward relatively to the surrounding bony channel.* Consequently, the spinal cord origin of the lower spinal nerves moves up far above the corresponding intervertebral foramina. From this it results that while the course of the upper cervical nerves is directly transverse, each succeeding nerve makes an angle with the cord, which becomes more and more acute (Fig. 5047, B), until in the most caudal segments the origins of the nerves almost attain parallelism with the cord (Fig. 5047, C). The roots of the lumbar and sacral nerves are thus compelled to travel a long distance within the spinal canal before they can make their exit, and as these roots are numerous, large, and run nearly parallel, they have been compared to the hairs of a horse's tail (cauda equina). The resemblance to that appendage is heightened by the mode of origin of the rootlets from the conus medullaris, which latter resembles the core of a horse's tail (Fig. 5047, B, 15, and 17, 17).

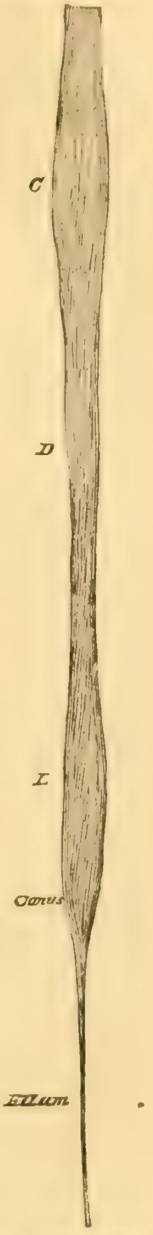

FIG. 5048.—Diagram after Measurements made by Author of Human Cord, to show Relative Dimensions of Various Parts. C, Cervical enlargement; D, dorsal region; L, lumbar enlargement.

The cephalic limit of the spinal cord is an arbitrary one, inasmuch as there is a complete continuity, both in structure and appearance, between the cephalic region of the cord and the oblongata (see description of Myelo-cerebral Transition). The boundary is assumed to correspond to the plane of the foramen magnum, and passes through the cord immediately cephalad of the first cervical pair. From this point to the caudal end of the conus, and excluding the filum, the length of the cord is between forty-one and forty-five centimetres, varying with the size and sex of the individual; for notwithstanding its greater relative length in the female, it is in that sex absolutely shorter than in the male. The weight of the cord is between twenty-seven and thirty-two grammes.

On the whole the cord, as stated, may be compared to a cylinder, but this cylinder is not a mathematical cylinder anywhere, and in some regions, as in the cervical, shows considerable departure from even an approximate cylindrical outline in cross-section. Aside from this there are considerable variations in dimensions. The chief of these are due to the two enlargements. Of these one corresponds to the origins of the four lower cervical and the first dorsal nerve, and is known as the cervical enlargement. The other corresponds to the origins of the lumbar and sacral nerves, and is named the lumbosacral enlargement. These names, therefore, do not indicate topographical situations, but physiological relations: the cervical enlargement corresponding to the origin of the arm-nerves, the lumbo-sacral enlargement to that of the leg-nerves. The cervical enlargement is characterized by a greater width than depth, the lumbo-sacral is more equal in its caudo-ventral and lateral diameters. A glance at Fig.

---

* In the new-born child the length of the cord is to that of the vertebral column as 855 to 1,000; in adults it is as 750 to 1,000. There is some individual variation. the cord of the female is slightly longer than that of the male, the difference amounting in extreme cases to half the altitude of a lumbar vertebral body. The flexures which the cord makes in accommodating itself to the bent course of the spinal canal are impressed upon its structure; in other words, the cord itself, even when removed from the spinal canal, shows a marked cervical flexure (Flesch).

tion will show these relations better than any description in words. The outline of the upper part of the cervical region is nearly circular; through the greater increase of the transverse diameter this becomes a transverse ovoid in the cervical enlargement (C7, C8), to again become nearly circular in the dorsal region; while in the lumbosacral enlargement a rounded quadrilateral is characteristic, again succeeded in the conus and filum by a more regularly circular shape.

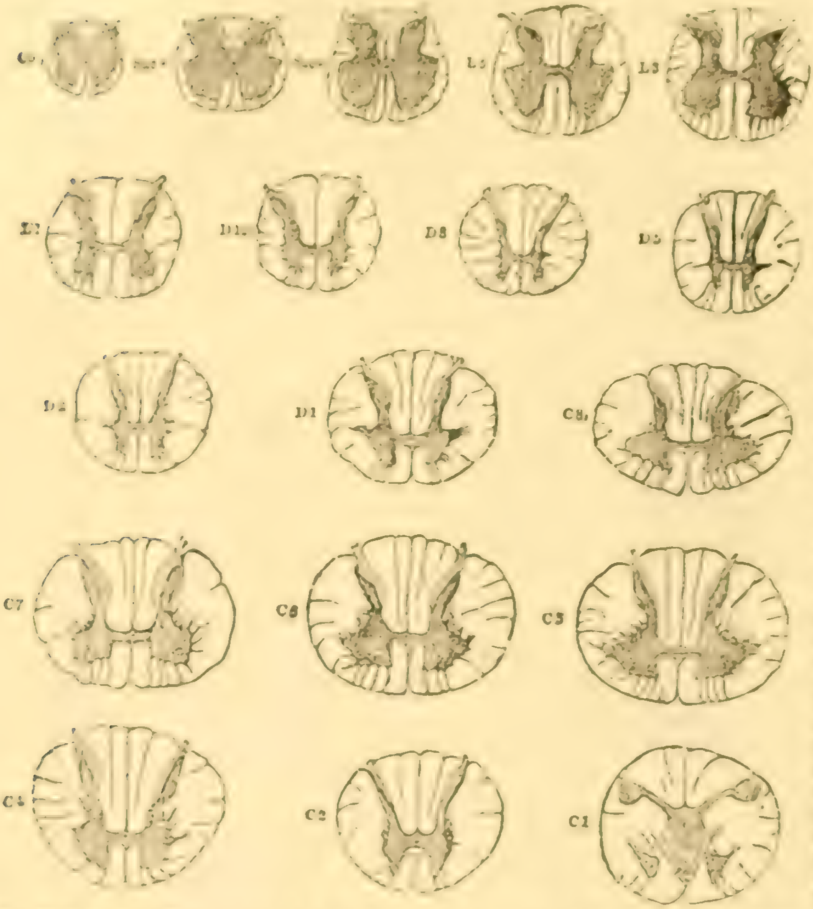

Fig. [illegible].—Sections Transverse of the Cord, taken at Successive Levels and beginning at the Lower Part of the Conus Terminalis. Twice the natural size. (After W. R. Gowers.) [illegible]

The cord, like the brain, possesses three investments: one nutritive, the pia, which immediately adjoins, and is connected with, its proper substance; one protective, and adjoining the bony canal, the dura; and a third, delicate intermediate structure, the arachnoidea, which fills out the extensive space intervening between dura and pia. The vessels of the pia give the ventral and dorsal faces of the cord their characteristic color and markings. In young healthy persons the color is between a clear white and a rosy tint; in older ones, a yellowish or greyish-yellowish discoloration is often observed, without indicating any ascertainable pathological state. As in the cerebral pia, opaque and punctate pigmentation is sometimes observed in the upper cervical region, particularly in the negro.

As the appendages of the cord are homologous with those of the brain, and identical with the corresponding dura cerebralis, arachnoidea cerebralis, and pia cerebralis in the main structural respects, it is the points of difference alone that need detain us here. The dura mater *spinalis* is thinner than the cerebral dura. This is to be accounted for by the fact that the cerebral dura represents at once the fibrous envelope of the neuraxis and the periosteum of the skull; at the foramen magnum its inner lamellæ alone are continued into the spinal dura mater; the outer become continuous with the periosteum of the spinal canal.* The spinal dura, therefore, corresponds only to the innermost or neuro-visceral part of the cerebral dura. This explains why the spinal dura, unlike the cerebral dura, is a free sac, independent of the lining of the surrounding bony canal. It constitutes a cylindrical bag, extending from the attachment at the foramen magnum free through the spinal canal far below the conus and fusing its walls, so as to lose its lumen at the level of the second or third sacral vertebra.† After losing its lumen the spinal dura continues on, fusing with the atrophied caudal prolongations of the arachnoid and pia, to become distinctly lost in the coccygeal periosteum. The connective-tissue band thus formed, superficially considered, bears the same relation to the dural sac which the filum (terminale) bears to the cord proper.‡

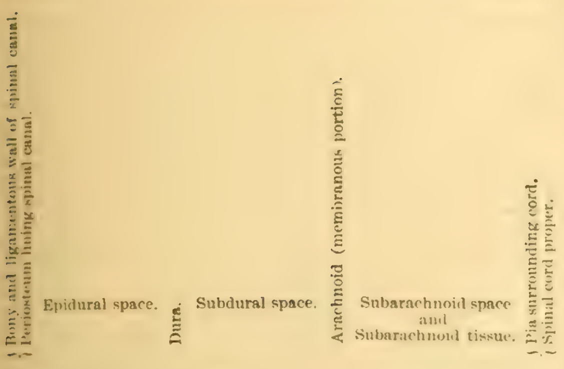
The *spinal arachnoid* is a delicate tissue without proper vessels, which presents an outer, smooth, membrane-like face to the dura, while internally it is continued and fused with the pia by means of a delicate cellular tissue, which may be regarded as the seat of a physiological dropsy. Its large meshes are filled with a clear fluid, the liquor cerebrospinalis. The outer smooth portion, which is near the dura, is sometimes discriminated as arachnoidea propria, the meshes between it and the pia as the *subarachnoid tissue*. The slit-like space, analogous to the spaces in the large serous visceral cavities of the body lined by a continuous endothelium, and which intervenes between the dura and arachnoid proper, is termed the *subdural space*; while the congeries of smaller cavities and meshes filled with cerebrospinal fluid in the subarachnoid tissue is known as the subarachnoid space. The delicate membranous sheets and webs of the latter are also lined by epithelium. The relations of the various membranous appendages and cavities surrounding the cord is shown in the following:

---

* This has [illegible] the *epidural space*. [illegible]

† [illegible]

‡ And is termed the filum *terminale externum*, a designation which [illegible]



Bony and ligamentous wall of spinal canal.
Periosteum lining spinal canal.
Epidural space.
Dura.
Subdural space.
Arachnoid (membranous portion).
Subarachnoid space and Subarachnoid tissue.
Pia surrounding cord.
Spinal cord proper.

Of the three slits which thus concentrically surround the cord, and facilitate its accommodating itself to the various flexions and rotations of the vertebral column during life, only the two innermost contain fluid, and that is of a serous character; the amount in the subdural space is very small, just sufficient to moisten the contiguous endothelial surfaces of the dura and arachnoid; that in the subarachnoid space is considerable.

The pia is composed of two connective-tissue layers. The outermost insensibly merges into the subarachnoid tissue, and is clothed by endothelium on its outer face. The inner layer, separated here and there from the outer by capillary slit-like spaces, is known as the *intima pia*; it contains elastic fibres and beautifully arranged circular fibrillæ. The vascular net-work of the pia is mainly situated between these, its two layers, and as they enter the substance of the cord receive an investiture from the intima, accompanied by a prolongation of the capillary slit-like spaces just referred to. These, in turn, are connected with the perivascular spaces, from which it results that the interior of the cord is traversed by a continuous lymphatic net-work connected with the spaces in the pia, and through these with the subarachnoid space.

Aside from the attachment afforded by the spinal nerve-roots and some delicate connective-tissue fibres uniting the dura to the arachnoid across the subdural space, the cord is mainly supported in its concentric protecting cavities by means of a series of triangular membranous processes, whose base is attached to the pia, and whose apex is attached to the dura. They flare out laterad from the lateral face of the cord, and are, on each side, between twenty and twenty-four in number. In their entity the series of each side are termed the ligamentum denticulatum (Fig. 5047, A, 9, 9, 9, shows dural insertion).

The blood-supply of the cord is derived from two sources: 1. The ventral (anterior) spinal artery, a median trunk with a double origin; and 2, the paired dorsal (posterior) spinal arteries. The former lies at the entrance of the ventral fissure of the cord, and continues in undiminished calibre for the entire length of the cord proper. It gives off, at nearly regular intervals, horizontal branches which pass to the depth of the fissure, and then penetrate, near the commissural part of the cord, to the mesal aspect of the ventral gray horn. The dorsal (posterior) spinal arteries send in similar but smaller branches at or near the dorsal roots, and in addition still smaller branches enter the numerous septa of the white substance, taking their origin in the surface net-work of the pia. Both the ventral system and the radiatory system of vessels send their main and their terminal branches to the gray substance, whose vascularity is so much richer than that of the white as to be estimated at between six and twelve times as great. It is a comparatively small number, and vessels of small calibre, which nourish the white substance, by means of a fine capillary net-work which surrounds the great longitudinal fibre system, and whose direction becomes vertical to that of the originating radiatory system.

The return circulation is mediated mainly by two large veins, the central veins of the cord, whose lumina constitute a characteristic feature of every section of the cord, being situated laterad of the central canal, in an almost directly transverse line with it. Numerous anastomosing branches connect it with the ventral (anterior) spinal vein, which accompanies the corresponding artery, lying dorsad of, or covered by, the latter. The dorsal (posterior) spinal vein takes up the return blood from the dorsal segment of the cord, by means of radiatory venules, and a surface net-work of the pia.

The lymph system of the cord is very intricate, and an important element in its physiology and pathology. Every blood-vessel, even the most minute, is ensheathed in a *perivascular lymph space*, which is lined by a continuous endothelium.[*] It has been recently demonstrated that the vascular and lymphatic channels of the cord have a direct connection with the perinuclear region of nerve-elements (Adamkiewicz). Of the largest kind of nerve-elements, it is now demonstrated that walled capillaries penetrate them, and that they thus have a circulation of their own (Fritsch).

There are in man thirty-three pairs of spinal nerves. Of these the two last, being rudimentary, are usually excluded in enumeration. The first pair emerges between the occiput and atlas, and is designated the first cervical, the other cervical pairs are named after the lower of the two vertebræ, which, conjoined, form the corresponding foramen, respectively the second, third, fourth, fifth, sixth, and seventh. Very inconsistently the pair emerging between the seventh cervical and first dorsal vertebra is termed the eighth cervical pair. The dorsal pairs are named after the upper of the two vertebræ which form the corresponding foramen, and this system is adhered to in regard to the lumbar, sacral, and coccygeal nerves.[†] We thus have:

Cervical pairs	8
Dorsal "	12
Lumbar "	5
Sacral "	5
Coccygeal "	3
	33 [‡]

All spinal nerves are made up of two roots by which they spring from the cord: the thus-far repeatedly mentioned dorsal (posterior or sensory) and ventral (anterior or motor) roots. A characteristic feature of the dorsal root, in which it differs from the ventral, is an intumescence made up of large nerve-elements, and known as the spinal ganglion (intervertebral ganglion). The conjoined spinal nerve, the two roots which build it up, and the spinal ganglion attached to the dorsal of these roots are to be regarded as part and parcel of the spinal segment.[§]

---

[*] There is but one perivascular sheath, and that being endothelial, is sometimes known as the adventitial sheath. The extra adventitial sheath of His has no existence in the healthy cord.

[†] Willis endeavored to evade the unfortunate contradiction, which recognizes one more cervical pair than there are cervical vertebræ, by enumerating the first cervical, or suboccipital, as a cranial nerve. Consistency would seem to require either this, or the naming of all cranial nerves according to the vertebra just caudad of its intervertebral foramen.

[‡] Subtracting the second and third coccygeal pairs, which, as rudimentary, may be here disposed of, there are thirty one pairs, as usually stated in text-books. The two coccygeal nerves in question, like the coccyx itself, are rudimentary relics of the caudate condition of the human embryo, and, according to evolutionists, of the caudate ancestry of man. They are so minute as to require the microscope for their identification, and were, until Rauber discovered their true nature, confounded with the vascular and connective tissues surrounding the filum terminale.

[§] The few topographical facts of interest may be stated briefly thus: Inasmuch as the spinal nerves emerge at a much lower level than their true origin from the cord the sixth dorsal pair although emerging between the sixth and seventh dorsal vertebræ originating from the cord at the level of the fifth dorsal body, the fifth lumbar pair originating nearly six vertebral bodies higher than it emerges—the spinal ganglion attached to their dorsal roots does not always correspond to the intervertebral foramina after which it is named. The cervical and upper dorsal ganglia correspond very nearly, but those of the sacral nerves are half-way between the cord-origin and vertebral exit, while that of the first coccygeal pair is actually contained in the dural sac of the cord. All others lie outside of the dural sac.

The development of the true segmental part of each spinal segment bears a definite relation to the somatic segment supplied by its nerves. In man, the part formed by the dorsal roots in building up the segment seems to be slightly in excess of that formed by the ventral roots;* but in animals whose cutaneous and general sensory periphery has become reduced, this relation is inverted (Figs. [illegible] and [illegible]). The reduction manifests itself not alone in the afferent or dorsal root, but in the dorsal horn, in the dorsal root-zones, and the columns of Clarke—in short, in the segmental dorsal gray. The physiological anatomist hence discriminates between the gray matter connected with the dorsal roots and that connected with the ventral roots. The former he regards as related to functions involving centripetal conduction (sensation), the latter as related to centrifugal functions (motion, secretion). The variety of nerve elements connected with the dorsal roots is greater than that of those connected with the ventral roots, and our uncertainty of knowledge regarding them is correspondingly greater. While the ventral roots, on entering the cord-substance, follow a direct course, connecting with the multipolar elements of the ventral horn† or the nerve plexus in that horn, and the functional differentiation in the ventral part of the cord is determined by the relation of groups of these elements to special motor peripheral organs, it is not so with the dorsal roots. These, already complicated by the interpolation of special ganglia before their entry into the cord, present two distinct fasciculi within the latter, one of which directly penetrates the caput gelatinosum, or apex of the dorsal horn, the other, skirting on its mesal aspect, to penetrate the trigonum (Fig. [illegible], D).

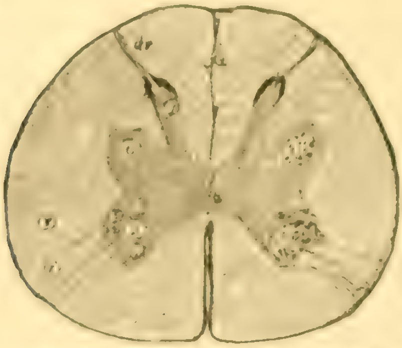


FIG. [illegible].—Transection of Terminal Cord from [illegible]. (*[illegible]*) *dr*, dorsal root; *v*, ventral [illegible]; [illegible] [illegible] of gray matter; [illegible] [illegible] groups of [illegible] ventral horn; [illegible], gray commissure.

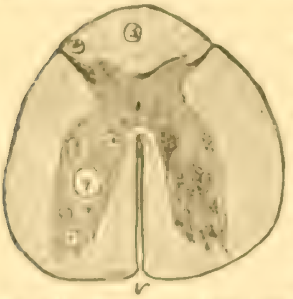

FIG. [illegible].—Transection from [illegible] [illegible] [illegible] [illegible] [illegible]; [illegible] ventral [illegible]; [illegible] [illegible]; [illegible] [illegible] [illegible] [illegible].

The ventral (anterior) face of the cord exhibits a deep fissure extending the entire length of the compact cord—the ventral or anterior fissure.‡ Cephalad this fissure becoming shallower through the crossing of the bundles of the pyramidal decussation, is continued into the interpyramidal or ventral sulcus of the oblongata. It is lined by the pia, and conveys the more important nutritive vessels to the depths of the cord-substance. On either side of this fissure, at distances varying with the diameter of the cord—being greater in the enlargements and lesser in the other parts—is a continuous series of fine rootlets which, at some distance from the cord, unite to form the anterior roots of the great spinal nerve pairs.

The dorsal (posterior) face shows a depression analogous to the ventral fissure, and which has been regarded as a dorsal or posterior fissure of the cord. But closer examination shows that, unlike the ventral fissure, the pia cannot be demonstrated to descend into and line the walls of the pretended fissure. The latter is merely a solid septum of connective substance bearing lymph and vascular channels. A very shallow sulcus marks it on the surface, which may be designated the *dorsal sulcus*, and which is particularly well marked in some in the lumbar cord. It becomes deeper in the oblongata, where it constitutes a veritable fissure between the clavæ. The solid septum which extends to the gray commissure, and in some levels is as deep as half the ventro-dorsal extent of the cord, is known as the *dorsal* or *post septum*.

About one millimetre to each side of the dorsal septum there is a shallow sulcus, continuous with that which, in the oblongata, forms the lateral boundary of the clava. This *sulcus [illegible]*, well marked in the cervical, becomes least of all marked in the dorsal cord. In a situation nearly corresponding to the origins of the ventral rootlets on the ventral face, a series of dorsal rootlets arise in a continuous row from a slight, furrowlike depression.

The principal points of resemblance and contrast between the ventral and dorsal faces of the cord are here summarized:

	On ventral face.	*On dorsal face.*
Median fissure . . .	Is a true fissure. Is [illegible].	Is [illegible] a septum. Is [illegible] but deeper.
[illegible] . . .	Absent [illegible].	Present in [illegible] part.
Root attachment . . .	No [illegible], [illegible] [illegible] [illegible] [illegible].	A [illegible] and [illegible] [illegible].
" "	[illegible] [illegible] [illegible] [illegible] [illegible] [illegible].	Is [illegible] gray [illegible].
" "	Inner limits of opposite [illegible] approach [illegible] nearly.	Inner limits of opposite [illegible] are farther apart.

A plastic conception of the various fissures, septa, sulci, and root-attachments of the cord is essential to an understanding of its inner topography. In Fig. [illegible] it has been attempted to show their relations, which may be embodied in the following propositions:

1. The ventral fissure from the ventral face and the dorsal septum from the dorsal face, penetrate so deeply into the cord-substance as nearly to meet. The cord is thus divided into two halves united by a very narrow bridge—the commissure. 2. On examining the cross-section of the cord, it is seen that the two forms of nerve-tissue known as gray and white substance (see [illegible] Histology, this volume) are represented in it, and arranged in a characteristic manner, which is constant in every region of the cord. The gray matter is interior, and the white exterior, in each half of the cord. 3. The gray core is drawn out into horns toward the emerging rootlets already mentioned. The one horn which extends toward the ventral roots is known as the ventral or anterior horn; the other, as the dorsal or posterior horn (Fig. [illegible]). 4. As the cross-section of each gray core is united across the middle line by a gray commissure, the aggregate appearance of the gray matter of the cord is that of a letter H. Furthermore, as the extremes of each horn join, or nearly approach, the emerging rootlets, there results a natural demarcation of the surrounding white substance into three great columns (Fig. 5053). The column whose cross-section is bounded by the ventral fissure mesad, the ventral roots and ventral horn laterad, is the ventral (anterior) column. The one similarly bounded by the dorsal septum mesad and the dorsal roots and horn

---

* The [illegible] [illegible] area of all dorsal roots [illegible] [illegible] of all ventral roots [illegible] [illegible] [illegible] [illegible]. [illegible].

† [illegible] it is [illegible] that [illegible] [illegible] [illegible] [illegible] [illegible] to the [illegible] [illegible] of the ventral horn.

‡ [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible].

laterad is the dorsal (posterior) column; the one between the two horns and roots is the lateral column. The ventral column has a free surface on the ventral face of the cord, the lateral on the lateral, and the dorsal on the dorsal.

Boundaries.	*Columns.*
Ventral fissure. Ventral horn and roots.	Ventral (anterior) column.
Dorsal horn and roots.	Lateral column.
Dorsal septum.	Dorsal (posterior) column.

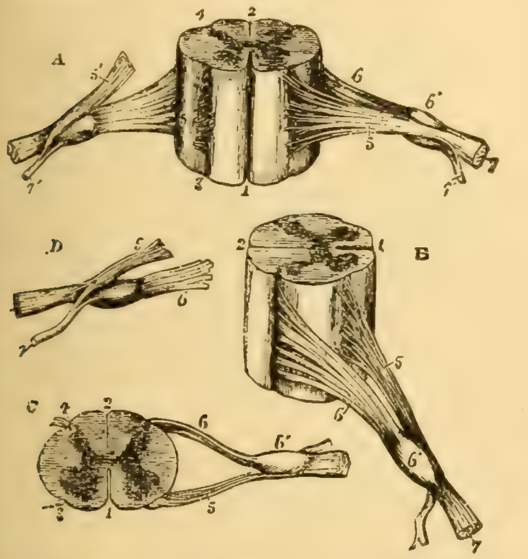

Fig. 5052.—Segments of Cord transsected so as to Separate the Part appertaining to one Spinal-nerve Pair from the next Segments above and below. (After Schwalbe.) A, the segment seen from its ventral face; B, seen from its lateral, and C, from its upper cut face; D, the relations of a spinal or intervertebral ganglion. 1, Ventral fissure; 2, dorsal septum; 3, spurious fissure left by evulsing ventral roots (in A they are enclosed on the left and retained on the right side); 4, sulcus for dorsal rootlets; 5, ventral, and 6, dorsal, root of spinal nerve; 6′, spinal ganglion; 7, proper root after leaving ganglion, subdividing into ventral and dorsal rami.

To have a proper conception of these various elements, they must be imagined not alone in the relations in which they are conventionally studied, that is, as exposed in transsections, but also as columnar structures having a continuous extent throughout the length of the cord. Each demicylinder of the cord is therefore to be conceived as containing a core of gray nerve-substance, drawn into a ventral ridge connected with the ventral roots, a dorsal ridge connected with the dorsal roots, while the white substance fills out the irregularities and completes the demicylindrical outline in three columns, one mesad of the ventral ridge, one mesad of the caudal ridge, and one between the two ridges.

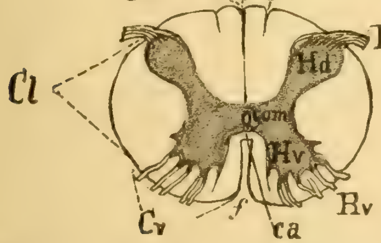

Fig. 5053.—Diagram of Transsection of Cervical Cord. The figures on the right side relate to the gray substance and emerging roots; those on the left side, to the white columns. *f*, Ventral fissure; *s*, dorsal sulcus; *Rv*, ventral (anterior) rootlets; *Rd*, dorsal (posterior) rootlets; *Hv*, ventral (anterior) horn; *Hd*, dorsal (posterior) horn; *com*, gray commissure with included central canal; *Cv*, ventral (anterior) column of white substance; *Cl*, lateral column; *Cd*, dorsal (posterior) column; *ca*, white commissure.

The commissure of the cord is, like each demicylinder, composed of both forms of nerve-substance. Its ventral part is white: *commissura alba;* its dorsal part is gray: *commissura grisea* (Fig. 5053, *ca*, and *com*). The ventral fissure, therefore, has for its floor the former, while the dorsal septum terminates on the latter. In the gray commissure is observed the lumen of a very small canal, which extends the entire length of the cord and into the filum. It opens cephalad into the fourth ventricle, and represents in the cord what the ventricles do in the brain, the medullary canal of the embryo (see article on Brain, Development of the, in Vol. I.). While this canal undergoes elaborate transformations in the cerebral part of the neural axis, it becomes so much reduced in the adult cord as to be identifiable by the microscope alone. Formerly it was assumed by some to open into the ventral fissure; by others, in the dorsal septum of the sacral part of the cord; it is now definitely ascertained to be continued through the filum,* which is the true caudal representative of the cord, in every morphological essential. The gray substance of the cord is of a faint reddish-gray tinge. In older persons the gray preponderates, and, according to the degree or absence of capillary injection, various shades of red, yellow, and even light slate-color may be noted. It is not uniform in this respect, even in the same section. Around the central canal, and in a particular band on the dorso-mesal periphery of the dorsal horn, it is very translucent and is termed gelatinous substance, that in the former situation being additionally qualified as the ***substantia gelatinosa centralis***, that in the latter as the *caput gelatinosum* † (Fig. 5054, *gc*, and *S. g. R.*).

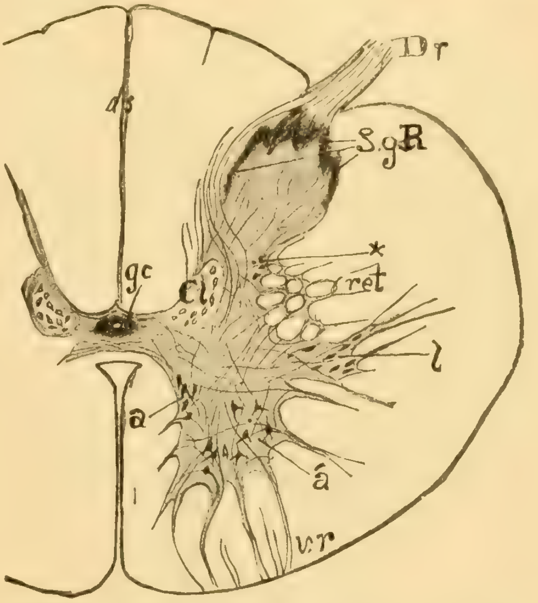

Fig. 5054.—Diagram of Gray Matter in a Transsection of Cord, combined from an Upper Cervical and a Middle Dorsal Level. The gelatinous substances are indicated by deep shade; the vesicular, by a light area with spots (nerve-elements); the spongy, by light shading and intersecting lines. *S.g.R*, caput gelatinosum; *gc*, substantia gelatinosa centralis; *Cl*, vesicular column of Clarke; *Dr*, dorsal or posterior roots; *v.r*, ventral or anterior roots; *a*, *a′*, *l*, *ret*, *, spongy substance; *a*, *a′*, cell-groups in ventral horn; *l*, in lateral horn; *ret*, reticular processes; *, sparse cells found at and near neck of dorsal or posterior horn; *ds*, dorsal or post septum.

In the cervical and dorsal cord, another area of gray matter is noted for its remarkable pallor. This it owes to the abundance of numerous myelinic fibres. From its columnar extent and Lockhart Clarke's demonstration in it of special vesicular nerve-elements, it is known as the vesicular column of Clarke (Fig. 5051). There are two, one on each side. To understand their situation it is necessary to refer to a feature of the contour of the dorsal horn hitherto not yet considered.* The horn is more massive at its connection with the nerve-root than at its junction with the remainder of the gray. The massive part is known as the head (*caput cornu dorsalis seu posterioris*), the narrow part as the neck (*cervix cornu*). Where the neck joins the gray commissure the vesicular columns of Clarke are found to occupy a triangular area: one acute mesal angle is directed toward (and sometimes encroaches† on) the commissure; another points toward the dorsal-root entry; the third rounded angle is directed lateral. The remainder of the gray substance, that is, all excluding the columns and the two gelatinous areas, is designated spongy substance. It corresponds in structure nearly with the motor nerve nuclei of the brain (see Brain Histology). The entire ventral horn, and, when present, that lateral peninsular extension of it which is sometimes termed the lateral horn (Fig. 5053), and the neck and body of the dorsal horn, are made up of this substance. It owes its characteristic features to the intrusion of a large number of myelinic and amyelinic nerve-fibres, which interlace in a bewildering manner, and hold in their meshes groups of nerve-cells and other structures to be described. Toward the ventral roots it is drawn out into projections, giving its outline a very irregular shape; and facing the lateral column it is broken up in a peculiar basket-work pattern by intruding nerve-fibres, causing an appearance, on a smaller scale, like that of the reticular field of the oblongata (*processus reticularis*, Fig. 5054, ret.).

---

* Its primitive embryonic relations (neur-enteric canal) are obliterated in the adult.

† Substantia gelatinosa Rolandi; it is continued into the oblongata and here becomes so massive as to force the overlying tissue out in the shape of the funiculus Rolandi (see Brain Histology).

Structure of the Central Gelatinous Substance.—Immediately adjoining the epithelia of the central canal, and gradually merging into the spongy substance which constitutes the remainder of the gray commissure, is a finely granular substance containing numerous free (?) nuclei and granular elements. Extremely fine nerve-fibrils are found among them, and often such appear to be connected with, or to meander among, the epithelia of the central canal.‡

Structure of the Caput Gelatinosum.—This substance clings to the spongy substance of the body of the dorsal horn like a tight-fitting cap. It is more voluminous in the cervical and lumbo-sacral enlargements than in the dorsal cord. Chemically it shows the reactions of nerve-substance; it stains very deeply in carmine. Opinion as to its histological nature has oscillated between every possible extreme, and until recently the view prevailed that it was not a nervous, but a connective, substance, acting as a "support" to the dorsal rootlets. Against this view it could be urged that higher animals, which have, as a rule, less connective substance than the lower, have a better developed caput gelatinosum.§ Further, this structure wastes in tabes dorsalis, although in that disorder the connective substances are increased. Finally, experiments performed after the atrophy method show that this substance depends for its nutrition on the intactness of the dorsal nerve-roots, or their sensory periphery. Recently Virchow the younger has conclusively shown that it is not composed of free nuclei, as was the general belief. He finds that each nucleus has its proper protoplasm and the other characteristic nerve-processes, but all so closely crowded that previous observers overlooked the demarcation between the various cells, regarding it as a uniform blastema. It may be affirmed, then, that the *caput gelatinosum* is a nervous substance composed of numerous closely crowded nerve-elements allied to the "granule type" of nerve-cell, with an intricate intervening plexus of very fine nerve-fibrils, derived from the dorsal (posterior or "sensory") nerve-roots. Of these some traverse it in a manner analogous to the arciform fibres which break through the dentated nucleus of the olive (Brain Histology), while others are lost at its periphery or interior.

Structure of the Spongy Substance.—The ground substance of this, the chief gray matter of the cord, is neuroglia or nerve-glue, a substance described in the article on Brain Histology. It is everywhere penetrated by nerve-fibres, some of which are derived from the nerve-roots, some from the great fibre-tracts of the cord, while others probably remain in the gray substance throughout their entire extent. They are of all dimensions, from the large axis-cylinder processes and myelinic fibres connected with the roots and fibre-tracts to fibrils so delicate that their very nature has been disputed.

One of the most important features of the spongy substance is the presence of multipolar nerve-elements. These are distributed in constant and definitely located groups. On pursuing the course of individual nerve-rootlets, it is seen that in running through the gray substance each spreads and forms a loop enclosing a cluster of these elements. Each group is demarcated from neighboring groups by the nerve-fibre intervals, and has a special situation in each level. Numerous pathological observations, chiefly based on the atrophy of special cell groups as related to mutilation or atrophy in special groups of muscles, whether caused by amputation, congenital absence of limbs, or infantile paralysis, show that they have a definite relation to certain muscles or organs endowed with muscular activity.

The structure of the large multipolar elements of the spongy substance is essentially the same as that of the similar elements in the cerebral cortex and cranial nerve nidi. An irregular mass of protoplasm, sometimes drawn out into a conical, more frequently a polygonal, shape, presenting numerous branching processes, is their essential constituent. In addition, they contain a clear, well-marked nucleus, round, oval, and sometimes angular, which appears to vary in staining reaction and contour, in conformity with certain nutritive or vital conditions of the cell itself, which are as yet imperfectly known. The largest elements have one* unbranched process of large size, which may frequently be traced into the axis-cylinder of a ventral nerve-root. In dimensions the multipolar elements vary considerably; large and small ones, presenting every transition to granular elements, can be found in every section. But the average size corresponds to the size of the muscular masses to which they are in demonstrable functional relation. They are therefore larger and more numerous in the cervical and lumbo-sacral intumescences than elsewhere in the cord; and here again, more bulky in the lumbo-sacral than in the cervical enlargement, just as the thigh muscles exceed those of the arm.

The manner in which the motor functions of the groups of multipolar nerve-elements is determined, is so intimately connected with the topography of the ventral and lateral horns of the cord that we may briefly state them. Certain mammals, such as the sloth, are characterized by a preponderance of flexor and ventral muscles over extensor and dorsal muscles. Others, such as the dolphin, have enormous extensors and dorsal muscles. On comparing the spinal cord of the dorsal levels of these two animals, it is found that in the sloth the radicles of the ventral or motor roots are more numerous in the mesal and in the dolphin more numerous in a lateral situation. Correspondingly, the cell groups in the mesal part of the ventral horn preponderate in the sloth, while those in the lateral part preponderate in the dolphin. From this fact it may be inferred that ventral muscular masses of the trunk are represented in mesal and dorsal

---

* This feature is not marked in the cervical and lumbar enlargements, but in the dorsal cord the horn is so attenuated that what is termed caput cornu [illegible] is [illegible].

† Aberrant varieties have been found by Pick (Arch. f. Psychiatrie, vii., p. 287) the areas of [illegible].

‡ In lower forms the central epithelia have been connected with fibres which are apparently identical with nerve-fibres. It is not surprising when we remember that the ependymal epithelium and the proper nerve-elements are both products of an identical embryonic tissue.

§ In man it actually shows a tendency to [illegible] exceeding those of the [illegible].

* Observers describe some elements with more than one process.

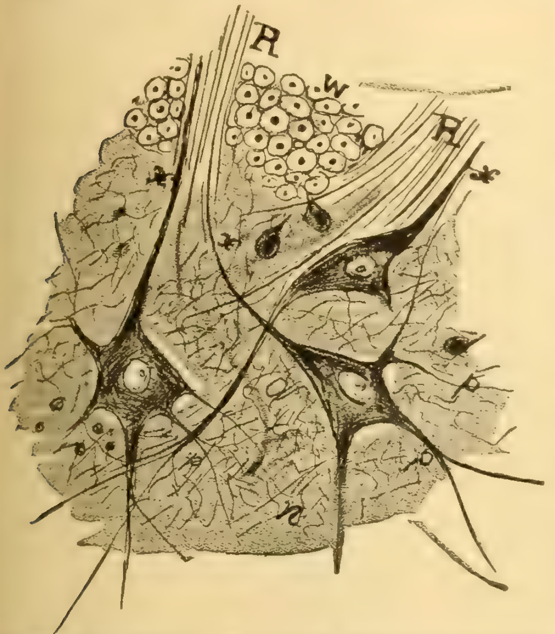

FIG. 5055.—Large Multipolar Elements from Ventral Horn in Cervical Enlargements. *R*, Ventral root fibres; *xx*, axis cylinder processes; *p*, protoplasmic processes; *n*, neuroglia of gray substance; *w*, white substance, showing myelinic fibres in cross-section.

ones in lateral cell groups. In all animals it is noted that, in the cervical and lumbo-sacral enlargements, the lateral part of the ventral horn is particularly well developed. Here the nidal * centres of the extremity muscles are to be sought for. In part, they may be located by means of their direct relations to nerve-roots, whose function has previously been determined by experiment, or by pathological observation already referred to. Thus amputation of the forearm is followed by a wasting of the cell groups at the levels of the seventh and eighth cervical and first dorsal nerves. Other similar observations show that within this extensive area, it is a more specialized one which is related to the muscles of the thumb. In like manner, the observation of cases of fracture at the level of the first lumbar vertebra proves that it is below the level of the intervertebral cartilage, intervening between the last dorsal and first lumbar vertebra, that the centre for the rectum and bladder is to be located. In the cetacea, the enormous atrophy of the extremity nuclei throws out the nucleus sacralis † in bold relief by contrast, and thus, pathological and comparative anatomical facts unite in pointing to this nucleus as the presumable centre for certain pelvic innervations. It corresponds to the origins of the third and fourth sacral nerves.

The groups related to special muscular masses are not strictly segmental; they often extend caudo-cephalad beyond a segment, and in successive sections their area varies considerably, and like the subnuclei of certain cranial nerves, they overlap each other (Brain Histology). The following have been well established: 1. A group in the lateral part of the ventral horn, which is the nidal centre of the sterno-cleido-mastoid and trapezius (see Spinal Accessory Nidus in article Brain Histology). 2. A powerful group extending from the fourth beyond the fifth cervical level, representing the great muscles of the shoulders (deltoid, supra and infra spinatus); it is located laterad on the root border. 3. Mesad of it and overlapping it, but mainly developed in the fifth and sixth levels, is the nidal centre of the pectorals. 4. From the sixth cervical to the first dorsal inclusive, are a number of overlapping groups related to the forearm and hand muscles, of these (5) one well-marked group in the last cervical and upper dorsal level, and consisting of several subgroups, is positively related to the great muscles of the thumb and those of the thenar eminence. Those of the hypothenar eminence are probably represented in another group of these levels. Less is known of the lumbar enlargement. 6. It is generally held that in the conus, as above stated, are located the atrophied coccygeal (caudal) centres, together with the well-developed centre for the bladder and rectum (nidus or nucleus sacralis); that immediately cephalad of this (7), from the level of the fifth lumbar to the second sacral origins, is the centre for the peronei and intrinsic muscles of the foot. 8. The columns of Clarke may each be regarded as a nidus of unusual length; they extend from the level of the eighth cervical origin.

Aside from the above, physiologically significant variations in the essential nervous elements of the cord, the local peculiarities of the special regions are epitomized in the following:

The *conus terminalis* is characterized by the predominance of gray over white substance. The latter is a mere thin rind of the former, particularly in the lateral column. The gray substance shows a very deep commissure, with very plump horns. The root entry is at so steep an angle that the radicles usually appear cut across obliquely (Fig. 5049, Co 1).

In the *lumbo-sacral enlargement*, the gray substance contributes most to the cord area, being absolutely more voluminous than in the cervical region. As we pass cephalad the commissure becomes gradually more attenuated, but the horns are more plump in contour than in the cervical region (Fig. 5049, Sac 2, L5, L3). The dorsal roots enter in a compact mass, and the belting fibres of the so-called root zones are particularly well marked. The caput gelatinosum is voluminous. At the upper part of the enlargement (Fig. 5049, L3, L1) the white substance attains more volume, owing to the beginning here of the crossed pyramid tract, and the tract of Goll's column.

---

* For explanation of this term see Brain Histology.

† So named by Stilling. Schwalbe regards it as a disconnected homologue of the columns of Clarke.

The dorsal cord (Fig. 5049, D12 to D2) is throughout characterized by a relative diminution of the gray substance, which appears in the typical H shape, with attenuated horns and small cell groups. A prominent feature is the presence throughout its extent of that paired area in the gray known as Clarke's vesicular column. A lateral spur is very distinct on the dorso-lateral part of the ventral horn, and sometimes spoken of as the lateral horn. The white substance continues increasing cephalad, but very slightly; the main increase is due to the addition of the direct cerebellar tract.

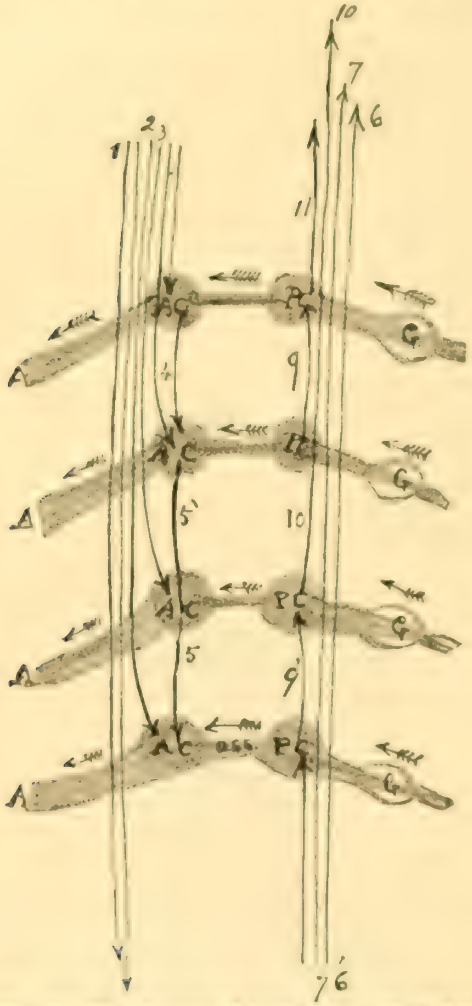

FIG. [illegible].—Diagram of Segmental Relations of Cord. [illegible]

The cervical enlargement gradually begins with the first or most cephalic dorsal segment, and extends to the fourth cervical segment inclusive. The general outline is transversely oval, both the gray and the white substances undergo a sudden increase. The gray horns have a more slender and graceful outline than in the lumbar region, and the white substance is at least twice the square area of that of the first lumbar level. The dorsal septum is consequently half as deep again as in the latter situation. A collateral sulcus, indistinctly marked in the middle dorsal levels, increases in distinctness in the cervical, and as we pass further cephalad. All the great known fibre systems are represented in the white columns.

The *upper cervical cord* shows the same relations of the white columns, which continue increasing; but owing to a collapse of the gray, similar to that observed in passing from the lumbar to the dorsal levels (Fig. 5049, C), the general contour becomes more round.

The *cephalo-cervical transition area* extends from the level of the upper cervical nerve pair to the clava. The cord shows its greatest volume of white substance here, as all the great tracts, whether centripetal or centrifugal, increase in area cephalad. At the same time the ventral horn becomes smaller, while the caput gelatinosum undergoes a great development, and the neck of the dorsal horn becoming elongated, the former becomes situated more laterad (Fig. 5049, C 1). It is the increasing volume of the dorsal white columns that drives the dorsal cornua aside. The reticular processes are also increased in number and area. The strands of the crossed pyramid tract insinuate themselves among these processes, and breaking through the body of the gray matter so as to decapitate the ventral horn, they cross the median line to apply themselves ecto-ventrad of the direct pyramid tract. The united pyramid tract thus causes a ventral prominence or column on the oblongata, to which it owes its name. After the translocation of the pyramid tract the column of Goll and the comma-shaped area of the column of Burdach end in two gray masses, the correspondingly named nuclei, and the spinal type of structure becomes gradually abolished, although some of its ingredients may be identified for considerable distances cephalad in the oblongata, and even in the pons. The transition from the cord to the oblongata is epitomized in the following table:

Cord Structure.	*Condition in Oblongata.*
Dorsal or postseptum.	Becomes a true fissure.
Column of Goll.	Isolated by its nuclear termination beneath the clava.
Column of Burdach.	Becomes a nucleus of the same name.
Ascending root of trigeminus.	Continued and augmented.
Caput gelatinosum.	Continued and augmented.
Direct cerebellar tract.	Moves more and more dorsad, and associates itself more cephalad to merge into the restiform, cerebellar peduncle.
Crossed pyramid tract.	Decussates and is extracted from the lateral to become added to the ventral pyramid.
Reticular processes.	After interruption by pyramid tract become augmented.
Ventral horn.	Becomes reduced to a rudiment, from which, as a starting point, the nuclei necessarily originate.
Ventral fissure.	Becomes shallower, the pyramid decussation taking place at its floor; cephalad of this it becomes the ventral or anterior longitudinal fissure of the oblongata.
Ventral or white commissure.	Undergoes a great increase and becomes identified with the decussation of the pyramids.
Dorsal or gray commissure.	Becomes augmented; at the part where the ventral horn was decapitated the hypoglossal nucleus and in a more dorsal situation the vagus nuclei are found.
Central canal.	Continues, to eventually open in the fourth ventricle.
Dorsal nerve roots.	Absent; nerve roots of the sensory and vegetative nuclei of the cranial nerve system may be regarded as their analogues.
Accessory nerve roots.	Continued in a corresponding situation.
Ventral nerve roots.	Represented by the hypoglossal roots.

Each spinal segment is composed of two sets of elements. One of these is strictly segmental; its gray and white tissues are in direct relation to the nerve roots which are connected with that segment. The gray matter in which these roots terminate, the rootlets themselves, and the intra-cinereal tracts which mediate reflex relations, have this character. But most of the strands of the white columns are not segmental, they simply traverse the segment to terminate in segments situated more caudad, if centrifugal; with segments more cephalad, or even with cerebral centres, if centripetal. To illustrate this, let us assume a segment in the cervical region. The motor (ventral) and sensory (dorsal) roots of the seventh cervical pair, the ventral and dorsal gray from which these roots arise, are the segmental morphological elements of that level, and, physiologically speaking, represent the reflex functions of the corresponding somatic segment. The pyramid tract, exposed on a cross-section at this level, is not segmental, as it runs caudad to the next succeeding levels, and in its greater part represents innervations of lumbar and sacral segments. In like manner the column of Goll, exposed on cross-section in this level, has no physiological relations to cervical nerve-roots or cervical gray matter. It is in relation with sacral and lumbar segments, and merely traverses the cervical segment to reach a higher cephalic destination. It is therefore necessary, in studying the anatomy of a given spinal segment, to discriminate between the true segmental part, which, crudely expressed, may be regarded as a reflex apparatus, and the non-segmental part, which represents more complex associated, or even cerebral, innervations. Among the tracts of each segment which add to the volume of the spinal cord in the enlargements are those of the ventral commissure. This commissure is more voluminous in the enlargements than in the remainder of the cord. The intersegmental, or short longitudinal tracts, are similarly more numerous in the enlargements, consequently the increased bulk of the cord in the enlargements is not alone due to the greater volume of the entering nerve-roots, the greater mass of the gray substance, but also to a local increase in the white columns.

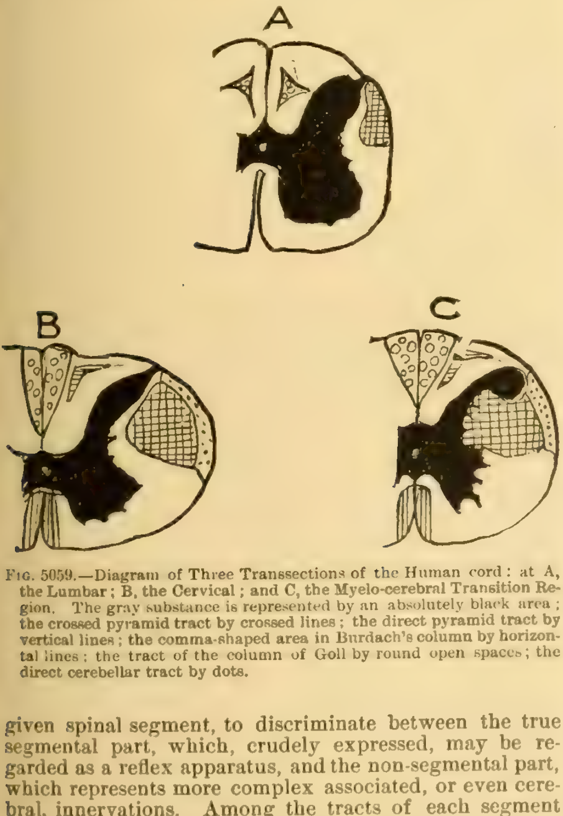

FIG. 5059.—Diagram of Three Transsections of the Human cord: at A, the Lumbar; B, the Cervical; and C, the Myelo-cerebral Transition Region. The gray substance is represented by an absolutely black area; the crossed pyramid tract by crossed lines; the direct pyramid tract by vertical lines; the comma-shaped area in Burdach's column by horizontal lines; the tract of the column of Goll by round open spaces; the direct cerebellar tract by dots.

The non-segmental or great longitudinal tracts, in so far as they are connected with the architecture and mechanism of the brain, have been already considered in the article on Brain Histology. It remains to describe their spinal relations in various levels, and to consider those tracts whose cerebral relations are as yet unknown.

The area occupied by the cerebro-spinal fibre systems is indicated in Fig. 5059. It is there shown that all these tracts increase cephalad, occupying a greater area in the myelo-cerebral transition (C) than in the cervical enlargement (B), and in the latter than in the lumbar region (A). In the latter only the tract of the column of Goll, and the crossed part of the pyramid tract, are represented. The direct cerebellar and direct pyramid tracts are added in the dorsal, and the comma-shaped area of Burdach's column in the cervical regions.

The *dorsal white columns* of each side are usually distinguished as the column of Goll (slender column, *funiculus gracilis*) and that of Burdach (wedge-shaped column, *funiculus cuneatus*). In the greater extent of the cord they can be readily recognized by means of the sulcus collateralis, or a septum which represents the latter. Further, the column of Goll has a distinctly different tinge, even in the fresh cord, and assumes a darker color in carmine than the column of Burdach. In the lower part of the lumbo-sacral enlargement it appears to originate as a triangular area on either side of, and at some distance from, the dorsal septum, and to grow out of the gnarled and twisted fasciculi resulting from the intertwining of longitudinal and root-fibres. Whether it originates directly from the root-fibres, or indirectly after interruption in the gray substance, is not yet determined; but this is positively known: 1. The tract of the column of Goll atrophies, if the lower extremity of the same side be amputated. 2. It atrophies and degenerates in an ascending direction. 3. It receives no demonstrable accession of fibres above the lumbar enlargement. 4. It runs cephalad to terminate in the nucleus of the same name. 5. That nucleus is connected with the interolivary tract; lesion of which latter, it is generally admitted, produces

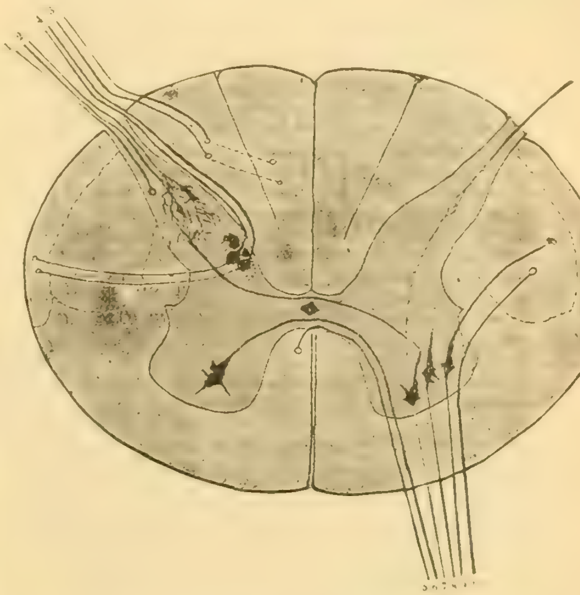

FIG. 5060.—Diagram of Transsection of Cord in Cervical Enlargement (after Edinger), showing Segmental and Non-segmental Tracts in their Root Relations. 1, 2, Direct fibres connecting with proper substance of the dorsal horn; 4, mesal tract connecting with the columns of Clarke; 3, tracts which ascend and descend some distance in the column of Burdach, whose destiny is not clearly known, but some of which enter the column of Goll; 5, a ventral root fibre derived from the direct pyramid tract, through the ventral commissure; 6, one derived from the opposite ventral horn through the same commissure; 7, one derived from a ventral horn cell of the same side, with reflex intra-cinereal crossed tract, indicated by a dark, and a direct (homolateral) tract indicated by a broken, line, which latter extends to the dorsal horn; 8, root-fibre from a cell with undemonstrable central connection; 9, a fibre derived from a multipolar cell, under the dominion of the crossed pyramid tract; 10, a direct root-fibre from the crossed pyramid tract; 5, 8, and 10 are supposititious tracts, and their existence is disputed.

disturbance of sensation. 4. The only form of sensation which accompanies at the myelo-cerebral transition is experimentally (Brown-Séquard) known to be the muscular sense. From all this it is inferred that the tract of the column of Goll represents the muscular-sense projection for the lower extremity of the same side.

The column of Burdach, unlike that of Goll, does not present a physiological unit. The largest and best individualized tract in it is represented on cross-section by a comma-shaped area (Fig. 5000, B and C). It originates in the cervical enlargement, increases cephalad, and terminates in the nucleus of the column of Burdach.* From its resemblance in structure, its participation in [illegible], and its analogy in termination with the tract of Goll's column, it is to be inferred that it represents the muscular-sense projection for the upper extremity.

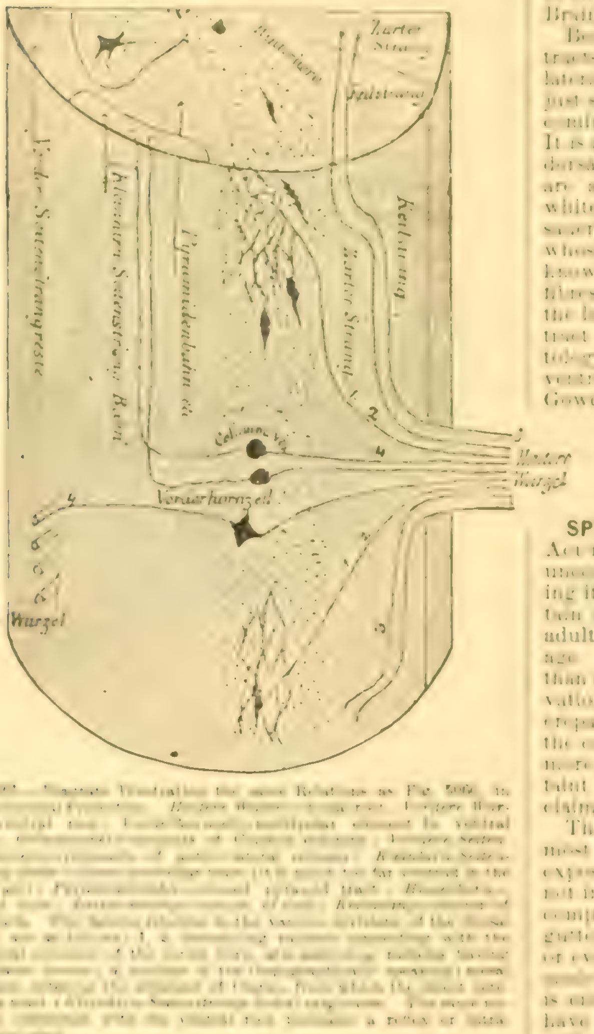

Fig. 5001.—Diagram Illustrating the same Relations as Fig. 5000, in Longitudinal Projection. [illegible]

The direct cerebellar tract lies on the periphery of the cord, and in direct contact with the pia, intervening between it and the crossed pyramidal tract (Fig. 5000, B and C). Only where it is absent, as in the lumbosacral enlargement, does the crossed pyramidal tract come in contact with the pia. It nearly reaches the dorsal root entry, and extends on an average over one-half to two-thirds of the periphery of the lateral column. On a cross-section it is seen that delicate nerve-bundles, originating in the columns of Clarke, traverse the gray substance, the pyramidal tract, and spreading out fan-shaped, enter and build up the direct cerebellar tract. Inasmuch as the columns of Clarke are themselves in relation with the dorsal roots, it follows that they are to be regarded as an interrupting station for a continuous tract, beginning in certain dorsal nerve roots and terminating in the cerebellum—for in the cerebellum (see Brain, Histology) the direct cerebellar tract eventually extends as an ingredient of the restiform column. Fig. 5000 shows this relation in transsection and Fig. 5001 in longitudinal projection. One unexplained fact is, that although segmentally the columns of Clarke belong to the dorsal region, in atrophic experiments they seem to be under the dominion of dorsal lumbo-sacral roots. They waste with disease of these roots and after amputations. Opinion as to their function varies, as stated in the article on Brain Histology.

Besides the direct cerebellar and the crossed pyramidal tracts, which make up the dorsal and greater part of the lateral column, there is a narrow rim of white substance just sufficient to prevent the crossed pyramidal tract from coming in contact with the dorsal horn and dorsal roots. It is assigned a special position under the dominion of the dorsal root; its further relations are unknown. There are a number of fibre systems contained in the zonal white surrounding the dorsal horn, described by Lissauer, and in the gray substance itself, described by Pal, whose exact significance is yet to be determined. Our knowledge of the destination of the greater part of the fibres of Burdach's column, and of the ventral part of the lateral column, is equally uncertain. The triangular tract of Helweg, referred to in the article on Brain Histology, appears either in juxtaposition with, or the most ventral part of, the antero-lateral tract described by Gowers, Sherrington, and Toothe. As described by the latter, it occupies a peripheral zone continuous, as it were, with the area of the direct cerebellar tract, in transsection.

E. C. Spitzka.

SPINAL CORD: ACUTE AND CHRONIC MYELITIS.

Acute Myelitis.—*Etiology.*—Acute myelitis is not an uncommon disease, though very little is known concerning its predisposing factors. With the exception of certain special varieties, it is usually a disease of early adult life, and grows more infrequent in middle and old age. The male sex seems to be much more predisposed than the female. Thus, among 33 cases under my observation there were 20 males and 13 females. This discrepancy is probably owing to the greater frequency of the exciting causes among males. Whether myelitis is more frequent in families suffering from a neuropathic taint is more than doubtful, though this has been claimed by some writers.

The exciting causes of myelitis are numerous. The most frequent one, in the writer's experience, has been exposure to cold and wet. Thus, the disease is observed not infrequently after a debauch, if the patient has been compelled to sleep on the damp ground, or lie in the gutter, etc. It may also result from working in ditches, or even from a brief exposure to wet and cold. The modus operandi of exposure in the production of myelitis is entirely unknown, although numerous experiments have been made to solve the question.

Traumatism plays a much less considerable part in the etiology of this disease. The injury may be inflicted directly upon the spinal cord, as the result of gunshot and stab wounds, direct blows to the back, or even blows on the head. Injury to adjacent parts may also lead to myelitis. For example, in one of the writer's cases an injury to the back gave rise to a myositis in the erector spinæ muscle, attended with suppuration. After a long interval the pus made its way along the roots of the spinal nerves, through the intervertebral foramina, to the pia mater, where it set up an acute meningitis, and then extended to the substance of the cord, setting up myelitis. A certain amount of myelitis always attends spinal meningitis, but it is usually confined to the outer layers, and does not produce any notable symptoms.

Myelitis is also a frequent result of injuries to the spine (fractures, dislocations, etc.) which are attended with direct pressure on the cord; or it may occur in spinal concussion, when there is no evidence of injury to the external parts. In the latter form, however, the myelitis is more apt to be subacute or chronic.

---

* [illegible]

Compression-myelitis is also observed quite often, usually as the result of Pott's disease, more rarely of cancer or other tumors of the vertebræ. In Pott's paraplegia the inflammation rarely results from direct pressure of the bones, but usually from that of a secondary pachymeningitis, externa and interna.

Attention has been directed in recent times to myelitis, commonly of the disseminated variety, occurring after infectious diseases, usually small-pox, but also after typhoid fever, diphtheria, puerperal fever, etc. This is also claimed by many writers with regard to syphilis, but our own experience does not corroborate this very strongly. Barlow reports a case of disseminated myelitis occurring during the eruptive stage of measles, and which proved fatal on the eleventh day of that disease. The occurrence of myelitis during the course of phthisis is very often noticed, but the connection between the two affections has not been clearly determined. To one point, however, we desire to call attention, viz., that tuberculosis of the spinal dura and pia mater is much more common than is generally believed. We have found it frequently in cases of tubercular cerebral meningitis, and in two cases the tubercles projected inward from the spinal pia mater to such an extent as to cause considerable softening. Perhaps the development of tubercles within the substance of the cord may also occur at times, and thus serve to explain the frequency of the disease during the course of pulmonary tuberculosis.

We may here state that certain cases of acute myelitis are regarded by some writers as an infectious process, resulting from the action of bacteria. But this view is a mere hypothesis, for which no proof has hitherto been offered.

A considerable number of cases have been reported, in which the disease was attributed to excessive fatigue. For example, it has been noticed in soldiers after forced marches, and is then supposed to be due to overaction of the spinal cord.

Toxic myelitis is also observed occasionally after poisoning with arsenic, lead, phosphorus, sulphide of carbon, and vegetable poisons.

Much stress was formerly laid upon the effect of ascending neuritis in the production of myelitis after disease of the bladder, kidneys, etc. This mode of origin must be extremely rare. There is no doubt that, in many cases which have been regarded as belonging to this category, the disease of the urinary tract was secondary to that of the spinal cord.

Finally, in a considerable proportion of cases, we are unable to discover any adequate cause for the development of the disease.

CLINICAL HISTORY.—Acute myelitis is rarely preceded by prodromal manifestations, unless this term be applied to the first symptoms of the beginning inflammation. In rare cases there is a feeling of general malaise, slight shivering sensations, or a distinct chill, and there may even be a certain degree of mild delirium; even general convulsions have been noticed at the onset of acute dorsal myelitis, and still more often in cervical myelitis. Marked febrile movement is not often noticeable, however acute the inflammation may be. There are several varieties of acute myelitis, the symptoms of which differ somewhat in numerous details.

The onset of acute myelitis varies considerably in its degree of suddenness. In rare cases it begins as quickly as an attack of cerebral apoplexy. The patient suddenly feels a sense of weight in his lower limbs, this increases, and at the end of a few minutes the limbs are paralyzed. Or the onset extends over a week or more. At first a feeling of numbness, or of pins and needles, is felt in the soles of the feet; this gradually spreads up the limbs, accompanied by increasing weakness of the parts, perhaps by severe pains in the muscles, particularly the calves of the legs, or by painful spasms of the muscles. Then the anaesthesia and motor paralysis continue to increase, sometimes uninterruptedly, sometimes by fits and starts, until they have attained their greatest intensity. The paralysis may be so complete that the patient is unable to move even the toes to the slightest extent.

Pain in the spinal column is not a pronounced symptom, nor do the patients, as a rule, complain much of tenderness in this region. The pains in the paralyzed muscles, sometimes in the joints, are extremely violent in certain cases, so that we have even seen this condition mistaken for acute articular rheumatism. These pains may continue during the entire acute stage of the disease. A more constant symptom is the cincture feeling, a term applied to a painful sense of constriction around the abdomen, or thorax, varying according to the site of the disease in the spinal cord; this is usually attended with circumscribed tenderness over the corresponding portion of the spine. The cincture feeling is sometimes described by the patients as very narrow, like a cord or thin ribbon; sometimes it is as broad as the hand.

In the majority of cases the pains in the limbs disappear as the paralysis becomes more pronounced, but in some instances they persist, even despite complete motor and sensory paralysis (anæsthesia dolorosa). When the pains in the limbs are severe they are usually attended with spasm or contracture of the affected muscles.

The bladder and bowels, especially the former, are usually implicated at an early period. The patient first experiences difficulty in passing water (paralysis of the detrusor), and must strain a good deal to start the flow. Finally, the paralysis of the detrusor may become complete, and the use of the catheter becomes necessary. Or the sphincter also becomes paralyzed, and incontinence results from overflow. The bowels are affected in a similar way, though less frequently. At first there is constipation, sometimes attended with extreme tympanites, from paralysis of the muscular coat of the bowels. Or the stools may pass away involuntarily, and, if anæsthesia is profound, this occurs without the patient's knowledge. In many cases, however, the functions of the bowels are quite undisturbed throughout the entire course of the disease. Even when voluntary evacuations are completely lost, the action of the bowels may sometimes be stimulated by reflex means, as by the passage of a catheter into the bladder, the irritation of the perineum, etc.

The cutaneous and tendon reflexes vary according to the exact site of the disease. Trophic symptoms are not an important feature in myelitis, apart from the atrophy of muscles seen in inflammation of the anterior horns of the cervical and lumbar enlargements. They are observed most frequently in the integument. Vesicular eruptions sometimes appear upon the paralyzed parts, and there may also be excessive desquamation of the outer layers of the skin. The formation of bed-sores, which sometimes occurs at such an early period as to indicate their trophic origin, will be considered later. We may also call attention to the fact that the changes in the urine, which are so common in this disease, are regarded by some writers as the result of trophic changes in the secreting structures of the kidneys.

Enlargement and tenderness of the knee-joints, sometimes attended with distinct effusion, occur rarely, and their interpretation is obscure. We have also found a similar "rheumatoid" condition in the ankle-joints in a few cases of myelitis.

Gowers reports a remarkable case of trophic disturbance in a patient suffering from subacute myelitis, in which the myelitic symptoms were complicated by cellulitis of the lower part of the abdomen. At the autopsy no local cause of the cellulitis could be discovered.

Vaso-motor symptoms are more frequent than the trophic changes, but possess little clinical importance. The temperature of the paralyzed parts is often changed. At first it is sometimes increased, but later, as a rule, it is decidedly lower than that of other parts of the body. Pitting of the limbs from slight subcutaneous œdema is also not infrequent.

The disease may be arrested at any period during its course, and may then sometimes slowly go on to complete recovery. This is possible even after all the limbs are completely paralyzed, and after extreme wasting of muscles has taken place. As a general thing, however, recovery is incomplete. In the majority of cases advance is made to a certain point, and then a standstill takes place at which the patient remains for years. In some of these cases, however, further improvement is possible even after a long interval, during which the patient has remained in statu quo. In the majority of instances, however, the non-fatal cases terminate in the condition known as spastic paraplegia. The lower limbs gradually become more and more rigid, until finally each limb is moved as if it were one solid body. The feet cannot be flexed, the toes are shuffled across the floor, and the pelvis must be raised further from the ground, in order to prevent the toes from catching in the floor. The limbs offer a decided resistance to passive motion. The tendon reflexes are often enormously increased. Ankle clonus often develops spontaneously if the patient, while sitting down, happens to bear his weight on the front part of the foot.

In much rarer cases the limbs become contractured in flexion, the thighs upon the abdomen, the legs on the thighs, the feet on the legs. At the same time the thighs are usually adducted strongly upon one another, so that one thigh is drawn forcibly across the other. In these cases bed-sores are very apt to develop at the points at which the limbs come constantly in contact with one another. The patients very often suffer from intense pains in the contractured limbs, especially when an attempt is made to overcome the contracture. At other times the pains come on spontaneously in violent paroxysms, which are usually very difficult to control.

Death occurs generally from extension of the inflammation upward and implication of the muscles of respiration; from gradual exhaustion, resulting usually from the formation of bed-sores; or from disease of the kidneys consequent upon cystitis following paralysis of the bladder.

Bed-sores develop over the sacrum, and are caused not alone by the protracted pressure on this part of the body, but also by soiling from urine and fæces, which is prevented with difficulty in many cases. In certain severe cases of inflammation of the lumbar enlargement they may occur at a very early period and then seem to be due directly to trophic changes in the skin.

With proper care and treatment the bed-sores may remain confined to the integument, but not infrequently they extend more deeply, spread to the bones, and give rise to pyæmia; or, as we have also seen, the inflammation extends through the sacral foramina, and sets up a rapidly fatal meningitis.

The occurrence of cystitis is also an important symptom. Perhaps in the majority of cases it results from the introduction of foul catheters, but it may also develop when such a cause cannot be discovered. The danger in this condition consists in the secondary development of acute interstitial nephritis as the result of the introduction of bacteria along the ureter from the decomposing urine in the bladder. This complication usually proves rapidly fatal, but the writer has seen a few cases in which the post-mortem appearances warranted the belief that the morbid condition in the kidneys may subside. In such cases, however, death was the result of another attack of the same kind. But on the whole, the renal affection seems to be a rare cause of death, even if the cystitis remains unchanged for a long time.

Close study of the symptoms enables us to localize the lesion very accurately in cases of transverse myelitis.

In myelitis of the lower part of the lumbar enlargement the motor paralysis is confined to the muscles supplied by the sciatic (gluteal region, posterior thigh group, and all the leg muscles, with the exception of the tibialis anticus). The sensory disturbances (complete or incomplete anæsthesia) extend over the entire lower limbs, with the exception of the parts supplied by the obturator and crural nerves (anterior and inner portion of thigh). Reflex movements in the paralyzed parts are abolished. The sphincter ani is paralyzed. When the lesion is a severe one the paralyzed muscles undergo atrophy, and degeneration reaction is observed.

In a lesion of the upper part of the lumbar enlargement the motor and sensory paralysis involves the lower limbs completely.

In a lesion of the dorsal cord, more or less complete motor and sensory paralysis is observed in the lower limbs throughout, the anæsthesia extending upward to the intercostal nerves given off at the site of the lesion. The bladder and rectum are paralyzed. The muscles undergo very little or no atrophy, and the electrical reactions are unchanged. The cutaneous and tendon reflexes are increased on account of the abolition of the inhibitory influence from the brain.

In a complete transverse lesion of the cervical cord the paralysis affects all the limbs; when the transverse lesion does not cut across the entire cord the paralysis may be confined to the upper limbs (cervical paraplegia). The muscles of the trunk are also involved in these cases and this process is a great source of danger to life on account of the resulting interference with respiration. In lesions of the lower part of the cervical enlargement the intercostals are paralyzed. If the lesion extends higher the diaphragm also becomes paralyzed, from implication of the nucleus of the phrenic nerves. As a general thing the muscles do not undergo atrophy, because the disease usually proves rapidly fatal. When the cilio-spinal centre is involved we may observe dilatation or contraction of the pupil, according as the centre in question is irritated or paralyzed.

Optic neuritis has also been observed in rare cases of myelitis of other parts of the cord (usually of the disseminated variety), but its relation to the spinal inflammation is not clear. The neuritis and myelitis probably are effects of the same underlying cause.

In lesions of the upper cervical cord the symptoms are similar to those just described, except that they are better marked; but in these cases the disease is apt to spread into the medulla oblongata, and to involve certain of the cerebral nerves. The following brief abstract will illustrate the history of acute myelitis of the upper cervical cord, extending into the medulla oblongata.

A. B—— contracted syphilis two months ago. At the present time he presents a roseola, and is suffering from slight sore throat. On November 12th he had sexual intercourse while standing. During the same night he complained of an uneasy feeling in the legs, and of slight numbness in the tips of both middle fingers and in the feet. On the next day he walked up five flights of stairs twice, then the legs began to feel heavy. He managed to get about his room on the following day (Saturday), but on Sunday morning was unable to rise from bed. At my first visit (November 16th, 6 P.M.) I found the patient in the following condition: Almost complete paralysis of the lower limbs; slight motion of the thighs; a little reflex action from the soles; numbness of the entire limbs. He could hold his water, but after it began to flow was unable to check it. Very marked paralysis of the upper limbs, especially the right limb, but most movements could be performed slowly; partial anæsthesia of the upper limbs and trunk, none of the face; voice a trifle hoarse; temperature normal; respirations, 16; pulse, 84 and of good quality. The patient does not use the diaphragm in breathing, but can do so quite well voluntarily. He says that he sometimes has difficulty in breathing, and can't cough as well as yesterday.

November 17th, 9 A.M.—Passed a bad night, unable to sleep at all; whenever he was about to doze off had to struggle for breath; had one bad attack of dyspnœa which lasted three hours. No reflex from the soles of the feet; power absolutely lost in lower limbs; also worse in upper limbs, particularly the right; sensation more blunted; passed a large quantity of urine at 5 A.M. Respiration, 20; pulse, 90; respirations interrupted occasionally by a long breath; more difficulty in breathing; still moves the diaphragm voluntarily, but not so vigorously as last night. Speech is more hoarse, the vowels are not enunciated very clearly. Slight anæsthesia of the left side of the face, paresis of the left internal rectus, also of the right side of the face. He has double vision over a small area a little to the left of the median line on the horizontal. All the right facial muscles are paretic; he is unable to close the right eye entirely.

November 17th, 8 P.M.—Condition unchanged, has slept at intervals, once for half an hour at a stretch.

November 18th, 10 A.M.—Left pupil slightly dilated, but reacts to light; left side of face not so numb; paresis of internal rectus improved; no double vision; enunciates vowels more distinctly. Paralysis of the limbs is a little more marked; no reflex from soles; urine passed freely. During the night had severe pain between the shoulders; respiration, 22; pulse, 86; diaphragm not so active, but respiration easy.

November 18th, 9 P.M.—Respiration, 33, and more labored; diaphragm weaker; pulse, 84 and weaker. Skin cool and covered with cold sweat; looks a little bluish; face flushed; patient looks excited and talks a good deal —says "he is off his nut because he has taken too much brandy;" pupils normal; speech more difficult, vowels less distinct; does not swallow so well. The patient died at five o'clock the following morning, after increasing difficulty in breathing.

Varieties.—Very little need be added with regard to the special forms of myelitis after our detailed account of the history of transverse lesions.

Westphal's disseminated myelitis, in which the inflammation appears in scattered foci, separated by healthy tissue, has not been studied very thoroughly. The symptoms generally begin less brusquely, and, unless several foci of inflammation are closely approximated to one another so that the cord is practically cut across by the lesion, they point distinctly to a focal lesion. For example, a small focus in the cervical enlargement may cause paralysis of one arm, perhaps of the leg on the same side; while another focus in the lumbar enlargement may cause paralysis of one or both legs, etc. Much depends in such cases on the close observation of the sequence of symptoms and on the etiology (chiefly acute infectious diseases and syphilis). It must be confessed, however, that the literature of disseminated myelitis is very scanty, and that most of our knowledge concerning it is purely hypothetical.

Compression myelitis is the term applied to inflammation of the spinal cord secondary to compressing lesions outside of the cord (caries, cancer, or exostoses of the vertebræ, erosion of vertebræ, and pressure of an aneurism), or to tumors of the cord itself, which give rise to compression of adjacent parts. This form of myelitis is usually very slow in its onset, but inasmuch as some cases begin abruptly, we will devote a little attention to it under the heading of acute myelitis.

It would be a mistake, however, to regard all cases usually included under this head as really the result of compression. In Pott's disease, for example, we find, as a rule, that the disease of the bone has given rise to peripachymeningitis, and also to pachymeningitis which, together with the narrowing of the canal incident to the displacement of the vertebræ, causes compression of the cord and secondary inflammation. But in not a few cases of Pott's paraplegia we find that the vertebral displacement has occurred in such a way that compression of the cord is not produced, and that the amount of meningeal thickening is too slight to produce compression. In such cases we may attribute the myelitis to the direct irritation of the cord by the products of meningeal inflammation.

In the majority of cases compression-myelitis is the result of Pott's disease, and the lesion is situated in the dorsal region. In this condition the disease is often preceded by symptoms of irritation of the roots of the nerves by the diseased bone or membranes, consisting of a cincture feeling around the abdomen and chest, or pains in the legs; sometimes there is an eruption of herpes zoster upon the trunk or lower limbs. It is a peculiar feature of this condition that the occurrence of paralysis may be preceded for quite a while by a marked exaggeration of the knee jerk and ankle clonus. In the same way, these symptoms may persist for a long time after the recovery of motor power.

After the motor paralysis has developed, the symptoms differ in no respect from those of ordinary transverse myelitis, except that there is usually a much greater discrepancy between motor and sensory paralysis, the latter being very often entirely absent. The paralysis exhibits very little tendency to extend beyond the parts originally involved. In a certain proportion of cases the lower limbs become contractured—the thighs flexed on the abdomen, the legs on the thighs—or shooting pains in the lower limbs become a prominent feature of the disease. To judge from his own experience, the writer is inclined to believe that this condition is particularly apt to develop when the myelitis is the result of irritation of the cord rather than of compression by morbid products.

When the compression myelitis is the result of cancer of the vertebræ, pains in the lower limbs and trunk are extremely distressing, and if cutaneous sensation is abolished at the same time, the condition is known as anæsthesia dolorosa. Apart from the excessive violence of the pains, this paraplegia dolorosa cannot be distinguished from other forms of compression myelitis.

Diffuse central myelitis is another rare variety of the disease, in which the lesion is confined chiefly to the central gray matter of the cord. It generally begins very suddenly with anæsthesia and loss of power in the lower limbs. The evidences of a severe cord lesion soon become manifest. The motor paralysis rapidly becomes complete, the cutaneous reflexes and the knee jerk are soon lost, the muscles undergo rapid atrophy and present degeneration reaction at an early period. The bladder is paralyzed from the start, and ugly bed-sores soon form over the sacrum. Then the paralysis and anæsthesia rapidly extend upward, involving the intercostal muscles and upper limbs. Finally, the muscles of deglutition and the diaphragm are attacked, and speedy death ensues. The entire course of the disease, indeed, presents a picture of malignancy which is rarely found in other forms of myelitis. In rare cases the acute symptoms subside and the disease passes into a chronic stage, but a certain degree of doubt attaches to the diagnosis in cases which do not terminate fatally.

In concluding the clinical history of myelitis we will refer briefly to a mode of termination which has been unnoticed by the majority of writers. In a number of cases which have come under our observation the disease appeared to begin as a transverse myelitis; but the symptoms cleared up in great part, and then merged into those of locomotor ataxia or multiple sclerosis. In the following case—by no means the most striking one—we were fortunate enough to obtain a post-mortem examination.

J. D——, thirty-five years of age, married; entered Randall's Island Hospital on September 4, 1883. The patient gives no evidence of syphilis; habits regular.

The present illness has lasted nine months; it began with ptosis of the right eye; shortly afterward he began to have shooting pains in the legs and arms. In a few weeks he had to quit work on account of the pains and weakness in the lower limbs. About five months ago the patient got so weak that he was unable to walk, and had trouble in holding his water.

Present condition (October 4, 1883).—Patient walks with assistance, but has a characteristic heel gait, and must watch the movements of his feet; he reels to and fro when standing with the eyes closed.

Anæsthesia and analgesia are present below Scarpa's triangle in both thighs and legs; patellar reflexes absent. Slight inco-ordination of upper limbs, and some numbness of the fingers. Partial ptosis of right eye; both pupils very much dilated, and react poorly to light; optic papillæ unchanged; special senses normal. The dynamometer is forced to forty by the right hand, to thirty-six by the left hand.

October 24th.—Had a pulmonary hæmorrhage; dulness and a few moist râles over the upper lobe of left lung.

The motor power of the lower limbs improved considerably, but the incoördination rapidly grew worse, the limbs jerking in every direction when any voluntary movement was attempted. There was very marked emaciation, but the muscular power finally appeared to be normal compared with the amount of muscular tissue retained. The pains disappeared almost entirely; sight remained normal. The phthisis continued to advance, and the patient died January 7, 1886, without the development of any fresh symptoms on the part of the nervous system.

Microscopic examination of the spinal cord showed complete sclerosis of the posterior columns (enormous increase of the neuroglia and of nuclei), together with a general increase of connective-tissue elements in the remaining portions of the cord, with the exception of the gray matter, which seemed to be perfectly normal. In addition, the blood-vessels of the posterior columns were very much dilated, and their walls were exceedingly thickened, particularly the adventitia, in which the nuclei were enormously increased. The nuclei around the central canal were increased in number, and there seemed to be, also, an increase of fibrous tissue in this locality. Here and there in the other columns of the cord were seen blood-vessels which also presented a considerable increase of nuclei.

PATHOLOGICAL ANATOMY.—In a good many cases of acute myelitis no change in the structure of the cord is visible to the naked eye. Sometimes the diseased parts are softened, and their color is changed. The cord cuts less firmly than in the normal state, the cut surface projects as if the cord were too large for the enveloping pia mater, and the normal differentiation between the white and gray matter becomes less distinct or is entirely effaced. The entire surface has a reddish tinge, sharply defined reddish streaks (distended blood-vessels) are often seen, particularly in the white matter; and here and there we occasionally notice minute red specks (capillary hæmorrhages). In some cases these hæmorrhages form the most marked change to the naked eye, and the cut surface has a bright red, or, at a later stage, chocolate color (hæmorrhagic myelitis). The degree of softening varies between very wide limits. In some cases it is entirely absent, in others it is so pronounced that the diseased part of the cord, but particularly the gray matter, is diffluent and flows out like cream.

Microscopic examination is usually necessary in order to be certain of the presence of myelitis. It is still a mooted question whether the changes begin in the blood-vessels or in the parenchymatous tissues of the cord, but it is more than probable that the primary changes occur in the vessels.

The blood-vessels (small arteries, veins, and capillaries) are distended with blood, the walls increased in thickness, and the nuclei have undergone proliferation. White and red blood-corpuscles are found in abundance within the sheaths of the vessels and the adjacent parts of the nervous tissues. The cellular elements of the neuroglia are also increased in size, and are much more numerous than usual. In addition, granular fatty cells are found in great numbers. These cells often contain one or more drops of myelin, and are the result of fatty degeneration of white blood-globules, which may or may not absorb myelin. They are not characteristic of myelitis, but are also found in softening from any cause. It is probable that the neuroglia cells, when they undergo proliferation, also take part in the production of these granular corpuscles. The granulo-fibrillar part of the neuroglia also undergoes proliferation, and becomes much more prominent than in the normal state.

The most important changes are found in the nerve-fibres and ganglion-cells. The medullary substance of the former coagulates into clumps of varying size, which gradually become smaller and smaller, and are finally converted into fatty granules. The most common change in the axis-cylinders consists of dilatation, which sometimes assumes enormous proportions, but is not distributed uniformly over the entire length of the fibre. In addition, the axis-cylinder loses the faint striation which it originally possesses, and in severe cases it finally undergoes complete disintegration.

The first change noticed in the ganglion-cells is the increasing homogeneity of their finely granular contents, which is always associated with some change in chemical constitution, as shown by the fact that they stain less readily with coloring reagents. The cell contents assume more of a yellowish, blurred look, the processes seem to retract and become thicker, the cell becomes rounded, and the nucleus grows more indistinct. Finally, the cell may shrivel up and be converted into a small shapeless mass, which usually contains an excess of pigment. Vacuoles are often found in the cells, but doubt has been cast upon the ante-mortem development of this condition. The corpora amylacea are often increased very much in number, but this is not characteristic of inflammation.

The majority of authors are agreed that severe inflammatory changes cannot be recovered from. This does not seem to be in accord with the writer's experience, that almost complete recovery may occur in certain cases in which the clinical history has pointed indubitably to a very severe and extensive inflammation of the spinal cord.

In extremely rare cases acute myelitis terminates in the formation of one or more small abscesses in the cord. The usual termination is by the development of an excessive amount of neuroglia tissue. The development of cysts as the result of absorption of the fluidified nervous structure is also a rare termination.

With regard to the secondary degenerations of the cord which are found after myelitis, we refer to page [illegible], Vol. VI.

Diagnosis.—Acute myelitis must be distinguished from meningitis. The latter affection is very much rarer, apart from those cases in which it is associated with inflammation of the cerebral pia mater, than acute myelitis. In the former the pains in the back and limbs, the cramps in the muscles, and hyperæsthesia are much more marked than in myelitis, and usually persist for a much longer time. Paralytic symptoms are not well marked, and the bladder and rectum, as a rule, are unaffected. In myelitis, on the other hand, the initial irritative symptoms are often entirely absent, or, in the very large majority of cases, soon give place to anæsthesia and motor paralysis. With the exception of certain cases of inflammation of the cervical cord, fever is usually absent or slight in myelitis; in meningitis there may be decided febrile movement.

In two cases we have seen acute myelitis mistaken for acute articular rheumatism—once in a child suffering from compression myelitis of Pott's disease, another time in an adult with extremely acute dorsal myelitis. In both patients the joints of the lower limbs were very tender on pressure, and in the adult there was high fever. In the former, however, examination of the spine revealed a well-marked kyphosis, the loss of power was disproportionate to the apparent severity of the pain, and the tendon reflexes were greatly exaggerated. In the latter the patient also suffered from rapid pulmonary phthisis, which explained the high fever; the pains were not confined to the joints, but were also marked in the muscles, and the lower limbs were anæsthetic (anæsthesia dolorosa).

Hysteria is sometimes mistaken for myelitis, especially when it occurs in young females, or *vice versa*, myelitis is sometimes, though less frequently, regarded as hysterical paraplegia. The occurrence of other undoubted evidences of hysteria is an important point in diagnosis, but too much stress should not be laid upon this feature, since it must be remembered that hysterical individuals are also liable to be attacked by myelitis. The etiology should also be taken into consideration, and in the absence of any of the causes previously mentioned, the diagnosis of myelitis in a young female should be looked upon with suspicion. In hysterical cases, however, the evidences of serious organic lesions of the cord are always wanting. There is no pronounced wasting of muscles, no change in their electrical excitability, no loss of power of the bladder and rectum. On careful observation, moreover, it is often found that the apparent paralysis varies in different positions of the body, and that there are sudden changes in motility which remain inexplicable on the theory of an organic disease of the cord.

The diagnosis from hæmorrhage of the cord is usually easy, except in cases of hæmorrhagic or apoplectiform myelitis, when the symptoms have come on with extreme rapidity. Hæmorrhage into the spinal cord is extremely rare, except as the result of injury. The symptoms of motor paralysis attain their utmost severity at once, and then, unless the hæmorrhage is situated high in the cervical region, begin to improve slowly up to a certain point. With the exception of the suddenness of the onset, and the previous occurrence of traumatism, there is really no means of differentiating spinal hæmorrhage from acute myelitis. In the majority of cases, indeed, the hæmorrhage is followed by myelitis, either as the result of the injury to the elements of the cord from the traumatism, or of the irritation excited by the clot.

Acute central myelitis is sometimes distinguished with difficulty from Landry's paralysis. In the latter disease, whose pathological anatomy is unknown, sensory symptoms are unimportant, or may be entirely absent. The motor paralysis begins in the lower limbs, but extends in a few days to the upper limbs, and then to the centres for respiration and deglutition, the disease rarely lasting more than from one to two weeks before terminating fatally. The electrical irritability of the paralyzed muscles is usually normal, but in certain doubtful cases diminution of faradic excitability has been reported. The functions of the bladder and rectum are usually undisturbed. It seems probable, from the histories of recently reported cases, that enlargement of the spleen is quite a constant feature of the disease. But despite these numerous points of difference between this disease and myelitis, the question of diagnosis will sometimes remain doubtful in those cases which terminate in recovery.

After the diagnosis of myelitis has been made, the question may arise, Is the spinal inflammation due to pressure? This is not always easy to answer. In the majority of cases of compression myelitis the primary lesion is caries of the vertebræ, and, as a general thing, the deformity of the spine is so pronounced that there can be very little doubt with regard to the diagnosis. In Pott's paraplegia, moreover, the exaggeration of the cutaneous and tendon reflexes is an important sign which may precede other symptoms for a considerable period, and may persist after other evidences of myelitis have disappeared. In addition, the sensory symptoms are usually much less pronounced than those in the motor sphere, and may even be entirely absent, despite complete paralysis of the limbs. In a few cases, however, particularly when the patient has been confined to bed on account of some other disease, spinal deformity may not be noticed, and the myelitis is then apt to be regarded as primary.

When compression-myelitis is secondary to cancer of the vertebræ, the recognition of the nature of the primary disease usually depends on the presence of a primary cancer in some other part of the body, on the violence of the pains in the paralyzed parts (especially if associated with anæsthesia), and the presence of a deformity of the spine which seems to be due to an irregular enlargement of the vertebral arches or lateral masses. It must not be forgotten, however, that cancer of other parts of the body may be associated with ordinary vertebral caries. In a case of this kind recently under my observation, I made the diagnosis of compression-myelitis from vertebral cancer, but the autopsy proved that the disease had been an ordinary Pott's paraplegia.

The diagnosis of the localization of the inflammation in the cord depends upon the grouping of symptoms, for which we refer the reader to the section on clinical history.

Prognosis.—Complete recovery from acute myelitis, with the exception of the compression-myelitis of Pott's disease, is a comparatively rare result. Incomplete recovery is by far the most frequent termination, although a fatal result is by no means uncommon. Other things being equal, the disease is more apt to terminate fatally, the higher the location of the lesion in the cord. If the centre for the phrenic nerve has been attacked, as shown by paralysis of the diaphragm, recovery is extremely rare. The occurrence of bed-sores is likewise of grave import, particularly if they develop at an early period. When they occur after the disease has lasted a long time, they often heal quite rapidly under suitable treatment. Mild cystitis is so common in myelitis that it can hardly be regarded as aggravating the prognosis, but in severe cases, especially if the bladder is completely paralyzed, there is always danger of the production of acute interstitial nephritis. The latter affection is almost inevitably fatal at an early period, though, in some cases, it seems to pass into a stage of quiescence.

The prognosis as regards recovery is also so much the more impaired the greater the degree of implication of the gray matter, as evidenced by rapid atrophy of the paralyzed muscles and degeneration reaction in these parts. But it must also be remembered that even the most marked atrophy of the muscles, and complete abolition of their electrical irritability, does not entirely preclude the possibility of a very satisfactory degree of recovery. I have had under observation a patient in whom the limbs were completely paralyzed, and wasted to the extreme, and degeneration reaction was present except in those muscles in which no reaction could be obtained (even the intercostals were partly paralyzed); and yet this patient, at the end of a year and a half, was able to walk about and to perform her duties in such a satisfactory manner that she requested her discharge from the hospital.

The occurrence of a spastic condition of the lower limbs constitutes an almost insuperable obstacle to any further improvement. The degree of motor power which is acquired in these cases, however, is usually quite considerable, and the patients are often able to move about quite freely, unless the rigidity of the limbs is excessive.

Pott's paraplegia generally offers a favorable prognosis, unless the vertebral caries itself, or its sequelæ, constitutes a serious menace to life. Improvement in apparently hopeless cases sometimes comes on quite suddenly, and the patient may recover even from a number of severe attacks. In these cases there is always danger of a relapse so long as the tendon reflexes remain exaggerated.

Treatment.—In order to avoid repetition this subject will be considered in connection with the treatment of chronic myelitis.

CHRONIC MYELITIS.—*Etiology.*—Chronic myelitis is a much rarer affection than the acute or subacute form of the disease. It is well to bear in mind that the term should not be applied to those cases in which a chronic condition of paraplegia is left over as a sequel of acute myelitis. The use of the term is justifiable only when the disease begins in a slow and insidious manner.

The causes of chronic myelitis are similar to those of the acute form. It is generally held that the difference in the mode of beginning is the result of differences in the intensity of the etiological factors—for example, sudden and violent exposure will produce acute myelitis, long continued and less severe exposure will produce chronic myelitis—but it seems to me that this view is based on theory rather than on well-established clinical facts. In traumatic cases a single traumatism may set up an inflammation of the cord which does not make its appearance until long after the symptoms of the original injury have subsided. Perhaps there has been some spinal pain for a few days or weeks after the injury, then the patient feels entirely well; but a few months later the signs of slowly advancing myelitis make their appearance.

Syphilis seems to exert a considerable influence as a predisposing cause, but it is questionable whether it acts by simply making the spinal tissues more vulnerable or by the production of gross lesions in the vessels or mem-tissues of the cord. It seems probable, however, that in a large proportion of such cases the former theory is correct, the syphilitic virus appearing to act as a potent predisposing factor, as it does in the production of locomotor ataxia.

Alcoholism also appears to exert a great influence in the production of chronic myelitis; but we must bear in mind that this vice is often connected with repeated exposure to cold and wet, and to violence, and that it is difficult to decide between the parts played by each of these factors.

Symptoms.—The symptoms of chronic myelitis are very similar to those of the acute form, except that they develop more slowly and insidiously. In some instances this gradual course may be interrupted occasionally by more or less acute exacerbations. In the majority of cases the disease affects the dorsal region, and hence the symptoms are those of slowly developing paraplegia. As in the acute form, the sensory symptoms are generally much less marked than the motor phenomena. The patient complains of formication and tingling in the feet, or a sense of numbness in the soles, so that the floor does not feel natural in walking. This condition may last a very long time, although no change in sensation can be noticed objectively after the most careful examination. Pain is not a prominent feature, although there is often complaint of a slight girdle feeling around the abdomen. Slight dull pains are often felt in the back and limbs, particularly after walking for some length of time. These symptoms may last a long time before any motor weakness becomes apparent. The patient notices that he becomes more tired than usual after walking, and finally begins to drag the legs. Rigidity of the lower limbs is an early and almost constant accompaniment of the loss of power (spastic paraplegia). In many cases, indeed, we have noticed a marked development of this spastic condition before any real loss of power could be detected. At the same time the tendon reflexes are notably increased. In some cases disturbances of sensation, which can be determined by objective examination, may be entirely absent, and subjective sensory disturbances may also be extremely slight, or wanting. The symptoms are then exactly similar to those of so-called primary lateral sclerosis, and may remain in this stage for several years before the advent of other symptoms attests the spread of the disease.

In a very small proportion of cases, particularly in those which are due to syphilis, the lesion is confined to a small section of the cord, and, if limited to one-half, may give rise to the symptoms of spinal hemiplegia (paralysis of motion on one side, paralysis of sensation on the opposite side). As a general thing, however, the lesion is not confined exactly to one-half of the cord, but extends somewhat into the other side, and motor and sensory symptoms are therefore observed in each limb, although the paralysis of motion is more marked in one, that of sensation in the other. In this form of the disease, sensory symptoms (anæsthesia, pains in the back and limbs) usually form an important feature.

As a general thing, the lesion slowly spreads along the cord in an upward or downward direction (usually the former), and other parts of the body become involved. The spread of the disease may be exceedingly slow, and even twenty or thirty years may elapse before the final termination. In other cases the chronic course may be interrupted by acute exacerbations. We have also seen several cases in which the symptoms of chronic myelitis appeared to merge later into those of posterior sclerosis or multiple spinal sclerosis.

Pathological Anatomy.—The pia mater over affected parts of the cord is often thickened and opaque, and more firmly adherent to the underlying structures. In many cases the cord itself may appear unchanged, but usually the myelitic portions are firm to the feel, show greater resistance on cutting than adjacent parts, and have a distinctly gray color. Here and there enlarged vessels are sometimes discernible. In rare cases we find cavities in the cord (syringomyelia), the origin of which is still a matter of discussion. The most generally accepted theory at the present time is that of the origin of the cavities in a gliomatous new formation. Joffroy and Achard, however, have recently written an excellent article in which they maintain, with great ability, the origin of these cavities as a result of chronic myelitis. The following is a brief summary of their views: The cavities are of varying size and shape, are situated chiefly in the cervical and dorsal regions, and almost exclusively in the gray matter, particularly of the posterior horns. They are not due to dilatation of the central canal, which is unchanged in some cases. The lesion may affect one or both sides of the cord; the surrounding tissues may be very slightly involved. A cavity sometimes occupies the centre of a focus of myelitis, which extends by preference into the lateral columns. Chronic inflammation of the pia mater may also be present. The writers believe that the disease is due to chronic myelitis, because at the upper and lower limits of the cavernous lesion the appearances are simply those of diffuse sclerosis, situated generally near the central canal. The cavities are due to the fact that the vessels in the focus of inflammation are obliterated by thickening of their walls or by thrombosis, and the resulting necrotic substance is absorbed.

The microscopical appearances are very similar to those left over after acute myelitis has passed into the chronic stage. The changes in the interstitial tissue are particularly noteworthy. The granular condition of the neuroglia is lost, and in its stead we find a fibrillated tissue, containing an unusually large number of neuroglia cells and round cells. The blood-vessels are usually very much dilated, their walls decidedly thickened, and their nuclei increased in number. The sheaths of the vessels are apt to contain broken-down white and red blood globules, pigment, and fat granules.

The axis-cylinders are found to vary greatly in size; some of them are remarkably large, others are very decidedly atrophied, and have lost their medullary sheath. The ganglion cells contain an increased amount of pigment, are diminished in size, and often destitute of processes, and many of them are converted into shapeless masses in which no definite structure is distinguishable.

Diagnosis.—The diagnosis of chronic myelitis is usually a comparatively easy matter, and is almost always tantamount to the recognition of a slowly developing paraplegia. It is not so apt as acute myelitis to be mistaken for hysterical paraplegia, because the latter disease usually begins much more abruptly than chronic myelitis, which may advance slowly for years. The frequent occurrence of changes in the electrical excitability of the muscles in chronic myelitis is also a distinctive feature.

Railway-spine, when due to chronic myelitis or meningo-myelitis, may prove a source of great difficulty in diagnosis, especially because the element of malingering so often comes into play in this condition. When this factor can be excluded, the diagnosis is based on the slow development of symptoms, at a variable period after the injury, which point to disseminated focal lesions of the cord: irregularly distributed paralyses, various paræsthesiæ, pain in the spine and limbs, disturbances of micturition, localized atrophies of muscles. A depressed and irritable condition of the mental faculties, with loss of memory, is quite common in this condition.

The diagnosis of chronic compression myelitis is made in the same way as that of the acute form, except that the symptoms develop much more slowly. Acute exacerbations are particularly apt to develop in this form of the disease.

Chronic myelitis can only be distinguished from the persistent paraplegia left over after an acute attack, by the history of the onset of the illness. When, for any reason, the patient is unable to furnish the previous history, the diagnosis is impossible.

Tumors of the spinal cord or its membranes are rare, and their differential diagnosis from chronic myelitis is extremely difficult. The clinical history of the former consists essentially of symptoms of irritation of the nerve roots, followed by those of compression of the cord. In some cases, however, the latter precede the former. The compression of the nerve-roots sometimes lasts for years before the evidences of compression of the cord make their appearance. Probably the most important point in the differential diagnosis is the great variation in the severity of the symptoms which is sometimes noticed. In addition, it is found not infrequently that the first evidences of compression of the cord occur in the form of spinal hemiplegia, owing to the fact that the tumor often develops first in one lateral half of the cord.

Prognosis.—The prognosis of chronic myelitis is always grave. Even chronic compression myelitis, which presents the most favorable prospects among the different forms of the disease, rarely terminates in recovery. Unless the slow course of the spinal inflammation is interrupted by acute exacerbations, the patient may linger for years. The longest lease of life is enjoyed in those cases of transverse myelitis in which the disease does not extend up the cord. The greatest danger in these cases arises from the development of cystitis and secondary interstitial nephritis.

In the syphilitic forms of chronic myelitis we are sometimes able to secure a fair degree of recovery, especially if treatment is begun before the disease has extended across the entire section of the cord. But even here it will be found that complete recovery is rarely practicable.

It is held by many writers that cases of railway-spine, which, as we have stated, is probably due to chronic myelitis and meningo-myelitis, usually recover; but this statement does not agree with the experience of the majority of unbiassed observers.

Treatment.—The treatment of acute and chronic myelitis will be considered under this heading, because the treatment of the latter form is similar to that of the sequelæ of acute myelitis.

The most important indication is to secure as absolute rest in bed as is possible under the circumstances. As soon as any symptoms make their appearance which suggest the onset of myelitis, the patient should take to bed and remain in the recumbent position. The wants of nature should be attended to with the aid of the bed-pan, in order to avoid, as much as possible, movement during the acts of urination and defecation. This is, in our eyes, by far the most important remedial agent at our command. It is often difficult to determine at what period it is best to allow the patient to begin to exercise the paralyzed limbs, but it is always better to err on the safe side. We have seen very marked improvement in a number of apparently hopeless cases, in which this plan had been faithfully carried out for a year to a year and a half.

Contracture of the tendo Achillis is a very common sequel of all forms of myelitis, and it has been suggested to me by one of my colleagues that the pressure of the bedclothes upon the feet may exercise some influence in the production of this unfortunate symptom. In order to obviate this, the bedclothes may be suspended on a barrel hoop placed across the lower part of the bed. But the contracture will develop, despite this precaution, in a considerable number of cases.

Next to rest, cleanliness is all-important, because its neglect is very apt to result in the production of bed-sores. This usually necessitates the most careful nursing. The external genitalia and gluteal regions must be frequently washed, and thoroughly but gently dried. At the slightest indication of the development of a bed-sore, an air-ring should be placed under the buttocks, care being taken that the joints of the ring are not sharp. If the evidences of dermatitis are not relieved speedily in this way, the patient should be placed on a water-bed. When a bed-sore has formed, we know of no better treatment than Brown-Séquard's method of application of cracked ice followed by a flaxseed poultice. This may be followed by dusting with iodoform, or, if the sore is too large, the application of a simple carbolated ointment.

The bladder must be carefully looked after. If the patient can urinate in the prone position, even after considerable effort, he should be encouraged to do so, in order to obviate the necessity of catheterization. But the latter must be resorted to at once, as soon as the bladder is no longer thoroughly emptied. The greatest precautions must be taken to keep the catheter thoroughly antiseptic in order to prevent the introduction of germs. Even a soft rubber catheter must be introduced very gently, inasmuch as the mucous membrane of the bladder is very apt to be congested, and bleeds readily under such conditions.

Counter-irritation is useful in very many cases. During the first stages of an acute myelitis the application of dry cups along the spinal column may be attended with some benefit. Vigorous counter-irritation with fly-blisters is indicated at a later period, but these do not promise much improvement after the disease has become stationary. In this connection we may mention that in a case of chronic myelitis in which all hope of recovery had long been abandoned, we noticed a remarkable degree of permanent improvement follow the development of a large carbuncle of the back.

The actual cautery is also recommended. We have never seen any benefit from its use, except in rare cases of compression myelitis. In such cases, however, it sometimes acts with remarkable rapidity.

Among other non-medicinal agents may be mentioned baths and electricity.

As a rule, the patient cannot tolerate extremes of temperature. We usually recommend a sitz-bath at a temperature of 100° to 110° F., in which the patient remains for from fifteen minutes to half an hour. If spastic phenomena are well marked, the bath may be as hot as can be borne by the patient. When the spastic phenomena are not prominent the patient may receive a full bath at a somewhat lower temperature. It is well in such cases to follow the bath with rubbing and massage.

Electricity, when faithfully and persistently applied, is often productive of excellent results. It is used as a spinal current, or directly to the paralyzed or contractured parts. When applied to the spine one large electrode should be placed over the site of disease, the other on some indifferent part of the body or spine, and should be held constantly in position for from three to five minutes. The direction of the current seems to be immaterial. Much better results are obtained from applying the current directly to the paralyzed parts. In the majority of cases the galvanic current is preferable, but the faradic current may be used when the muscular contractility remains normal. The current should be merely strong enough to produce visible contraction of the paralyzed parts. The constant stabile galvanic current is used in the treatment of contractures, the electrodes being applied directly to the nerves supplying the contractured muscles. At the same time the interrupted galvanic or faradic current may be applied to the antagonists. In our own experience very little, if any, benefit has been derived from spinal galvanization; but, on the other hand, we have obtained most excellent results from the patient, persistent use of local electrization. This even holds true of cases of marked contractures of the lower limbs, but a good deal will then be gained by the electrical course combined with tenotomy of the contractured parts.

Medicinal treatment does not play a great part in the management of this disease. Ergot has been highly recommended in the acute stages, and hypodermic injections of ergotine have been employed at the onset of hæmorrhagic myelitis. We have never seen the slightest advantage from its use, and have abandoned it altogether. Iodide of potassium has also been recommended very highly, and Dr. Gibney speaks in the most favorable terms of its administration in large doses (even ʒ j.–ij., t. i. d., in children), in the compression myelitis of Pott's disease. It is very difficult to form an opinion upon the value of this agent in myelitis, but it has seemed to us to exercise a certain amount of beneficial effect. But we have employed it so faithfully, and with such little effect, in Pott's paraplegia, that we are compelled to deny any special influence in this form of the disease. Weir Mitchell has recently recommended suspension in this disease, but the value of the measure must be determined by future investigation.

The only medicinal agent which has seemed to have a decided influence in our hands is strychnine. This drug may be administered as soon as the acute symptoms have ceased to advance, and it is by no means contraindicated by the occurrence of spastic symptoms. The dose may be raised gradually from gr. $\frac{1}{60}$ to gr. $\frac{1}{20}$ t. i. d., and may be given continuously for months.

So long as any improvement is observed, the patient should be kept as quiet as possible. Later, gentle exercise may be allowed, but the patient must not be permitted to tire himself. Sexual intercourse is particularly to be avoided. Even after the condition of the patient has been stationary for a long time, benefit is sometimes derived from another course of treatment with electricity, counter-irritation, and strychnine. *Leopold Putzel.*

SPINAL CORD, SURGERY OF THE. The attention of the surgical world, already on the *qui vive* in the matter of cerebral surgery, was again instantly arrested by an important paper of Horsley and Gowers[1] in which was reported for the first time the removal of a spinal tumor. The patient was a man, forty-two years of age, who for three years had suffered a great deal beneath the left scapula, and for four months had been paraplegic. The motor and sensory paralysis extended to the base of the sixth dorsal nerve, with spasms in the legs and feet, clonus of the rectus, cystitis, and retention of the urine. On June 9, 1887, the tumor was removed and the wound healed by the first intention. The patient gradually recovered to such an extent that he was able to dance and to walk three miles with ease. This case was quickly followed by the remarkable paper of Macewen,[2] in which he records six cases in which the posterior arches of the vertebræ had been removed. Three of the cases were paraplegics from connective-tissue tumors at the angular curvature of the spine, and were completely cured by removal of the tumor. Two of the other cases succumbed—one a week after the operation, the other some months later—from general tuberculosis. The sixth case was one of paraplegia from traumatism, which was cured by opening the spinal canal, elevating the depressed arch of the twelfth dorsal vertebra, and dissecting away the connective-tissue tumor on the theca of the cord, extending from the eleventh dorsal to the second lumbar vertebra. The tumor was one-fourth inch thick. In addition to these, Macewen has evacuated an abscess in the posterior mediastinum which was exercising pressure on the heart and bronchi. The operation was completely successful. Macewen did the first of these spinal operations on May 9, 1883, and reported the case in *The Lancet*, 1885, i., 881. Since then Wright, of Manchester,[3] has reported an operation on a case of angular curvature, with temporary, but no permanent benefit. Thornburn, of Manchester, has reported two cases, in one of which[4] Mr. Jones trephined a boy for dislocation of the second lumbar vertebra, with partial paraplegia. He removed some dense cicatricial tissue. Twenty months later he could walk three miles, and was still improving. In the other case,[5] Mr. Southam trephined the third dorsal arch and evacuated some pus from an apparent idiopathic abscess outside the dura, but without success.

Mr. Keetley[6] operated unsuccessfully on a fracture of the spine with complete rupture of the cord. Rogers[7] has reported a successful case of prevertebral abscess in the dorsal region, which was evacuated by the resection of a number of ribs and the transverse process of a vertebra. Besides evacuating some pus, he removed some fragments of bone in the vertebral canal. Deaver and Lloyd[8] report a case of tumor of the cervical spine which was removed unsuccessfully. The dura was not opened, but was merely punctured by a small exploring needle, which showed it to be tougher and thicker than normal. The swelling on the side of the spine was found to be the thickened and somewhat displaced lamina of the vertebra. There was said to be some osteomyelitis.

In the *St. Louis Medical and Surgical Journal* for June, 1888, Dr. W. T. Wilkins reports a case of a child born "with a growth on its back," the mother having been severely injured the day before its birth. On operation on the day after birth, the last dorsal and first lumbar vertebræ were found separated a half inch, and a hernia protruded through the fissure. The spinal cord was pushed to one side. The hernia was reduced, the two vertebræ held together by a figure-of-8 carbolized silk ligature passing through the intervertebral notches of the two vertebræ above and below, and the child was practically well in a few days.

In the *Medical News*, December 22, 1888, Dr. Morton reports a case (in which I assisted him) in which, for fracture and dislocation of the vertebræ, he removed the laminæ and articulating processes of the first lumbar vertebra and exposed the canal. The wound was drained, sutured, and dressed antiseptically, and the patient made an excellent operative recovery, though the paraplegia is still almost total. In the same journal Dr. Roberts alludes to a case of Dr. J. W. White of removal of the posterior arches of three or four cervical vertebræ in the search for a supposed tumor. None was found, but the patient's condition bettered after the operation. Abbe[9] reports a case of tubercular tumor compressing the cord, with paraplegia. The operation gave exit to two ounces of cheesy pus. The posterior arches of the eighth, ninth, and tenth dorsal vertebræ, and a mass of dense connective tissue, were removed. The cord for nearly two inches and a half was compressed against the anterior wall of the canal. Nine weeks later he could walk with the support of a chair, and was still improving.

These, so far as I have been able to discover, are the only operations on the spine so far published, but I am aware that two or three other unpublished operations have been performed. These cases show that in angular curvature of the spine, with implication of the cord, much may be done by way of relief, and with good prospects, in not a few cases, of cure of a recent compression; that pressure on the cord from traumatism, in favorable cases, may very probably be greatly relieved; that abscesses in the posterior mediastinum or in the vertebral canal are not beyond the reach of surgical aid; that a tumor of the cord may be successfully removed, and the patient sometimes cured. Of course it is quite too early in the history of spinal surgery, as of cranial, to draw any definite conclusions, but these cases at least point out the way in which we should travel. Experience will undoubtedly demonstrate that we can do far more than has been done or hitherto dreamed of as possible. Indeed in Mr. Horsley's paper he has analyzed fifty-seven cases of tumor of the cord and has shown that eighty per cent. would probably have recovered had they been operated upon, whereas every one died, a reproach to surgery.

Operative Technique.—The following directions are derived partly from personal conversations with Mr. Horsley, and partly from the experience which I have had upon the cadaver with the aid of Dr. Wm. J. Taylor. I have as yet had no suitable case for operation upon the living subject.

The site of the operation should be thoroughly disinfected, and the same antiseptic precautions followed as advised in operations on the brain (p. 299). An ample incision should be made in the middle line. The laminæ and the transverse processes of the vertebræ should be exposed on one side, and the muscular tissue separated from them quite thoroughly, with the periosteum, so far as practicable. In doing so the deep lumbar or other fascia should be incised transversely in order to give room. Sponges should then be stuffed into the wound in order to check the bleeding by pressure, and larger vessels should be seized by hæmostatic forceps. The same procedure should then be carried out upon the opposite side of the spinous processes. An opening into the canal may now be made either by a saw or by a trephine, and afterward may be enlarged by a saw, rongeur forceps, or strong bone-forceps, as may be desired. Mr. Horsley prefers strong angular bone-forceps. On the cadaver I have found that the rongeur forceps answers very well. The trephine should not be over three-fourths of an inch in diameter, and should be placed as near the spine as possible and directed somewhat obliquely inward, in order to avoid injuring the nerves in the intervertebral foramina. It must not be forgotten that the laminæ are thin, and that the trephine penetrates them very much more rapidly than it does the skull. The ligamenta subflava will give but little trouble in the upper spine, but as we go downward they become much more developed, and are proportionately more of a hindrance in gaining access to the canal. The fatty tissue between the dura and the bone will now be exposed, and is apt to be more or less full of large veins, which in Lloyd and Deaver's case were remarkable by their absence. It is best to tear through this tissue in the middle line and to push it out of the way. Mr. Horsley tells me that this tissue is remarkably compressible, and that this squeezing it out of the way aids materially in checking the hæmorrhage. If the dura has to be opened, Horsley recommends that the anæsthesia should be very complete on account of the great sensitiveness of the posterior column. The dura should be lifted, and the opening in the middle line should be of such an extent as is necessary to afford a good view of the cord. It may be held aside by a hook or a thread, if necessary. If necessary it may be incised transversely, but if the intention is to close the dura after the operation, it is better that this should not be done. By a blunt hook or by an aneurism-needle, I find that the cord can be lifted and moved laterally to such an extent as to enable us to inspect its anterior surface, and also the condition of the anterior wall of the canal in front of the cord. When such operative procedure as is necessary has been completed, the dura can be closed by a curved Hagedorn needle, or by the little suture-needle for the dura which I have devised (Fig. 4869, p. 210). The closure of the dura is very important in order to prevent the continuous loss of cerebro-spinal fluid. The wound, external to the cord, should be drained by a rubber tube and horse-hairs. The drainage-tube should be removed at the end of twenty-four hours, leaving only a few horse-hairs in place for capillary drainage for from three to five days. The wound should be closed in the usual way, and the ordinary antiseptic dressing applied. Possibly, two lateral binder's board, felt, or plaster-of-Paris splints may be of value to secure rest for the first few days.

Dr. S. Weir Mitchell (*Amer. Jour. of the Med. Sci.*, May, 1889) and Dr. H. C. Wood (*Medical News*, 1889, i., 76) have recently reported some remarkable results in Pott's disease from extension continued for a considerable time. Dr. Mitchell applies the traction to the chin and occiput, and Dr. Wood, by suspenders applied by a plaster-jacket. Even marked palsies have been benefited or cured. This mode of treatment deserves careful investigation, and seems to promise much. *W. W. Keen.*

SPLEEN: HISTOLOGY AND PHYSIOLOGY OF.

HISTOLOGY.—The spleen may be divided conveniently, from a histological stand-point, into a supporting framework composed of connective tissue and unstriped muscle-fibres, and a parenchyma contained within the meshes of the framework. The framework or skeleton consists of a firm capsule enveloping the organ, and of a series of trabeculæ which, arising from the inner surface of the capsule, pass into the interior, divide, and subdivide, and anastomose with one another until, becoming finer and finer, they are lost in the parenchyma. At the hilus the trabeculæ which pass inward from the capsule carry within themselves the large arteries, veins, and lymphatics belonging to the spleen, and unite with the trabeculæ from other portions of the capsule to form the internal supporting framework. With this brief general sketch of the structure of the spleen, we can take up the different portions separately, and discuss their histology in more detail. Unfortunately, the minute anatomy of the spleen in some respects is still in doubt, so that it will be necessary to give conflicting views without being able to say to which side the balance of evidence tends. This is the more unfortunate as there seems to be no reason why careful investigation, with the present improved methods, should not settle definitely several of the points in dispute.

The capsule consists of a thin coat of peritoneum, provided with a layer of endothelial cells, and beneath this the much thicker tunica propria. This latter is composed of white connective-tissue fibres and cells, with a variable, though usually large, admixture of elastic tissue and unstriped muscle-fibres. In some animals, as the dog, the cat, and the pig, the muscle is present in large quantities, and is arranged, according to some histologists, in two layers, a longitudinal and a transverse; in man the quantity of muscle in the capsule and the spleen generally is relatively much smaller. The trabecular net-work continued into the interior of the spleen from the capsule is composed of the same histological elements as the capsule. In the dog and the cat, according to Kyber, the smaller trabeculæ are formed almost entirely of muscular tissue. We can easily recognize the muscle-cells, in stained sections of the spleen, by their characteristic elongated nuclei.

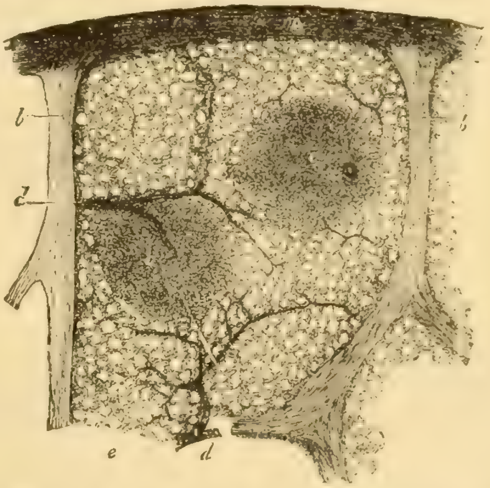

FIG. 5062.—Vertical Section of a Superficial Portion of the Spleen. A, peritoneal and fibrous covering; *b*, trabeculæ; *c c*, Malpighian corpuscles, in one of which an artery is seen cut transversely, in another longitudinally; *d*, injected arterial twigs; *e*, spleen-pulp. Magnified with a low power. (After Kolliker.)

The spleen parenchyma lying between the trabeculæ consists of the so-called spleen-pulp, the most characteristic portion of the spleen, of the Malpighian corpuscles and the lymphoid sheaths connected with them, and of the finer branches of the blood-vessels. The Malpighian corpuscles are easily seen, in most cases, upon a fresh-cut surface of the spleen, as white specks visible to the naked eye. Formerly they were described as distinct vesicular bodies, surrounded by a membranous sac and lying upon the smaller arterial branches, usually at their bifurcation. It is now known that this view is erroneous. The Malpighian corpuscles are simply collections of lymphoid tissue of exactly the same structure, as far as can be determined, as the lymphoid nodules found in various other parts of the body. In fact, the smaller arteries of the spleen, after reaching a certain size, are completely ensheathed by a thicker or thinner layer of lymphoid tissue, and what are usually described as Malpighian corpuscles are merely local enlargements of this sheath, the increase being sometimes only on one side of the vessel, sometimes on all sides, so that the corpuscle is pierced by the artery. The Malpighian corpuscles in man have an average diameter of 0.45 mm.; in the horse, 0.6 mm.; in the rabbit, cat, and dog, about 0.35 mm. (Kyber);

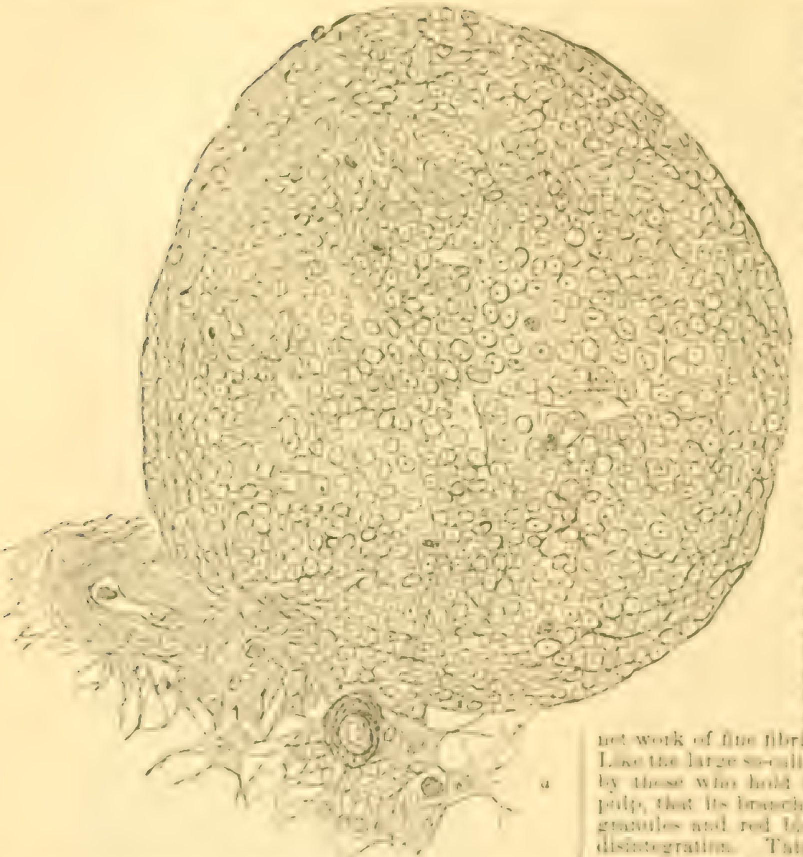

Fig. 5063.—A Malpighian Corpuscle from the Spleen of a Cat. The figure shows a small portion of the spleen pulp which surrounds the corpuscle. In the pulp is seen the cross-section of an artery to the right and of a vein to the left, both surrounded by lymphoid tissue. a, Wall of the corpuscle. (From a camera-lucida drawing of a spleen hardened in corrosive sublimate.)

they are always of a more or less spherical shape. It is said that the corpuscles are larger and more easily seen by the naked eye in an animal after a full meal than in one which has been starved. Microscopically, each corpuscle has the appearance represented in Fig. 5063. By far the most striking element in it is the ordinary lymph leucocyte; in fact, the Malpighian corpuscle seems to be a mass of these bodies, though usually only the clear vesicular nucleus with one or more conspicuous nucleoli is distinctly seen as represented in the drawing. The outlines of the cell-body are not shown in the sections, as a rule, though the granular protoplasm composing it is seen lying between the nuclei. As in other lymph nodules these leucocytes are embedded in an adenoid reticulum. On the periphery of the corpuscles the meshes of this reticulum are smaller and the fibrils are more distinct, while the leucocytes are closer and more tightly packed. Toward the middle, the reticulum becomes finer, with larger meshes, and the leucocytes are generally of a larger size and not so close together. The reticulum is said to show, in places, nuclei at the nodal points of the fibres as in other lymph tissues, indicating its derivation from metamorphosed cells. The Malpighian corpuscles are well supplied with blood; each receives a small artery from the main trunk to which it lies, as shown in Fig. 5064. This branch breaks up into an ordinary capillary net-work within the corpuscle. How the blood is collected from this capillary region is undetermined; at least two different views being held by the histologists who have made special investigations into the structure of the spleen. According to one view, the blood after leaving the capillaries passes into the venous radicles, and thence successively into larger and larger veins forming a connected vascular system, as in other organs. According to the other, the blood from the capillaries of the Malpighian bodies passes finally into the interstices between the pulp-cells, flowing there in irregular channels without definite walls and bathing the pulp-cells directly; from these channels it is gathered up by the small veins.

The pulp of the spleen is, perhaps, the most difficult part to understand; its structure is described differently by different authors. Most of the standard English histologies describe the pulp as consisting of large, flattened, branched connective-tissue or endothelial cells; during life these are probably soft and of a reddish-brown color, and form a honeycombed matrix by the union of their processes, through which the blood percolates. In addition, one finds in the meshes lymphoid cells of various sizes, the larger ones of which are called by Schäfer splenic cells, and are said to contain in many cases red blood-corpuscles. Schäfer states also that in some portions of the spleen the honeycomb of branched cells is replaced by a net-work of fine fibrils resembling an adenoid reticulum. Like the large so-called splenic cells, it is generally stated by those who hold to this view of the structure of the pulp, that its branched cells frequently contain pigment granules and red blood-corpuscles in various stages of disintegration. This appearance is considered as the strongest proof of the theory that the function of the pulp-cells is to destroy the red corpuscles. Figs. 5065,

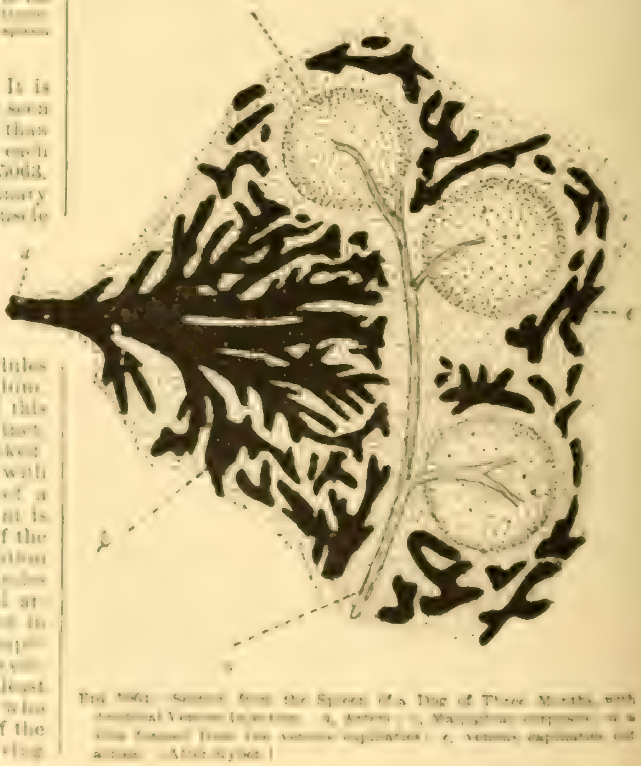

Fig. 5064.—Section from the Spleen of a Dog of Three Months, with [illegible] Venous Injection. a, Artery; b, Malpighian corpuscles; [illegible] formed from the venous capillaries; c, venous capillaries [illegible]. (After [illegible].)

and 5066, copied from Schäfer and Klein, respectively, give an idea of this view of the structure of the pulp. On the other hand, Kyber, Stöhr, and others, describe the pulp as consisting of a reticulum of fine fibres, in whose meshes are contained many leucocytes, as in the reticulum of the Malpighian corpuscles. Between these cells there exists what Kyber calls a granular intermediate substance, and the larger cells are described as containing, occasionally, red corpuscles. Kyber, Kölliker, and others affirm, moreover, as has been stated before, that the spaces in the pulp are not traversed by the blood stream; that, on the contrary, the blood-vessels here, as in other organs, form a closed system, the arteries passing into capillaries, and these again into the veins. Kyber believes that the pulp-tissue forms cords or tracts which lie in among the vascular tracts, and that the fine reticulum of the pulp connects directly with the reticulum of the lymphoid sheaths of the arteries and of the Malpighian corpuscles. In fact, the only distinction one can make between the two is that the reticulum of the pulp is finer and has smaller meshes. In this reticulum, in young animals, round or spherical nuclei can be found in great abundance, but in older animals they are met with only occasionally. Their occurrence indicates that the network was originally formed by the union of the processes of branched cells, the cellular character of the reticulum disappearing in the older animals. We must await further investigation before making a decision as to which of these views of the pulp structure is correct.

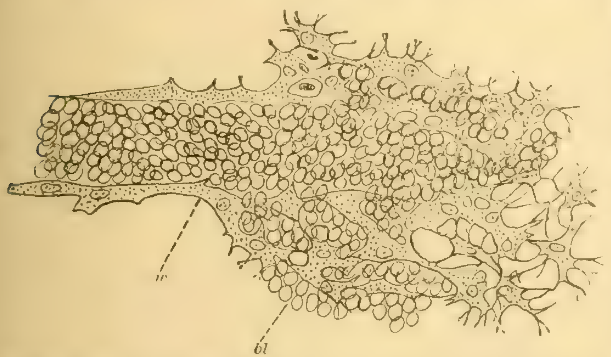

Fig. 5065.—Section of the Spleen-pulp, showing the Mode of Origin of a Small Vein in the Interstices of the Pulp. *v*, The vein filled with blood-corpuscles; *bl*, blood-corpuscles filling up the interstices of the retiform tissue of the pulp; *w*, wall of the vein. (Taken from Schäfer.)

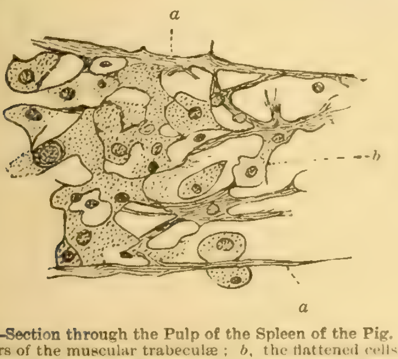

Fig. 5066.—Section through the Pulp of the Spleen of the Pig. *a*, Last outrunners of the muscular trabeculæ; *b*, the flattened cells, forming the honeycombed matrix of the pulp. In the meshes of this matrix are contained lymphoid cells of various sizes. (From Klein.)

With regard to the course of the arteries and veins in the spleen, something has been already said. One of the most careful accounts published is that by Kyber, founded upon a study of injected specimens. Most of the following description is taken from his paper. The splenic artery, before reaching the spleen, divides into a number of branches, from four to ten in the case of man, and thirty or more in dogs and cats. After entering the spleen the arteries run in the large trabeculæ along with the veins, and branch dendritically into smaller and smaller divisions. When the small arteries have reached a certain size, about 0.15 to 0.20 mm. in the human spleen, they part company with the veins, their connective-tissue sheaths become looser and infiltrated with lymph leucocytes, and finally the artery is surrounded by lymphoid tissue upon which, at intervals, the enlargements known as Malpighian corpuscles are developed. From time to time now the artery gives off smaller branches, each of which breaks up into a bundle of very fine arteries, and these end finally in the arterial capillaries. So far, it is important to notice, there are no anastomoses between the ultimate divisions of the main arterial stems which enter the spleen. The spleen, in fact, as far as the arteries are concerned, is a lobulated organ, the arterial supply of each lobule being independent of the others. The arterial capillaries are distributed in part to the Malpighian corpuscles, and in part, according to most authors, directly to the pulp. Those entering the Malpighian corpuscles form an ordinary capillary plexus, and some of the branches emerging from this plexus pass into the pulp to help make the capillary system there. The capillaries of the pulp do not form plexuses, but run isolated from one another, and on many of these fine vessels (called arteries by Klein) are found peculiar bodies to which the name of capillary sheaths has been given. They are more or less spherical structures, and each is pierced by one of the small vessels. The histology of these bodies is not yet satisfactorily known. They were described by the older histologists (Billroth, Schweiger-Seidel) as possessing a membrane, but Kyber believes that they are composed of a fine net-work with closer meshes than that of the surrounding tissue, and filled with lymph leucocytes; while Klein thinks that they consist of concentrically arranged endothelioid plates. With reference to the histology of the vascular system beyond the capillaries, there is a fundamental difference of opinion. The different views held have been mentioned already in speaking of the pulp-tissue. Many histologists believe that the capillaries open into the irregular spaces between the pulp-cells, whence the blood is collected first into incomplete tubes, the venous sinuses, which then pass into the veins proper, and finally entering the trabeculæ unite from different parts of the spleen to form the large efferent trunks. According to Kyber, whose view is in its general features that of many of the German histologists who have studied the subject specially, the capillaries have definite walls, and pass suddenly into vessels of larger size, the capillary veins, and these anastomose freely with one another, thus destroying the lobular character of the organ preserved in the distribution of the arteries. The capillary veins open into larger veins, which unite dendritically to form the chief trunks. Upon this view the splenic pulp-cells do not come into direct contact with the blood stream, and it is difficult to see how, under these conditions, they can function as destroyers of the red blood-corpuscles by directly ingesting them, as is usually described.

A possible compromise between the two views is found in a recent paper by Sokoloff. From investigations made upon the spleen of the rabbit, dog, and man, he concludes that the blood-stream under normal conditions moves in a system of closed vessels lined everywhere with endothelium. But in places the walls of the vessels are exceedingly delicate, and even a slight degree of hyperæmia will lead to a diapedesis of blood-corpuscles into the pulp-tissue, while in acute venous hyperæmia the interstices of the pulp become filled with red corpuscles.

The lymphatics of the spleen are very numerous, and their distribution has been carefully studied. The capsule contains a plexus of large vessels which are continuous with others found in the trabeculæ, and these in turn anastomose with a system of perivascular lymphatics accompanying the arteries. The connection of the lymphatic vessels with the lymphoid tissue, Malpighian corpuscles, etc., if any exists, has not yet been made out satisfactorily.

PHYSIOLOGY.—The function or functions of the spleen have always been a puzzle to the physiologist. Many curious theories have been proposed at different times to explain its use, founded in some cases upon careful experiments or observations, in some cases elaborated simply by processes of introspection, but in all cases unsatisfactory. The better methods, the more cautious deductions of modern physiology, have proved nearly as unsuccessful as the loose experiments and illogical conclusions of former days in arriving at anything positive and undisputed concerning the function of this organ, though modern investigations, it is true, have rendered valuable service in showing the absurdity or impossibility of many of the older theories, and in making us acquainted with a number of facts, with reference to the spleen, which may be looked upon as solid acquisitions, and which, when more carefully studied, will lead eventually to an understanding of its function. A brief mention of some of the hypotheses which were made by the older physiologists before passing on to an exposition of the present theories may not be without value, inasmuch as it will serve to show how completely the use of this organ has evaded the careful inquiries of the most able men, and how persistent the effort has been to invent some hypothesis which should give it a "raison d'être."

Hippocrates and Aristotle believed that the spleen in some way drew the watery parts of the food from the stomach, while Galen thought that it attracted certain juices from the liver which were further elaborated within its own substance, and partly retained as nutriment, partly transmitted to the stomach by the veins. After the discovery of the circulation, the favorite view seems to have been that the spleen purified the blood of its thick, melancholic portions. In the latter part of the seventeenth century Malpighi described for the first time the Malpighian bodies, though his idea of their structure was erroneous. He believed them to be small membranous sacs capable of forming a liquid secretion, and this conception prevailed among physiologists, with some modification, until well into the nineteenth century. Malpighi thought that these little sacs burst from time to time, and the liquid contents, passing into the veins, caused the formation of certain products in the blood, which, in turn, were carried to the liver, and were useful in the formation of the bile. During this period a number of very odd theories were proposed, some of them apparently without any sort of experimental proof, such as that of Havers, who taught that the spleen makes the synovial liquid. In 1722 Stukely suggested a theory which found many advocates, and in a somewhat modified form is often taught at the present day. He thought that the spleen acted as a diverticulum which was capable of receiving the surplus blood whenever this element, from any reason, was in excess; that it acted, in fact, as a safety-valve for the systemic circulation. The discovery, made shortly afterward, that the spleen shows considerable variations in size at different times, seemed to support this hypothesis and may account for its popularity. The great Haller, disregarding the important discoveries which had been made concerning the structure of the spleen, taught that it was composed entirely of arteries and veins. With regard to its use, he speaks in his "First Lines" of the blood becoming fermented in the spleen by the [illegible] of the adjacent colon, etc., the final product being something which, when taken to the liver by the blood, stimulates that organ to an increased secretion of bile. Hewson thought that the spleen had the power of changing the lymph particles formed in the lymphatic glands and thymus into red blood corpuscles; while Home, at the beginning of the present century, attempted to show that the spleen is the organ through which fluids are conveyed after absorption from the cardiac portion of the stomach. [illegible] supposed that the spleen belongs to the class of erectile tissues, and Tiedemann and Gmelin concluded from their experiments that the spleen is an organ closely connected with the lymphatic system, and that it "secretes a coagulating fluid from the arterial blood, which is taken up by the absorbents and conveyed to the thoracic duct." As late as 1827 Arthaud was guilty of believing that the spleen is simply a plexus of nerves, and functions as an electrical apparatus. Johannes Müller first formulated, perhaps, the general view of modern times, that the spleen has for its function the production of some change in the blood circulating through it; what that change is was of course unknown to him as it is to us. Gray, from whose book, "Upon the Structure and Use of the Spleen," the foregoing historical account has been chiefly taken, believed that the spleen regulates both the quantity and quality of the blood. It is interesting to notice that he asserted in many cases that the general nutritive condition of an animal was improved by extirpation of the spleen, and he explained this satisfactorily upon his theory, leaving us to infer that, perhaps, the regulating action of the spleen under normal conditions is of a disadvantageous character to the body as a whole.

Since the middle of the present century the conviction seems to have become established in the minds of physiologists that the spleen in some way is connected with the life-history of the red blood corpuscles. Either it takes part in the production of these bodies or else it is the organ in which they are destroyed, or possibly, in the opinion of some, it fulfils, curiously enough, both of these functions, serving as the grave as well as the birthplace of the blood corpuscles. Perhaps the balance of evidence, such as it is, inclines toward the hypothesis that the red corpuscles are destroyed in the spleen. Kölliker was the first seriously to advocate this view, and a clear account of his reasons for it may be found in his article on the spleen in Todd's "Cyclopædia of Anatomy and Physiology." The chief proof of his theory lies in the fact that one can find in the spleen, according to him, numbers of large white splenic corpuscles which contain within themselves one or many red corpuscles in various stages of disintegration. He traced the initial cause of this destruction of the corpuscles to the alterations in volume of the spleen. As the spleen expands and fills itself with blood, a stagnation, or possibly even an extravasation, occurs in the smaller vessels, and in this stagnant blood either the red corpuscles are dissolved, or, as stated, they are taken into the substance of the large splenic cells and there gradually disappear. This latter process he claims to have seen in all its stages. Ecker also described similar phenomena and gave them the same interpretation. Both he and Kölliker believed that the material of the disintegrated or dissolved red corpuscles was eventually taken to the liver through the portal vein, and there further decomposed to form the biliary pigments. An air of probability is given to this latter supposition by the fact that the splenic blood returns to the heart through the portal circulation; indeed, this connection between the two organs has always been looked upon, since the discovery of the circulation, as signifying some functional dependence of the one upon the other. Further evidence in favor of the theory that the red corpuscles are destroyed in the spleen has been found in the presence in the spleen of certain chemical products usually looked upon as indicative of active metabolic changes, substances such as uric acid, xanthin, leucin, tyrosin, several of the fatty acids, lactic acid, succinic acid, cholesterin, and, in addition, an albuminate containing iron. Properly considered, the occurrence of these products means only that active metabolisms of some kind are in progress, but that these metabolisms are connected with the death of the red corpuscles is at present a gratuitous assumption. This hypothesis, then, rests chiefly, if not entirely, upon a histological basis. That this alone is not satisfactory is felt by anyone who examines the spleen microscopically, for the existence of splenic cells containing red corpuscles has been doubted or denied by a number of observers; certainly they are not met with in every spleen, for the writer of this article has had occasion to examine many spleens in one animal, the cat, and has never yet seen splenic cells filled with red corpuscles as described by Kölliker. Occasionally, it is true, he has found such cells containing a single red corpuscle, but the ingestion of the corpuscle in these cases may easily have happened after death in consequence of the stagnation of the blood in the meshes of the spleen, as it is well known that the large splenic cells in question are actively amœboid. If the destruction of the red corpuscles by this method were the chief function of the spleen, one would expect to meet with such microscopic evidence of it more frequently and more constantly, considering the great number of red corpuscles which is supposed to be undergoing destruction at any one time. However, we find in most of the histologies the statement that such blood-corpuscle-containing cells occur in the spleen, the statement presumably resting on personal observations by the author; and the explanation usually adopted is the one of Kölliker, that it is a function of these cells to destroy the red corpuscles. So that it is fair to assert that this hypothesis is generally accepted at the present time. It is, perhaps, the only function of the spleen that is described with any show of certainty, though, as I have tried to indicate, the evidence for it is obviously unsatisfactory, and will scarcely stand a critical examination. If one chooses to believe that the red corpuscles are destroyed in the spleen, not by absorption into the substance of its amœboid cells, but by simple dissolution in the plasma while in that organ, there is nothing either to prove or disprove the belief, though a certain amount of possible evidence may be brought forward in favor of it, such as the large percentage of iron contained in the substance of the spleen, even when the blood is thoroughly washed out.

With regard to the theory that the spleen takes part in the formation of new red corpuscles, we are now in a position to discuss the question with some degree of certainty. The theory is always based at the present day, so far as the writer is aware, upon the assertion that developing nucleated red corpuscles can be found in the spleen. The recent investigations of Bizzozero, and Bizzozero and Torre, and others, have shown that this statement is probably erroneous; that among the higher mammalia, including man, one cannot find in the spleen of the healthy adult animal any evidence of this nature to show that it takes part in the production of red corpuscles. In fact the connection of the spleen with the formation of new red corpuscles, during fœtal and extra-uterine life, has been pretty clearly ascertained, thanks to the labors of Kölliker, Foa, Bizzozero, and others. The writer of this article, in experiments not yet published, made upon the regeneration of the blood-corpuscles in the cat, has been able to corroborate fully the general features of the connection of the spleen with this function, as stated by the authors just quoted; it is as follows: In the young fœtus, shortly after the spleen is formed, one can find in it numerous nucleated red corpuscles showing signs of an active multiplication by karyokinetic division, so that there can be no doubt that the spleen does possess this function during fœtal life. Before the appearance of the spleen the production of red corpuscles is confined to the liver, but toward the end of fœtal life, and for a variable period after birth, not only the spleen, but the marrow of the bones also, takes part with the liver in making new corpuscles. However, shortly after birth—in the cat by the third, or at the latest the fourth week—this function has disappeared entirely not only from the liver, but from the spleen also. Henceforward, throughout healthy adult life, the formation of red corpuscles is confined to the marrow of the bones, the spleen no longer takes part in the process.

Bizzozero and Torre have examined the spleens in a number of animals belonging to the different classes of vertebrates, and state that in none of them except the tailed amphibians does the adult spleen contain developing red corpuscles. But in the ordinary mammals, as the dog and the cat, and probably in man, the spleen of the adult under certain conditions can resume its fœtal function. Recently Bizzozero, and Bizzozero and Salvioli, have shown that in dogs and guinea-pigs, after the animal has been bled severely two or more times, the spleen upon examination is found to contain nucleated red corpuscles. The writer can confirm these observations from similar experiments made by him upon cats. In the normal healthy cat no nucleated red corpuscles can be found in the spleen; but if the animal is bled very strongly one or more times, and the spleen is examined twenty-four hours after the last bleeding, one finds in it a number of the nucleated corpuscles tinged with hæmoglobin, and frequently in different stages of division, showing, apparently, that the spleen has again taken on the function of making blood-corpuscles. Furthermore, Pellacani, and also Foa, state that in the spleens of human beings suffering from extreme anæmia before death, they have found nucleated red corpuscles, though in the spleen of man, normally, none are contained. These facts show quite conclusively that when the circulation is depleted of its red corpuscles by sudden and severe hæmorrhage, or in the human subject by the pathological conditions which bring on continued anæmia, the marrow of the bones is no longer able to supply the increased demand for new corpuscles, and the spleen takes part as an accessory organ in their production, as in fœtal life.

That the spleen is able to revert in this way to its embryonic function seems to depend upon the fact that, even in the healthy adult, one finds in it nucleated cells like nucleated red corpuscles, except that they contain no trace of hæmoglobin. Similar colorless cells are found in the marrow, and are regarded as the parent form of the nucleated red corpuscles. To these colorless predecessors of the red corpuscles Löwit has recently given the name erythroblasts, and states his belief that they are found not only in the marrow and spleen but also in the lymph glands. In the spleen these cells apparently do not, under normal conditions, develop into red corpuscles, at least not in the spleen itself; while under the stimulus of excessive anæmia they again begin this course of development. In this connection the recent investigations of Foa, Tizzoni, and Griffini and Tizzoni, are of peculiar interest. Foa states that if a portion of the spleen is excised by means of scissors or a cautery, the loss is replaced, after a certain time, by a new growth, and the portion of the spleen undergoing regeneration passes through the same stages as the developing spleen of the fœtus, that is, it contains a number of nucleated red corpuscles and giant cells. Tizzoni obtained the same result from partial excision of the spleen, and affirms, moreover, that when the organ is entirely removed new splenic nodules are formed in the great omentum, which show during their development the presence of nucleated red corpuscles. Foa, however, denies that under such conditions new splenic nodules are formed.

As far as the white corpuscles of the circulating blood are concerned, it is at present uncertain, or only an inference, whether or not the spleen takes part in their formation. The case may be fairly stated as follows: We know that the spleen contains a quantity of lymphoid tissue, both in the form of the Malpighian bodies and as the sheaths of diffuse lymphoid tissue surrounding the smaller arteries. It is at present the general belief that the white corpuscles of the blood are derived from the lymph leucocytes furnished by the lymphatic glands and other collections of lymphoid tissue scattered throughout the body. Accepting this theory, we must believe that the lymphoid tissue of the spleen also gives its quota of white corpuscles to the blood. The only weak point in the argument is the fundamental assumption that the white blood-corpuscles are simply modified lymph leucocytes; without doubt this is still open to question, though it is almost universally conceded to be true. In any case this spleen-tissue proper—the so-called pulp—cannot be considered as taking any part in the formation of white blood-corpuscles.

Efforts have been made to arrive at the function of the spleen by excising the organ entirely, and then determining the disturbances or changes in the animal produced by this operation; but the results have been entirely negative. The experiment has been performed frequently by physiologists on the lower animals, and a number of times by surgeons on the human subject, with the invariable result that even the entire removal of the spleen has no direct injurious result, so far as can be determined, upon a healthy animal. We are therefore justified in believing that the spleen is not absolutely necessary for the maintenance of the life of the animal. Whatever functions it may perform are of such a nature that they can be carried on by some other organ or organs after its removal. A number of physiologists have stated that in dogs, after excision of the spleen, the animal shows a ferocious disposition and an extraordinary appetite, but it is doubtful whether this result is peculiar to removal of the spleen. First records that he has noticed a similar change in animals from which one of the kidneys was taken. In any case, the change in the appetite and temper throws no light at all on the function of the spleen. Something more definite, as the result of excision of the spleen, is the effect on the lymphatic glands. Many observers state that in post-mortem examination of the animals operated on, these glands are usually found enlarged, indicating that the function previously performed by the spleen had fallen upon them. But this again is unsatisfactory, because, in the first place, the lymphatic glands have only one function that we are acquainted with, namely, that of making lymph leucocytes, and they can therefore only take the place of the lymphatic tissue contained in the spleen, and not of the spleen tissue; so that granting the observation to be correct, it throws no light on the peculiar function of the spleen. In the second place, other observers, equally as reliable, deny that any enlargement of the lymphatic glands occurs; while others, still, say that it happens in some cases but not in all. On the whole, then, we cannot place much weight upon this observation. Similar statements have been made concerning the effect of removal of the spleen upon the marrow of the bones. It is said that the marrow of the long bones becomes hyperæmic, and the yellow marrow is changed to red, capable of producing red corpuscles. If this is found to be true, as a permanent effect of excision of the spleen, it will be strong evidence, of course, in favor of the view that the spleen normally takes part in the manufacture of red corpuscles. But the observation rests upon insufficient experiments, is denied by some, and it is quite possible that when it occurs it is simply a temporary result of the loss of blood, as it is well known that in ordinary bleeding it is usual to get this effect on the marrow. Another result of total excision of the spleen, described by some authors, is the development of new spleens or splenic nodules. If this is so we can understand why so little apparent injury follows the operation. This statement has been warmly supported in the last few years by Griffini and Tizzoni. They assert, from numerous experiments, that after total excision a number of accessory splenic nodules are formed in the great omentum possessing the characteristic elements of the normal spleen. On the other hand, Foà contends that in every case where supernumerary splenic nodules are found after excision they were really present before the operation, as the omentum retains an embryonic tendency to produce these bodies, which may be aroused into action by a number of different causes. From this brief summary it is easy to see that the method of excision has not contributed much positive information to our knowledge of the spleen, though it has shown that this organ is not so essential as its large size would seem to indicate.

One of the most remarkable things about the spleen is that it undergoes frequent, and sometimes very great, changes in size, not only in malarial fever and other pathological conditions, but in the perfectly healthy person. This has long been known, and, in fact, the enlargement of the spleen has been shown to be connected with the periods of digestion of food. The spleen begins to increase in size after eating, and is said to reach a maximum about the fifth hour after a meal has been taken. This, together with the evidences in the spleen of the existence of active metabolic changes, and the fact that the splenic blood passes into the portal circulation, makes it possible that the spleen takes some part in the elaboration of the food during or after digestion, but anything more definite it is impossible to state. However, one physiologist, Schiff, has attempted to show a very definite connection between the spleen and the pancreas with reference to digestion in the small intestine, though the attempt has not met with any success in the minds of most physiologists. Schiff found that after excision of the spleen the pancreatic secretion could no longer digest proteids, that is, the pancreas was not able to make its proteolytic ferment trypsin. The explanation of this effect was that the pancreas by itself can only form a preliminary material—to use the term now introduced by Heidenhain, can only make a zymogen or trypsinogen, and to convert this zymogen into trypsin requires a ferment, which, under normal conditions, is formed in the spleen and carried to the pancreas by the blood stream. Schiff's fundamental experiment has been entirely unsuccessful in the hands of other physiologists. Ewald found that the pancreatic juice, after excision of the spleen, digested proteid without difficulty, and Heidenhain states, in the most positive terms, that in several dogs from which he had previously removed the spleen he was able to get a pancreatic juice, by means of a fistula, which digested fibrin in a perfectly normal manner. The only person who has been able to confirm Schiff's theory at all is Herzen. In one series of experiments, Herzen made a number of infusions of pancreas and of spleen, taken from dogs under different conditions, and determined their action when used singly or together upon fibrin. His results were as follows:

1. An infusion of the pancreas of a hungering dog was inactive.

2. The same infusion, when mixed with the spleen pulp from the same animal, was likewise inactive.

3. The same infusion of pancreas, mixed with the spleen pulp from a dog in full digestion, had a strong digestive action on the fibrin.

4. Infusion of pancreas, plus infusion of the spleen of a hungering dog, was inactive.

5. Infusion of pancreas, plus infusion of the spleen from a dog in digestion, had a digestive action.

In response to criticisms made by Heidenhain upon the methods used by him in these experiments, Herzen has recently completed a new series arranged in this way: He prepared, first, an infusion of the pancreas from five different dogs, and, next, an infusion of the spleen of two dogs in full digestion. With each of the five pancreatic infusions he made the following mixtures, and tested their digestive powers upon both fibrin and coagulated albumen.

1. One volume of pancreatic infusion, plus 2 volumes of water.

2. One volume of pancreatic infusion, plus 2 volumes of five per cent. boracic acid solution.

3. One volume of pancreatic infusion, plus 2 volumes of infusion of spleen in five per cent. boracic acid.

4. One volume of pancreatic infusion, plus 2 volumes of aqueous infusion of spleen.

He found that in all cases Nos. 3 and 4, the mixtures of pancreas infusion with spleen infusion, had a more powerful digestive action than the others. He concluded from this that the zymogen formed in the pancreas is changed to trypsin by a ferment formed in the spleen during its periodic dilatation. This conclusion is obviously illogical, and not warranted by the experiments. His infusions of pancreas without admixture of the spleen possessed digestive powers, and all that he is justified in concluding from his experiments, granting that they were perfectly accurate, is that an infusion of the spleen has the property of increasing the digestive action of extracts of pancreas, but that by no means proves that the spleen forms a special ferment capable of changing trypsinogen to trypsin. We can increase the digestive action of pancreas extracts by a number of reagents, all of which are supposed to act by changing the trypsinogen more completely into trypsin: to say that the infusion of spleen has the same effect, because of the presence in it of a special ferment which it is the function of the spleen to make, is not justified, unless purer preparations of such a ferment are obtained, and until it is shown that the favorable action of the spleen infusion was not owing to its alkaline reaction, to the presence of some of the extractives usually found in it, or to some similar cause. Besides, if Herzen's theory were correct, the excision of the spleen should at least weaken decidedly the digestive power of the pancreatic secretion, but the experiments of Ewald and Heidenhain prove that this is not the case.

The most hopeful experiments that have been made upon the spleen, in the past few years, are those of Roy. He placed the spleens of living animals in a metal box filled with oil, and made tight by a flexible membrane lining it, and adhering to the contained organs. The instrument is known as the oncometer, and when in use its cavity, filled with oil, is connected by tubing with a recording apparatus, the oncograph. This latter gives a tracing showing the variations in volume of the oil in the oncometer, or, in other words, the variations in the size of the spleen. The whole apparatus can be so arranged that the spleen is kept at its normal temperature during an experiment, and its blood-vessels, nerves, and lymphatics are not interfered with. The most remarkable result that came out of Roy's experiments was the discovery of the fact that the spleen is never entirely at rest, but is continually expanding and contracting with a rhythm which is fairly regular. The expansions and contractions, or systoles and diastoles, as Roy terms them, number on an average about 62 to 63 in a minute for the dog and cat. The extremes of rapidity of rhythm were from 46 seconds to 2 minutes 3 seconds for each contraction. As a reason for these splenic beats, Roy asserts that the force which impels the blood through the substance of the spleen is not, as in other organs, the pressure in the arteries, but the contractions of the spleen itself. The machinery for these spleen contractions is found, of course, in the muscle-fibres scattered throughout the capsule and trabecular framework. In addition to these quick and rhythmic contractions, the spleen undergoes remarkable variations in size, slow expansions and contractions, lasting perhaps through hours. A number of different conditions may bring about these slow changes of bulk—for instance, the injection of various substances into the blood—and Roy believes, from his observations upon the spleen while in the oncometer, that under normal healthy conditions it is continually undergoing, from one reason or another, gradual variations in volume like those usually described as occurring during the digestion of a meal. As stated above, the object of the quick rhythmic contractions seems to be the driving of the blood through the spleen substance itself. The mass of blood in the spleen, Roy says, seems to be cut off to a great extent from the arterial system. Although this fact has been surmised by most physiologists, from the great capacity of the vein capillaries of the spongy spleen compared with that of the arteries, Roy now gives a definite proof for it. He finds that if the aorta of an animal with its spleen in the oncometer is clamped below the diaphragm, the blood-pressure in the spleen does not drop quickly as it does in other organs, the kidney for example, but, on the contrary, falls very slowly, indicating, as Roy expresses it, that the passages by which the blood enters the substance of the spleen must be very narrow. By means of his oncometer Roy was able to study more accurately than had before been possible the effect of stimulation of the nerves of the spleen. His experiments upon this point confirm and extend the older observations of Tarchanoff and others. He finds that direct stimulation of the vaso-motor centre in the medulla by electricity, or indirect stimulation of the same centre by making the animal dyspnœic, brings on a rapid and strong contraction of the spleen, a vaso-constrictor effect caused by a narrowing of the arteries in the spleen, and possibly also by a contraction of the spleen-muscle itself. In like manner, stimulation of the central end of a sensory nerve causes a contraction of the spleen, and finally, direct electrical stimulation of the divided splanchnic or vagus produces the same result. The last experiment shows that the vaso-constrictor nerves pass in part to the spleen through the vagus and splanchnic nerves, by way of the solar plexus. But the spleen evidently receives nerve-filaments from some other source, inasmuch as after section of the two splanchnics and the two vagi, stimulation of a sensory nerve will still cause a reflex contraction of the organ. Moreover, it was found that section of all the principal nerves going to the spleen had so little effect on its rhythmic contractions that Roy thinks it probable that these movements are regulated by some mechanism in the spleen itself, that is, by an intrinsic nervous apparatus, or by the automatic contractility of the muscle-fibres. These observations are a very welcome addition to our knowledge of the physiological properties of the spleen. Though they seem to give no direct information as to the functional value of the spleen to the body, there is no doubt that when followed out more thoroughly they will furnish material aid in the discovery of the long looked-for function of this organ.

SULPHONAL. (Spelled also Sulfonal.) Under this name Professor A. Kast recently (April, 1888) called attention[1] to the action of a new chemical compound which, in physiological and clinical experiments, he had found to be an efficient and harmless hypnotic. It was discovered by E. Baumann in 1885, and by him named diethyl-sulphon-dimethyl-methane. Its formula is $(CH_3)_2 = C = (SO_2C_2H_5)_2$.

Preparation.[2]—Dry hydrochloric acid gas is passed into a mixture of two parts of ethyl-mercaptan and one part of acetone. The liquid gradually becomes warm and turbid, and separates into two layers, of which the upper is mercaptol, and the lower dilute hydrochloric acid:

$$\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right>C=O+\begin{matrix}HS.C_2H_5\\HSC_2H_5\end{matrix}=\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right>C\left<\begin{matrix}SC_2H_5\\SC_2H_5\end{matrix}\right.+H_2O.$$

Acetone. *Mercaptan.* *Mercaptol.*

The mercaptol is removed from the watery layer, washed first with water, and then with a dilute solution of hydrate of sodium, dried by means of chloride of calcium, and finally distilled. To oxidize the mercaptol and thus convert it into sulphonal, it is agitated with a five per cent. solution of permanganate of potassium, which is added as long as it becomes decolorized, or until the mixture becomes permanently red, showing that oxidation is complete. Occasionally, a few drops of acetic acid or dilute sulphuric acid are added, to combine with the liberated alkali. Finally, the liquid is heated in a water-bath and filtered hot. As it cools, the sulphonal crystallizes out. The crystals are obtained perfectly pure by recrystallizing several times from boiling water or alcohol:

$$\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right>C\left<\begin{matrix}SC_2H_5\\SC_2H_5\end{matrix}\right.+\begin{matrix}O_2\\O_2\end{matrix}=\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right>C\left<\begin{matrix}SO_2C_2H_5.\\SO_2C_2H_5.\end{matrix}\right.$$

Mercaptol. *Sulphonal.*

Properties.—Sulphonal crystallizes in colorless prisms which are inodorous and nearly tasteless. Most writers describe pure sulphonal as destitute of any perceptible taste, while others found it, when mixed with various liquids, slightly bitter. It is soluble in about 15 parts of boiling water, in about 100 parts of water at 37° to 38° C., and in about 500 parts at 15° C.; in 2 parts of boiling alcohol, in 65 parts of alcohol at 15° C., and in 110 parts of fifty per cent. alcohol.

Its solubility[2] in water is somewhat increased by the presence of small quantities of chloride of sodium, hydrochloric acid, and peptones. Thus it dissolves in 290 parts of a two per cent. solution of chloride of sodium at 40° C., and in 290 parts of a two per mille solution of hydrochloric acid at blood heat (38° to 40° C.). A hot solution of sulphonal, added to artificial gastric juice containing an abundance of peptones in solution, will not crystallize out in one hour when the liquid is cooled to blood-heat, even when the sulphonal constitutes one per cent. of the liquid.

Sulphonal is a remarkably stable compound.[3] At ordinary temperatures concentrated sulphuric acid, fuming nitric acid, nitro-hydrochloric acid, caustic potassa and soda, chlorine and bromine, do not affect it.

Tests.—Sulphonal should be colorless, odorless, and tasteless, or only very slightly bitter. Applied in substance to moistened red or blue litmus-paper, it should be perfectly neutral. It should melt at 125° to 126° C., and when incinerated should leave no incombustible residue. A hot watery two per cent. solution should not be altered by the addition of chloride of barium or nitrate of silver; and ten c.c. of the solution, on the addition of one drop of volumetric solution of permanganate of potassium, should become permanently red.[4]

Physiological Action.—According to Professor Kast, moderate doses of sulphonal, two grammes (30 grains), given to dogs, in about half an hour produce inco-ordinate movements, beginning in the legs, and soon extending to the trunk. The animals quickly become very helpless, and stagger about as if intoxicated with alcohol. In a short time they are unable to stand, lie down, and fall into a profound sleep. After awakening they are still somewhat uncertain in their movements, but speedily regain their normal condition, and then exhibit no trace of disagreeable effects. Very powerful dogs often present only the ataxic movements, but no hypnotic condition. Toxic doses cause severe convulsions, soon followed by deep stupor, and in about ten hours by death. The blood-pressure was carefully examined, and found normal during and after doses which caused prolonged sleep.

From the phenomena observed in animals after moderate doses of sulphonal, Kast concluded that this substance has a very decided physiological action, and probably first acts upon the gray cortex of the cerebrum.

In healthy middle-aged men, sulphonal, in doses of two to three grammes given early in the afternoon, several hours after dinner, soon causes sleepiness and dulness, which continue for some hours. Even these slight effects may not take place in very strong men, especially if they walk about in the open air. But they become more marked, and are soon followed by sleep lasting four or five hours, if the person lie down in a noiseless apartment. Thus, given to healthy men, in doses of two to three grammes, at a time when sleep is not required, sulphonal does not act like the narcotics and hypnotics which force sleep, but only produces a certain degree of dulness and languor, which is apt to increase and produce a spontaneous need of sleep. Ataxic movements, such as almost constantly occur in dogs, were never observed in men.

According to the investigations of Wm. J. Smith,[5] sulphonal, given in moderate doses, is completely changed in the organism into readily soluble organic compounds of sulphur. The quantity of sulphuric acid excreted is not altered, which shows that the organic compounds have great stability. Sulphonal exerts no influence on tissue-change, and does not increase or diminish the quantity of nitrogen eliminated. Large doses given to a dog for five weeks caused no disturbance of the animal's health, but minute quantities of unchanged sulphonal could be detected in his urine.

Therapeutical Uses.—The hypnotic action of sulphonal was tested by Kast about one hundred and twenty times on thirty patients. In most cases the sleeplessness was due to over-excitation of the brain, and occurred in neurotic patients; in some the insomnia was caused by organic cerebral disease, or was due to senility, or fever, or to disordered circulation from heart disease. Nearly invariably, in from one-half to two hours, quiet and dreamless sleep ensued, and lasted from five to eight hours. During the sleep the functions of circulation and respiration were somewhat slowed, as in natural sleep, but no deviation of the blood-pressure from the normal state could be observed. After awakening, the patients felt refreshed and presented no after-effects, except that in a few instances a feeling of fatigue and languor existed during the following morning or day.

Since the publication of Kast's observations sulphonal has been extensively used as a hypnotic in cases of insomnia. It was found to be most effective in nervous sleeplessness, and generally also when insomnia was caused by disease of the brain, disordered circulation, and neuralgia. It failed in some cases of delirium tremens, and had little effect in some hysterical, maniacal, and delirious patients. It also failed when insomnia was caused by severe cough, or intense pain other than neuralgia. Usually no disagreeable effects followed its action, or at most some dulness, languor, and sleepiness on the following day. In a few instances after repeated administration, there followed headache, vertigo, and tinnitus aurium, and in others eruptions resembling measles or scarlatina, attended with itching, and lasting several days.

Dose and Administration.—The average dose for patients of medium weight is two grammes (30 grains). Females rarely require more than from one to two grammes, while strong, heavy men often need from two to four grammes. The dose deemed appropriate should be given about two hours before bedtime, and one or two hours after the last meal, as then all the conditions are present which favor speedy solution and absorption: an abundance of liquid, chloride of sodium, hydrochloric acid, and peptones. The patient should be directed to take the dose in about half a pint of warm liquid—tea, bouillon, soup, etc.

℞ Sulphonal .... ʒ j.-ij.

SUPRA-PUBIC CYSTOTOMY. The early history of this operation is so well known that but a brief sketch will be necessary.

In the year 1561, Pierre Franco, cutting a boy about two years of age by the perineal incision, found a stone too large to be drawn out through the pelvis; and driven by the importunities of the parents and the necessities of the case, he pressed the stone up from below with the fingers in the rectum, and cut down upon it over the pubes by an incision a little to one side of the median line.

Through this opening he succeeded in removing the stone, and although the child was very sick after the operation he finally recovered.

So impressed was Franco with the difficulties and dangers of this operation, and with the belief that wounds of the body of the bladder were almost necessarily fatal, that he advised strongly against a repetition of the procedure which had proved so successful in his hands.

In the year 1580, François Rousset, who had become interested in the subject, perceiving the importance of distention of the bladder to increase the space between the peritoneal fold and the pubic bone through which the operation could be made, advised that the bladder be filled with barley-water, milk, or some mucilaginous fluid, and that the penis be afterward compressed to prevent the escape of the distending fluid. For cases of small and contracted bladder he advised efforts at gradual distention by diuretic drinks, with forced retention of urine as preliminary treatment.

The operation, he thought, should be done on the patient in a horizontal position, with the pelvis raised, so that the force of gravity should tend to draw away the intestines, and that the liquid in the bladder might tend to gravitate toward the fundus and press it upward.

He advised that the incision should be made in the median line between the recti and pyramidales muscles, down to the bladder wall, which should then be entered by a small opening, to be afterward enlarged according to need with a probe-pointed bistoury. The peritoneum is to be retracted and protected by the forefinger during the incision of the bladder-wall.

These recommendations of Rousset are given at some length to show that, thus early, a plan was proposed which differed but little from that carried out in the modern operation. This is the more interesting when it is known that Rousset was not a surgeon, and therefore never performed the operation he so ably planned.

The operation did not obtain a firm foothold in the surgical world until the eighteenth century, when it was revived by Douglas (1719), Cheselden (1723), and Morand; but then only as an exceptional method.

Toward the end of that century (1779), Fr. Côme (Baseilhac) introduced the sonde-à-dard, with the aid of which he did many successful operations. His method of using this instrument was as follows:

When the median incision, close above the pubes, had been carried down to the bladder-wall, the sound, with its concealed dart, was introduced into the bladder. The operator then put the forefinger and thumb of his left hand to the bottom of the wound, and with his right hand carried the beak of the sound, with a see-saw movement, along the anterior bladder-wall until its point came under the middle of the wound. The handle of the sound was now depressed, and the point raised a nipple-like projection of the bladder-wall, which was seized with the left finger and thumb. During this part of the operation the peritoneum was carefully pushed toward the umbilicus.

The sharp-pointed director was now pushed out of the sound, appeared through the bladder-wall, and served as a guide to a bistoury which made a small opening through which the index-finger was at once slipped to hook up and hold the bladder, and to serve as a guide for further incisions, and for the manipulations of removing the stone.

Fr. Côme also practised and recommended a perineal incision for the purposes of drainage in patients cut over the pubes.

For more than a century after this the operation remained practically at a standstill in the matter of technique; and in the estimation of surgeons it steadily declined in importance, on account of its high mortality and of the improved methods of treating large stones through the perineal incision with powerful crushing instruments.

In the "Dictionnaire de Médecine," published in Paris in 1844, is a fair summary of the feeling of that time. The advantages of the operation, in the avoidance of hæmorrhage and of interference with the urethra and prostate, are dwelt upon, as well as the fact that it is the only possible operation in cases of very large stones.

On the other hand, the author draws a gloomy picture of the course and fatal effects of urinary infiltration, and closes by saying: "It is, then, owing to the danger of urinary infiltration after this operation that the great majority of surgeons have preferred, and still prefer, the narrow and embarrassed route that the perineum presents to urinary calculi."

This opinion of the operation, expressed in 1844, was not materially altered during the subsequent thirty years, and it was reserved for the removal of very large stones which could not be got out through the pelvis.

The technique usually followed during this period was essentially that of Fr. Côme, with the sonde à-dard, although occasionally the operation was done after the manner recommended by Rousset, over a full bladder.

In October, 1878, Dr. Garson, of Edinburgh, published some investigations, made in the laboratory of Professor Braune, of Leipzig, upon the changes of position of the pelvic organs, when the rectum was distended by an inflated rubber bag.

The surgical importance of his observations was at once manifest, for he found that the bladder was lifted out of the pelvis to a very considerable degree, and that thus the prevesical peritoneal fold was widely separated from the symphysis pubis, giving ample room for the performance of the supra-pubic incision without fear of injury to the peritoneum. At about the same time Professor Braune brought this matter to the attention of German surgeons, and in 1880 Professor Petersen appeared with an article, in Langenbeck's *Archiv für Klinische Chirurgie*, recommending the procedure as a good one surgically, reporting two cases operated on in this way, and recounting a number of additional observations on the cadaver.

From that time but little has been added to the technique of the operation, and the following description of procedure conforms pretty closely to that given by Petersen:

Preparatory Treatment.—If the bladder is much contracted, efforts may be made with warm injections to gradually stretch it to a reasonable capacity, and if there is cystitis present, with fermenting urine and mucus, an emollient and mildly antiseptic solution of borax or boracic acid may be used for this irrigation. On the day of the operation the bowels are to be thoroughly emptied by laxatives and enemata.

Operation. — The patient being fully etherized, an oval or pear-shaped rubber bag with a pipe attached is introduced into the rectum. This is more easily done before the bladder is filled. Before distending the rectal bag the bladder should be thoroughly irrigated and then filled with a boracic-acid solution.

The distention of the bladder should be done with extreme care, as rupture of the viscus has occurred in several instances during this procedure. If a bulb syringe is used, the hand recognizes the amount of resistance and can judge with considerable accuracy of the tension in the bladder. It is to be borne in mind that these bladders have usually been long diseased, and are not infrequently weakened by ulceration or sacculation. In most cases from six to ten ounces may safely be thrown in.

To prevent subsequent leakage of the water from the bladder, an elastic band should be tied around the penis. The catheter through which the injection has been made may either be withdrawn or closed with a clamp. The rectal bag is now to be slowly filled with water, and here, too, great care should be taken against over-distention, for there is danger not only of rupture of the rectum, but also of so increasing the tension in the bladder by pressure as to cause a rupture there. During the filling of the rectal balloon the rise of the bladder into the abdomen can be watched by palpation and percussion.

The accompanying figures show very well the effect of this rectal distention on the position of the bladder and of the prevesical fold of the peritoneum. They are reduced from full-sized illustrations of an article by Fehleisen, in Langenbeck's *Archiv für Klinische Chirurgie*, which were made for him from frozen sections of the cadaver.

In Fig. 5067, when the bladder is moderately distended, while the rectum is empty, the peritoneum reaches almost down to the upper edge of the pubes; while in Fig. 5068, although the bladder contains less water than that in Fig. 5067, yet the filling of the rectum so forces it up out of the pelvis as to lift the peritoneal fold to a good distance from the symphysis pubis. In Figs. 5069 and 5070 we see the same point still more strikingly illustrated.

Bouley has made investigations on this subject, and has deduced the following rule for determining the position of the peritoneal fold by percussion and palpation of the bladder: "When the apex of the bladder stands more than five and less than nine centimetres above the pubes the peritoneal reflection will be found three centimetres below this point. If the bladder reaches more than nine and less than sixteen centimetres above the symphysis the peritoneum will extend four centimetres below its apex.

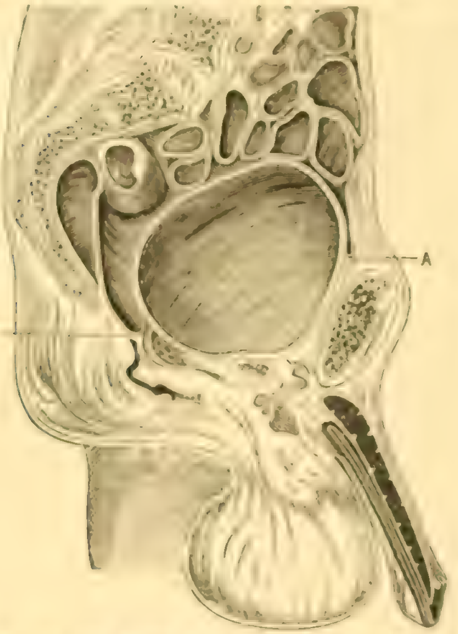

FIG. 5067.—Cut from Frozen Section. Bladder contains ten fluidounces. A, prevesical fold of peritoneum; B, retrovesical peritoneum. [illegible]

Besides the lifting of the peritoneum and consequent enlarging of the space through which the operation can be done, the rectal distention has a second good effect in pressing the bladder close up against the abdominal wall and fixing it there, so that it can be readily opened without obliging the operator to grope behind the pubes for it. It is this effect of the rectal ballonnement which has done the most to reduce the mortality of the modern operation.

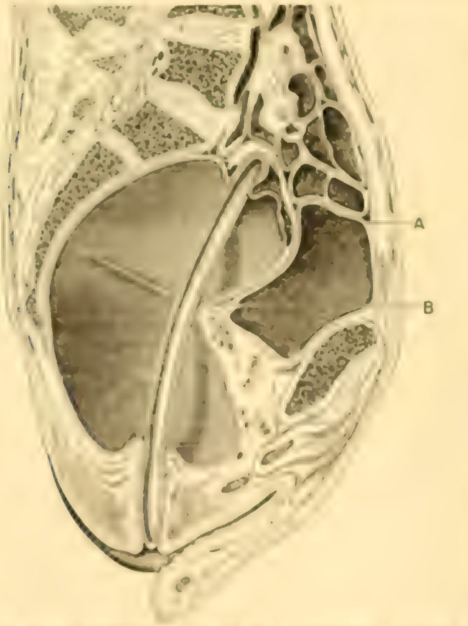

FIG. 5069.—Bladder contains six and a half fluidounces. [illegible] A and B mark the peritoneal folds.

Formerly, a good operator could with care avoid injury of the peritoneum, but in the exercise of the traction requisite, the loose attachments about the neck of the bladder were often considerably separated, thus opening the way for infiltration of urine and septic absorption, which were the usual causes of death in these cases. As most of this handling is now avoided, infiltration of urine and phlegmonous processes have become more rare.

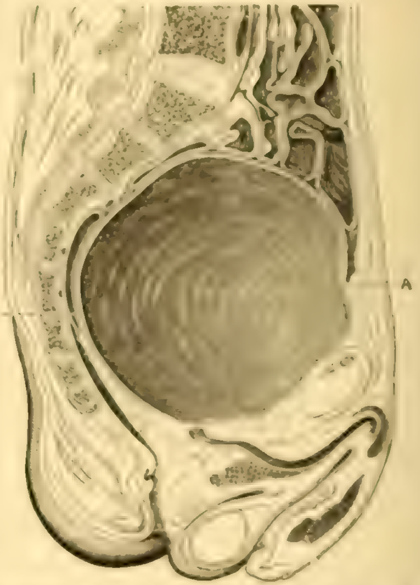

FIG. 5068.—Bladder distended with twenty fluidounces. A and B, folds of peritoneum.

To return now to the steps of the operation. When the bladder and rectum have been filled, or so far distended as seems safe, and the field of operation has been thoroughly scrubbed and shaved, an incision is made in

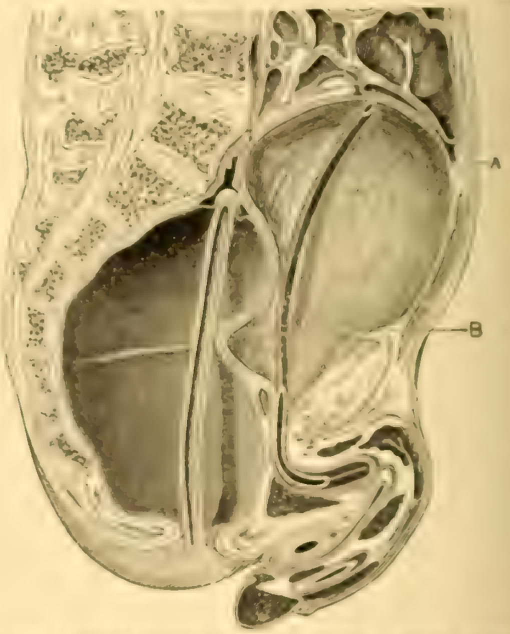

FIG. 5070.—Bladder contains fourteen fluidounces. Rectum distended with sixteen fluidounces. A and B, folds of peritoneum.

the median line, extending two and a half to four inches upward from over the symphysis pubis. The length of this opening will be varied according to the thickness of the abdominal wall.

The incision is carried down between the recti and pyramidales muscles into the prevesical space (cavum Retzii).

In many cases the bladder-wall is now at once in plain view, but in others a layer of cellular tissue, containing more or less fat, has to be separated. This should be done by dividing it directly down toward the bladder, and any dissection or separation of these loose tissues laterally should be carefully avoided.

Sometimes veins of considerable size lie at the bottom of the prevesical space, and these, when seen, may be clamped and cut, or, if possible, pushed to one side. If they are injured and give rise to troublesome hæmorrhage, it should be borne in mind that this bleeding usually stops when the bladder-wall is incised, much as the venous hæmorrhage in the neck, in the operation of tracheotomy, ceases when the trachea is opened. So that, if the bleeding points are not easily seen and caught up, the search should not be prolonged, but the bladder should be at once opened.

It will occasionally be found that the peritoneal fold is held down in close proximity to the pubes by a prolongation of delicate fascia (transversalis fascia, fascia propria of Velpeau) which attaches it to that bone. When this is the case it can be easily separated with the scalpel and drawn upward.

The bladder, when uncovered, should be opened by a clean thrust of the knife. The left forefinger, which is, during this part of the operation, protecting, and when necessary, holding up the prevesical fold of the peritoneum, should be at once slipped into the opening while it is distended by the escaping urine. The incision can then be enlarged according to need, either by stretching or with a probe-pointed bistoury. If the cystotomy has been done for the removal of a stone, the opening should be sufficiently large to allow the passage of the calculus without undue bruising of the edges of the incision.

The After-treatment of the Supra-pubic Wound.—The first important question we have to decide, in the matter of the after-treatment, is whether to apply sutures to the bladder wound or not. There is considerable difference of feeling among operators as to the wisdom of doing so. Statistics are too meagre to prove either plan decidedly superior, but as far as they go they show that patients have done better when the bladder wound was not closed, but was used for drainage. The added danger in the cases where the wound was closed seems to come from the increased chance of infiltration of urine and septic infection when the bladder leaks after the outer part of the wound has partly united.

The failure to unite has, no doubt, been due in many instances to the fact that improper cases were chosen for closure. It is evident that when the bladder-wall is much inflamed, especially in old and broken-down subjects, the chances of healing by first intention are very small, and the dangers of urinary infiltration are proportionately large. Only those cases, then, should be selected for suture in which the bladder is tolerably free from inflammation.

Further, if there is much hæmorrhage into the bladder, which cannot be checked at the end of the operation, this is to be looked on as a contraindication to the closure of the bladder-wound by sutures. For it is difficult in such cases, by perineal tube or catheter, to conduct off the urine, owing to the stoppage of the tubes by clots; and when these are clogged the efforts of the bladder to free itself soon reopen the wound.

In spite of these drawbacks in the use of the sutures of the bladder, the quick recoveries which are obtained in those cases in which the suture does hold are so striking that operators are constantly endeavoring, by improvement in technique, to make first intention of the supra-pubic wound a comparatively sure thing, and many are so sanguine as to believe that this effort will finally be successful, and will place the supra-pubic incision easily at the head of the procedures for treating the interior of the bladder.

Many forms of continued and interrupted sutures have been used in these wounds, but perhaps the most useful one has been the interrupted Lembert suture, which is easily applied and has the advantage of bringing broad surfaces together.

In applying any suture it is a good plan first to fix a thread at each end of the incision, by which the wound may be steadily held in view during the application of the intermediate stitches.

Some operators have advised that the outer surface of the bladder-wall be dissected off for a short distance around the incision, in order to prepare a fresh, raw surface which shall readily unite when drawn together by sutures. Antal suggests that an oval surface be thus denuded before the cavity of the bladder is opened, and that the incision be then made in the middle of this refreshed area. Whatever plan is used, care should be taken that none of the stitches penetrate the cavity of the organ, for not only would they favor the escape of the urine and thus make first intention almost impossible, but they would also be likely to serve as a nucleus around which calcareous deposits would form.

When the bladder wound is sutured, provision has to be made for the escape of urine, either by passing a catheter through the urethra and securing it there, or by putting a tube out through the perineum. The latter plan affords the best drainage, but involves an additional operation. Dr. Keyes has sought to reduce this operation to a minimum by the following procedure: He passes a sound from the bladder into the membranous urethra, and making its point prominent in the perineum, cuts down upon it by a very small incision. Through the opening thus made, a probe is passed up into the bladder, which draws after itself a thread, which in turn pulls in a catheter.

The other plan for the treatment of these wounds, and the one which thus far has had the most success, is by keeping the wound open and draining the bladder through it.

It is well to use two tubes for this, and their ends should be carried down to the bottom of the bladder when it is collapsed in the pelvis after the rectal bag is removed. The use of two tubes is a safeguard against the escape of urine being stopped by clots, and they are useful for irrigation. They should be secured to the skin, and their ends should be left long enough to dip down into a bottle between the thighs, or, if preferred, they may have attached to them a longer piece of tubing which hangs down over the side of the bed, and acts as a siphon to draw the urine out of the bladder. Some operators prefer to keep their patients on the side or belly, to favor drainage, but this is usually not necessary.

After thorough irrigation the wound should be dressed antiseptically, with iodoform gauze covering it closely around the tubes, and an absorbent dressing outside of this.

For the first few days the bladder may be irrigated with a solution of boracic acid several times in the twenty-four hours. After a few days one tube may be left out, and a catheter may be passed through the urethra and tied in. When this is working satisfactorily, and after the wound has contracted pretty well, the remaining tube may be removed, and the supra-pubic wound soon closes.

Indications for the Choice of the Supra-pubic Operation.—It is difficult at this time to lay down any exact rules for guidance in the selection of this operation. The modern operation of epicystotomy is so new as to be still on trial, and the statistics of mortality after it are not yet sufficiently determined to allow a fair comparison with the older rival methods. Furthermore, among these rival operations we have one (litholapaxy) which is almost equally young, and since the adoption of antiseptic precautions in surgery the results of the other cutting operations have been so vastly improved that, for purposes of comparison, only statistics of operations done since the general adoption of aseptic methods can be allowed. The operators of the present day are making the statistics by which this question will finally be judged.

Certain things are, however, plain. We have several operations, among which a selection may properly be made, which are wholly dissimilar in their methods and which have each their own difficulties and advantages. The cases to which these operations are to be applied are often complicated by a variety of conditions which may make now one, now another, procedure preferable. That surgeon will, therefore, be the most successful who, being an advocate of no system, studies each case with the purpose of applying to it that method of operation which best meets its needs, and avoids the dangers that surround it.

In considering the operation before us it will perhaps be easiest to discuss in turn the various conditions to which it may or has been applied.

First in importance we have *the removal of stone*. Until very recently this was the only application which the high operation found; and as the perineal operations had a smaller mortality the supra-pubic incision was reserved only for those cases in which the stone was too large for safe removal through the pelvis.

Since the revival of epicystotomy, with the improved modern technique and under the protection of antiseptic precautions, there have been a certain number of surgeons, mostly in Germany, or in those countries that get their medical instruction largely from German sources, who have gone so far as to claim that this is the proper operation for all cases of stone. These advocates of supra-pubic lithotomy claim that it is superior to the perineal operations because it avoids injury of important structures, such as the urethra, the prostate, and seminal ducts; because the hæmorrhage in it is less and is more under control; and because in case of any complication, such as a sacculated stone, the condition can be more readily recognized through the high incision, and more understandingly remedied. They say, further, that litholapaxy requires more skill and experience for its safe performance, as well as more complicated and expensive instruments.

These are all theoretical objections, and their value can only be finally established by long experience. The question in the meantime is, not what operation can be most safely entrusted to a tyro, but which operation has the lowest mortality in the hands of qualified surgeons, and under what circumstances is it not applicable, and is another to be selected.

Judging as well as possible from experience thus far obtained, it is the opinion of the most generally recognized authorities in this branch of surgery that litholapaxy is the safest operation in adult patients, and that in children the choice lies between it and lateral lithotomy.

The most important array of cases of supra-pubic lithotomy that have yet been published are those of Dr. Assendelft of Russia. In Langenbeck's *Archiv f. Klin. Chirurgie*, Band xxxvi., 1st and 2d Heft, he publishes the report of 102 cases of supra-pubic lithotomy, with only two deaths. One of the fatal cases he considers due to bronchitis and other troubles not connected with the bladder, and in no way dependent upon the operation, so that he gives his death-rate as about one per cent.

These are the best reported results after supra-pubic incision, and it is therefore important to give them careful consideration. Examining the cases first in regard to age, we find that the patients were all young people. Forty-one of them were under five years of age, twenty-four of them were between five and ten, twenty-nine were between ten and twenty, and only eight were over twenty, the oldest being twenty-eight at the time of the operation.

His cases were all, therefore, of an age at which the best results can be expected from any operation; and although his low death-rate attests his care and skill, it cannot place the high operation above others; for Freyer has achieved the feat of cutting one hundred and forty-three boys by the lateral perineal incision without a death.

Further, we find that in Dr. Assendelft's cases the stones were often very small; in thirty-seven cases they did not reach a drachm in weight. These cases cannot, therefore, be accepted as establishing the death-rate proper to supra-pubic lithotomy, but they give us additional courage to employ this operation when, from the size of the stone or for other reasons, the safer operations are inapplicable.

What are the cases, then, in which the safer operations, litholapaxy and perineal lithotomy, are inapplicable? As has been pointed out in the article on Diseases of the Bladder, in Vol. I. of this HANDBOOK, litholapaxy can be applied to all adult cases of stone, with the following exceptions:

1. A very large and hard stone may resist every attempt at crushing.

2. A stone may have as a nucleus a foreign body, such as a piece of bone or a bullet, too hard to crush, and too large to come through a tube.

3. An encysted stone may be out of reach of the lithotrite.

4. Some writers consider that stricture of the urethra may prohibit litholapaxy. This cannot often happen, for strictures, however close, yield readily to divulsion, which may be immediately followed by the crushing and evacuation of the stone.

5. False passages may exist, which so interfere with the introduction of instruments that the dangers of the operation are greatly enhanced, and the question of lithotomy is to be entertained.

6. The hip may be anchylosed in a position which interferes with the use of instruments through the urethra.

To these might be added two other exceptional conditions pointed out by Dittel:

7. The bladder may shut down so tightly on a large stone that there is no room for the manipulation of instruments.

8. A stone which projects into the urethra, unless it can be dislodged and pushed back into the bladder, cannot be crushed.

When the stone is too large to be crushed, or when a good-sized stone exists in a much contracted bladder, the supra-pubic incision is probably the best operation to select for its removal. Thompson has pointed out that the bruising of a perineal wound by the dragging of a large or rough stone through it, adds greatly to the risk of the operation; and it is better, therefore, when cutting is necessary, to select the high operation for stones of a size to occasion much stretching and laceration along the perineal route.

In the case of an encysted stone the supra-pubic operation has the great advantage that it gives the operator a much better chance than he can get through a perineal opening, to study the condition of things and to meet the difficulties intelligently. It is, therefore, the operation of choice in these cases.

A foreign body, if not large, may be removed by the median perineal incision; but if too large to come safely through the perineum, it should be extracted supra-pubically.

The same may be said of those stones that send prolongations into the urethra. Ordinarily these urethro-vesical calculi are not too large for removal by the perineal incision; and this operation has the decided advantage, that if more calculi are present along the urethra they may be reached and drawn out without any additional incision.

If strictures or false passages seem to make the operation of crushing too hazardous, the choice of the proper cutting method will depend on the size of the stone and the possibility of getting a staff into the bladder. When the urethra is permeable, and the stone is of moderate size, the perineal cut should be made. If, however, the bladder cannot be reached by an instrument large enough to serve as a guide, or when the stone is a large one (two ounces or over in weight), the supra-pubic incision should be resorted to.

An anchylosed hip may so interfere with the management of a guide that the perineal operation is impossible.

and the high operation must be used. When the staff can be used, however, the decision will turn upon the size of the stone.

One other condition remains to be considered which may influence our selection of a cutting operation, and that is, the size and conformation of the prostate. If this gland is so altered in shape that it causes an obstruction to the flow of urine, it may act as a predisposing cause for the formation of stone, and by leading to fermentation of the urine may keep up a constant irritation and inflammation of the bladder. When this is the case it will often be best to select an operation for the removal of the stone which will at the same time enable us to correct the faulty shape of the prostate.

If the stone is small and the prostate of moderate size, we may, by a median operation, dispose of the calculus and at the same time incise or remove the third lobe, which is the obstructing part of the gland.

If the stone, however, is too large for removal by the perineum, the supra-pubic incision must be used. It may occasionally happen, also, that the prostate is so large that it would not be possible, through the perineum, to reach and properly operate on that part which projects into the bladder. In such a case the supra-pubic method would again be the proper one to select, and of the indications for this we shall speak presently.

The Removal of Tumors of the Bladder.—Petersen, in his article on Sectio Alta, which appeared in the *Archiv f. Klin. Chirurgie*, vol. xxv., 1880, in which he reported the first cases operated upon by him with rectal ballonnement, pointed out the applicability of the high operation to the removal of tumors of the posterior bladder-wall, and also suggested the possibility of removing, by supra-pubic incision, a third lobe of the prostate that was obstructing the flow of urine.

It was not long before these suggestions were carried out, and in 1884 Professor Guyon and other French surgeons came out strongly in favor of this operation for the removal of tumors, and pointed out very clearly the advantages of this method over the boutonnière, or median perineal operation, which Thompson had then recently made prominent for these cases.

Although it was not until this time that the applicability of the high operation to all cases of bladder tumor was prominently urged, still it is to be remembered, in the interests of history, that Gussenbauer, in 1876, had reported a case in Billroth's clinic in which a large, solid tumor of the bladder, that had been examined through a perineal incision, was successfully removed over the pubes. Volkmann had also had a similar case later, which ended fatally.

The great and particular advantage of epicystotomy for the treatment of neoplasms of the bladder is, of course, the possibility of seeing the tumor, and acting intelligently for its removal.

As most of these tumors are situated at or about the trigone, it is evident of how great service the rectal ballonnement is in bringing them into view, and into easy reach. For this purpose a pear-shaped bag is perhaps the best, as it lies in the lower part of the pelvis and pushes the floor of the bladder upward toward the pubes.

The technique of the operation is the same as when done for stone, until the bladder is opened. After this the wound may be held apart with retractors, and the posterior bladder-wall thus brought into view. For this purpose long, flat spatulæ of zinc are useful to hold aside the lateral walls, which are pressed in by the intra-abdominal pressure, and make the view of the trigone otherwise impossible. The tumor, when exposed, may be removed with a wire noose or a pair of scissors. If pedunculated, it may be twisted off with a pair of nipping-forceps, and the base from which it grew may be cleaned up with a sharp curette.

Removal of Prostatic Outgrowths.—The cases in which these are properly approached over the pubes are rare. When they can be reached through the perineum this is the better route to select, both on account of the lesser risk to life and because the perineal wound provides better drainage. This last is an important consideration, as in these cases the bladder cavity much resembles a foul abscess.

When, however, the size of the prostate and the depth of the perineum make it impossible to reach the bladder face of the prostate by the boutonnière operation, and at the same time the serious nature of the symptoms from obstruction make some effort for relief necessary, a supra-pubic cystotomy may be resorted to. Occasionally, also, when the bladder has been opened over the pubes for the removal of a large stone, if an obstructing median lobe of the prostate is found, it may be excised without adding greatly to the risks of the operation.

Retrograde Catheterization of the Urethra.—In a few instances of impassable stricture the supra-pubic operation has been done in order to enable the operator to pass an instrument from behind forward to the strictured point, there to cut down upon it from the perineum, and thus open the posterior section of the urethra.

It must happen very rarely that it is not possible with care to follow the urethra backward through the stricture, and thus to accomplish the same object[1] without the added danger of a supra-pubic wound. *A. T. Cabot.*

SYMPATHETIC NERVOUS SYSTEM. To Bichat we owe the conception that the nervous system is composed of two general divisions, differing in their anatomical arrangement and their functions; the one presiding over voluntary motion and perception, the other over involuntary acts and the processes of assimilation and nutrition. The first he called the system of organic life, the other the system of inorganic life. Others have described the latter as the vegetative system, under the impression that it especially presides over nutrition and growth, the so-called vegetative functions; others, bearing in mind its extensive relations throughout the body, have believed that it forms a common bond between remote structures serving to correlate their functions, and have therefore named it the great sympathetic system — a name generally employed. The progress of physiological and anatomical knowledge has somewhat changed this view, and it may be still further modified. For that reason it would be better

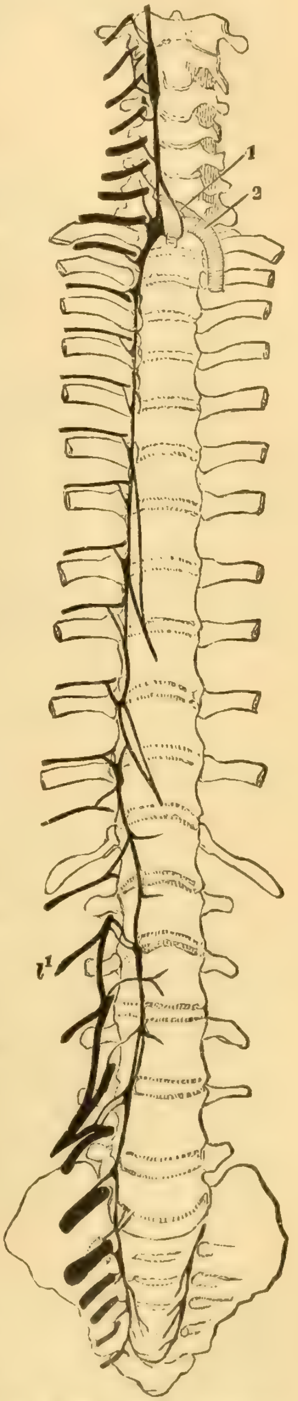

FIG. 5071. — The Interganglionic Cord. 1, Ansa Vieussenii; 2, right subclavian artery.

to adopt some name derived entirely from its anatomical relations or structure. The name that is perhaps to be preferred for the whole system is that of the GANGLIONIC NERVOUS SYSTEM, based upon one of its most significant peculiarities.

The system in question consists of two principal divisions. First, the main trunks or sympathetic nerves, forming two cords lying on either side of the spine, under cover of the ribs in the dorsal region, and near the transverse processes elsewhere, interrupted at intervals by small ganglia which receive branches from the spinal nerves (see Fig. 5071). Second, a system of plexuses accompanying the great vascular trunks and supplying the viscera. At first these plexuses are large meshed, but as they proceed toward the periphery the net-work becomes finer and finer. Interspersed freely among them, usually at the decussation of the fibres, are small ganglia. The terminal branches of the plexuses are sometimes contained within the very walls of the viscera, and the ganglia upon them become microscopic in size. The fibres are usually grayish or non-medullated.

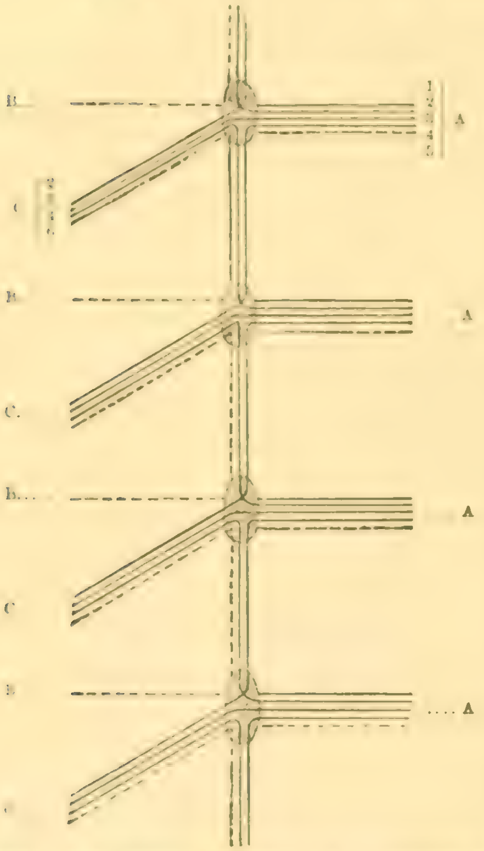

Fig. 5072.—Scheme showing the Formation of the Interganglionic Cord and Distribution of the Fibres of the Sympathetic. A, A, A, A, Fibres passing from the spinal nerves to the sympathetic ganglia. These are seen to be composed of the following classes of fibres: 1, those terminating in the ganglion; 5, those which pass through the ganglion to be immediately distributed to the visceral branches [illegible]; 2, 3, those which pass by means of the interganglionic cord to [illegible] nerves given off from ganglia above or below; these may be considered [illegible] for other ganglia along the cord; 4, [illegible] fibres passing from the ganglion to be connected with the spinal nerves. B, B, B, B, [illegible] to the periphery. C, C, C, C, [illegible] branches of the sympathetic, composed of fibres 2, 3, 4, 6; [illegible] fibres originating from ganglia above or below, and passing up along the interganglionic cord to be distributed with distant visceral branches. It will be noted that the interganglionic cord is made up entirely of fibres 2, 3, and 4, there being no [illegible] fibres having merely a connecting function.

These two grand divisions are connected by several trunks, the principal ones being known respectively, from their terminations, as the cardiac and splanchnic nerves.

The gray fibres of the sympathetic system are evidently of a more primitive type than the more complex medullated fibres constituting the bulk of the cerebro-spinal nerves. They are of the same structure as the first nerve fibres which appear in the fœtus, and resemble those which arise as a new formation in the course of a nerve which has been destroyed. The whole system of plexuses with interspersed ganglia bears a strong resemblance to the earlier types of the nervous system found in invertebrate animals, where there is no cerebro-spinal system proper.

It has therefore been a favorite idea with anatomists to consider the sympathetic system as a species of survival, holding that in the viscera, less exposed to outside influences, there has been less differentiation of structure. This view is supported by many other characteristic features of the viscera. But it should not be forgotten that embryology clearly teaches that the sympathetic system is embryologically identical with the cerebro-spinal, and in no sense such a separate apparatus as might be thought to be implied by this consideration. It is merely a peculiar anatomical arrangement taken on by those branches of the cerebro-spinal system which are distributed to the viscera.

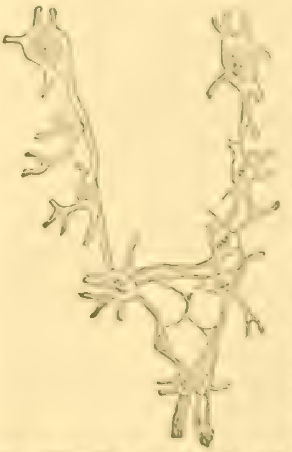

Fig. 5073.—The Ansa Sacralis, with the Last Four Pairs of Sacral Ganglia and the Ganglion Impar. (After Krause.)

Low forms of vertebrates, such as the lamprey (petromyzon), have no sympathetic nerve proper, branches from the spinal nerves passing directly to the viscera. Small ganglia are attached to these visceral branches, apparently arising as segregations from the ganglia upon the spinal nerves. As the viscera become more important and complicated they are supplied by branches from several spinal nerves, and the ganglia from which the branches proceed consequently become more or less interunited by fibres crossing both from below and from above. These cross branches from the interganglionic cord or sympathetic nerve. An examination of Fig. 5072 will show that this cord is entirely a secondary product, composed of filaments which afterward proceed peripherally, none of the fibres being merely internodal in the sense of beginning in one ganglion and ending in another.

The interganglionic cord was formerly supposed to be a cranial nerve, and was known to the elder anatomists as the great intercostal or trisplanchnic nerve. This is not surprising when its mode of origin is known. It is usually considered as commencing at the superior cervical ganglion, which lies at the base of the skull, but branches from this may be traced upward along the internal carotid artery, first as the carotid nerves, and finally as the carotid plexus to the base of the brain. Beclard even carried it so far as the anterior communicating artery, upon which he supposed the nerves of opposite sides to meet, forming at their junction a small ganglion. This is not confirmed by the investigations of recent anatomists. It is much more likely, as will be explained hereafter, that the spheno-palatine ganglion ought to be considered as the superior terminal station of the sympathetic.

The ganglia found upon the cord as it passes down along the spine are evidently segmental in their character. In the dorsal and lumbar regions they correspond to the spinal nerves; in the cervical they are reduced in number, owing to the fact that several of them unite to form single ganglia.

At the lower end of the spine the number of ganglia again becomes irregular. There are usually but four sacral ganglia, and the sympathetic trunks of the two sides are united by means of a loop (ansa sacralis) in a single coccygeal ganglion (G. impar, G. Walteri, Fig. 5073).

The connection of the various ganglia with the spinal nerves is shown in Figs. 5074 and 5075, but the details of the connection are diagrammatically given in Fig. 5076, from which it will be seen that fibres pass from both the posterior root (spinal ganglion) and anterior root of each spinal nerve to the ganglion of the sympathetic, and that this in turn gives off branches which pass to both the anterior and posterior branches of the spinal nerves, as well as a visceral branch and another small twig which, uniting with a similar one from the spinal ganglion, forms the nervus sinu-vertebralis of Luschka, which takes a recurrent course, passing back through the intervertebral foramina into the spinal canal, where it supplies the membranes of the cord. In the cranium this nerve is represented by the various recurrent branches given off from the three great divisions of the trifacial and the recurrent branch of the pneumogastric, also known as the posterior meningeal nerve or ramus duræ matris.

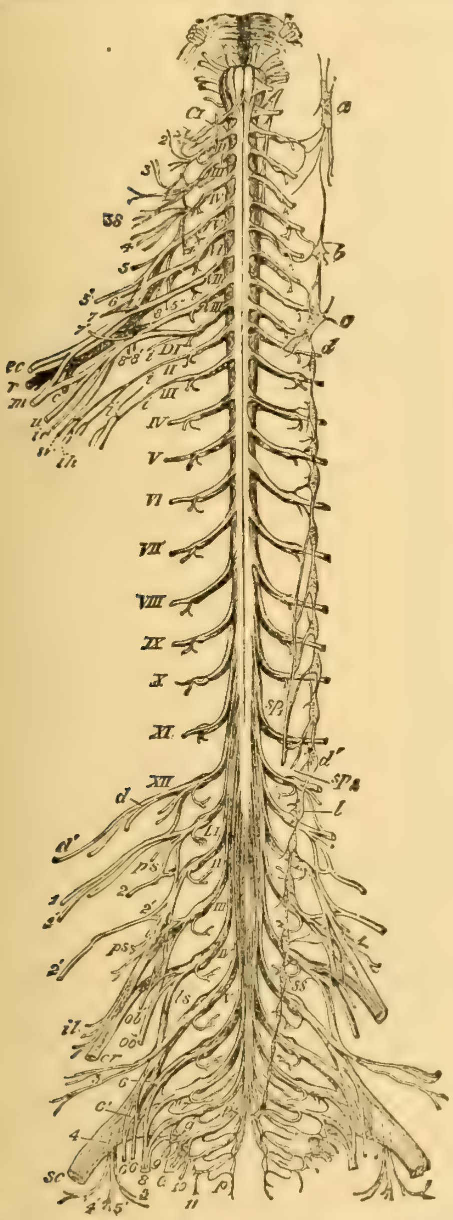

FIG. 5074.—Diagram showing the Spinal Cord from before, with the Attachment of the Principal Nerves. On the right-hand side of the diagram the connections with the sympathetic nerve are shown: on the left-hand side, the plexuses of the anterior roots. (From Ferrier.)

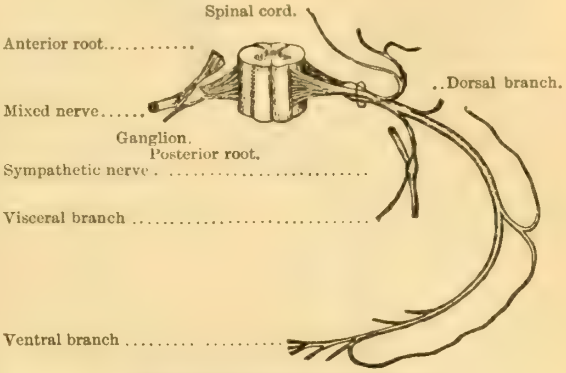

FIG. 5075.—Diagram of a Spinal Nerve.

The typical arrangement of the ganglia and the connecting cord is subject to considerable variation, there being often two or more strings instead of one passing from one ganglion to another. The cord sometimes fails altogether. Ganglia may be fused together, or there may be more than the usual number, caused by the separation of small masses from the main body.

In structure the sympathetic ganglia are markedly different from the spinal ganglia, from which they are believed to originate. The nerve-cells which they contain are, in higher vertebrates, multipolar and pigmented, there being none of those peculiar unipolar cells with dividing fibres which are characteristic of the spinal ganglia. Each cell has an investing membrane which is continued upon the processes and probably becomes eventually the sheath of the nerve-fibres. Unlike the spinal ganglia the number of efferent fibres considerably exceeds that of the afferent. Although not certainly known, it is believed that all the processes of the cells end in non-medullated nerve-fibres.

FIG. 5076.—Diagram showing Connections of a Sympathetic Ganglion.

The ganglia appear, therefore, to be veritable relay-stations connected with the cerebro-spinal system by means of medullated nerve-fibres and giving off non-medullated fibres, passing both with the spinal nerves and by their own visceral branches peripherally. It should be remembered that a considerable number of medullated nerve-fibres pass from the spinal nerves directly through the ganglia and are distributed with the others (see Fig. 5077). Each ganglion has an investment of connective tissue in all respects similar to that of the spinal ganglia.

The peripheral fibres of the sympathetic appear to have a great variety of functions. They are believed not only to be sensitive (the sensation conveyed being of an ill-defined character), but also motor, as shown in the heart. As a peculiar case of the latter may perhaps be classed the vaso-motor fibres which control the smooth muscles of the vascular system, and cause many of the phenomena connected with the nutrition of the parts to which the vessel is distributed. Formerly certain fibres (trophic fibres) were believed to have a direct control of the nutrition of certain organs. It appears more probable at present that these are merely vaso-motor fibres. More obscure are the functions of fibres described as *secretory*, and others as *inhibitory*. The former act directly upon the glands, increasing their activity; the latter restrain the action of the glandular and other organs. There is much that is yet very obscure as to the anatomical distinction and termination of the various fibres.

Fig. 5077 gives a diagrammatic statement of the upper cervical and cranial portion of the sympathetic, together with its connection with the cranial nerves.

The superior cervical ganglion (42), also called the cranio-cervical ganglion, receives branches of communication from the glosso-pharyngeal, pneumogastric, and hypoglossal nerves of the cranium, and the first four cervical nerves. It must therefore be considered as arising from a fusion of those segments of the sympathetic relating to the metameres of the vagus group and the first four cervical metameres.

Considerable discussion has arisen as to whether the sympathetic cord can be traced further upward to the region of

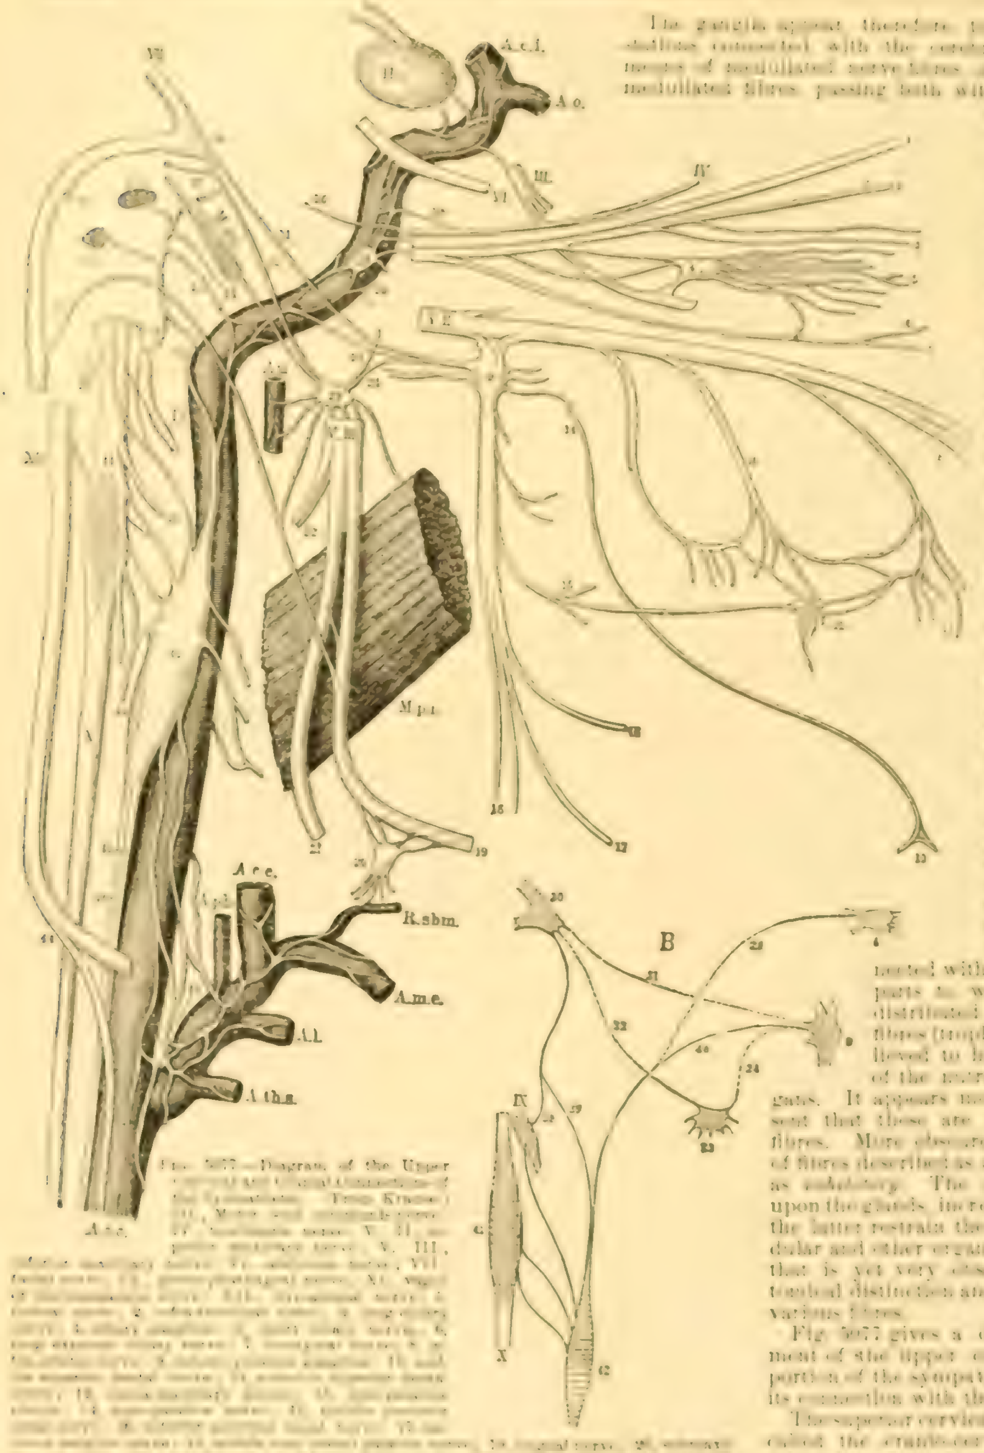

Fig. 5077.—Diagram of the Upper Cervical and Cranial Connections of the Sympathetic. (From Krause.) III., Motor oculi (oculomotor) nerve; IV., trochlearis nerve; V. II., superior maxillary nerve; V. III., [illegible]

the trigeminus. The direct continuation of the cord is by the carotid nerves and plexus. Connecting with the carotid plexus, or with its continuation the cavernous plexus, are branches derived from the third, fourth, fifth, and sixth cranial nerves, that is to say, the trigeminus group. Some anatomists call these the anterior superior roots of the sympathetic, the connections of the superior cervical ganglion with the vagus group as the posterior superior roots, and those with the spinal nerves as the inferior roots.

One of the principal branches of the carotid plexus is the great deep petrosal nerve (25), a branch of the Vidian, which passes to the spheno-palatine ganglion (9). This ganglion possesses the connections of a regular segmental ganglion of the sympathetic, and gives off visceral branches distributed to the pharynx. The view held by Meckel, that it was the highest member of the segmental ganglia of the sympathetic, was, therefore, probably correct. Since we are here at the last of the series, the internodal cord is reduced to a minimum.

Of the other ganglia of the cranium connected with the sympathetic, the ciliary, otic, and submaxillary are to be considered as peripheral ganglia. They contain the characteristic multipolar cells of the sympathetic ganglia. The ganglia of the pneumogastric and glosso-pharyngeal nerves, the geniculate ganglion of the facial, and the Gasserian ganglion, all contain unipolar cells, and are to be reckoned as spinal ganglia.

It is to be noted that each of the above-named sympathetic ganglia has connections with a motor and a sensory nerve as well as with the sympathetic. These connections are known as the roots or radices of the ganglia, or, respectively, as the radix motoria, radix sensitiva, and radix sympathetica.

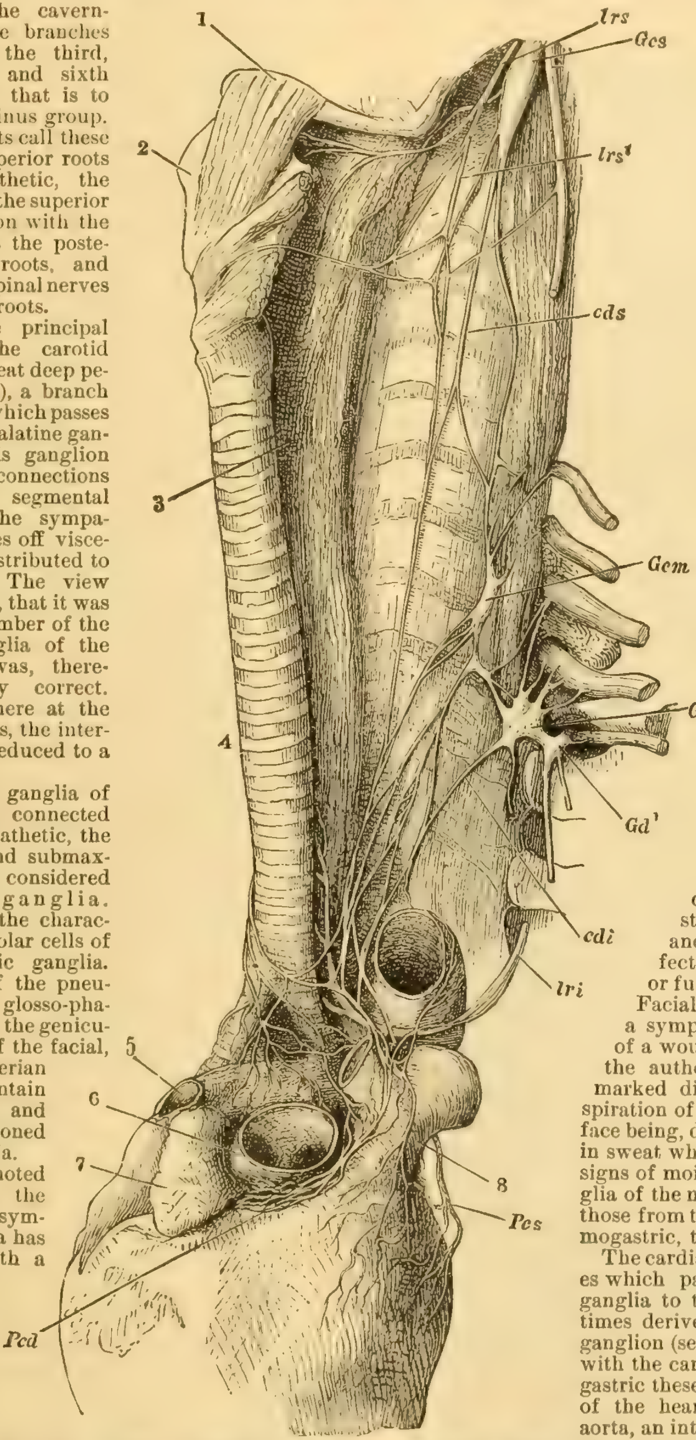

FIG. 5078.—Cervical Sympathetic Ganglia and the Cardiac Nerves. (Henle.) 1, Hyoid bone; 2, larynx; 3, œsophagus; 4, trachea; *lrs*, superior laryngeal nerve; *lrs'*, external laryngeal nerve; *lri*, lower end of inferior laryngeal nerve; *Gcs, Gcm, Gci*, superior, middle, and inferior cervical ganglia; *Gd'*, first thoracic ganglion; *cds, cdi*, superior and inferior cardiac nerves; *Pcd, Pcs*, coronary plexuses; 5, superior vena cava; 6, aorta; 7, right auricular appendage; 8, pulmonary artery.

A number of minute inconstant ganglia have been described by different authors. Such are the carotid ganglion of Krause (No. 27, Fig. 5077) in the carotid plexus; the temporal ganglion on the external carotid artery, which appears to have a relation to the parotid gland like that which the submaxillary ganglion has to the submaxillary gland.

Branches from the superior cervical ganglion form plexuses on the external carotid and its branches. The inter-carotid ganglion (Fig. 5077, No. 47) is not now considered as nervous in its character, but rather as a vestige of atrophied branchial vessels.

The other ganglia of the neck are shown in Fig. 5078. The middle cervical ganglion (*Gcm*) is situated near the sixth cervical vertebra and the inferior thyroid artery. It connects with the fifth and sixth cervical nerves. Occasionally it is absent. It sends a plexus to the inferior thyroid artery. Opposite the transverse process of the seventh cervical vertebra, or a little below, is found the third cervical ganglion (*Gci*), often united with the first thoracic. It sends a plexus to the subclavian artery, usually passing a loop around it (ansa Vieussenii, Fig. 5071). The position of the sympathetic cord being quite deep, it is rarely injured. In some cases it has been severed by a stab or pressed upon by tumors, and this is sometimes found to affect in some manner the nutrition or functions of that side of the face. Facial hemiatrophy is thought to be a sympathetic neurosis. In one case of a wound on the side, coming under the author's observation, there was a marked difference in the amount of perspiration of the two sides—one-half of the face being, during hot summer days, bathed in sweat while the injured side showed no signs of moisture. Branches from the ganglia of the neck pass to form, together with those from the glosso-pharyngeal and pneumogastric, the pharyngeal plexus.

The cardiac nerves are peripheral branches which pass from each of the cervical ganglia to the heart, a branch being sometimes derived also from the first thoracic ganglion (see Fig. 5078, *cds, cdi*). Uniting with the cardiac branches of the pneumogastric these nerves form, around the base of the heart and under the arch of the aorta, an intricate plexus (plexus cardiacus, plexus aorticus superior), usually divided into a superficial portion in front of the aorta and a deep portion behind and below, the latter being the larger. From this plexus offsets pass to the coronary arteries, along the descending aorta, the pulmonary arteries, and bronchi, to take part in a second great plexus, the pulmonary, also formed by union with the pneumogastric. It is continued along the œsophagus. Filaments from the cardiac plexus pierce the wall of the heart supplying its substance, many microscopic ganglia being developed in their course. Among the most important of these is the ganglion of Wrisberg, about the centre of the plexus. In the frog the ganglia within the substance of the heart have been noticed to have special functions, and to insure the beating of that organ after its nervous connections are severed. Indeed it appears clear, from numerous and varied experiments that have been made on this subject, that the principal controlling agency of the movements of the heart lies in these little ganglia. Bearing in mind this fact we are able to understand why a comparatively slight cause may sometimes at once arrest permanently the heart's action. The doctrine sometimes taught that a puncture even into the heart's substance may be made with a fine trocar is surely extremely dangerous, as it is well known that a lesion of some of these ganglia is at once fatal. The ancients supposed the main seat of the emotions to be in the heart itself, and the obscure sensation of oppression in the cardiac region caused by depressing emotions is popularly recognized in many ways.

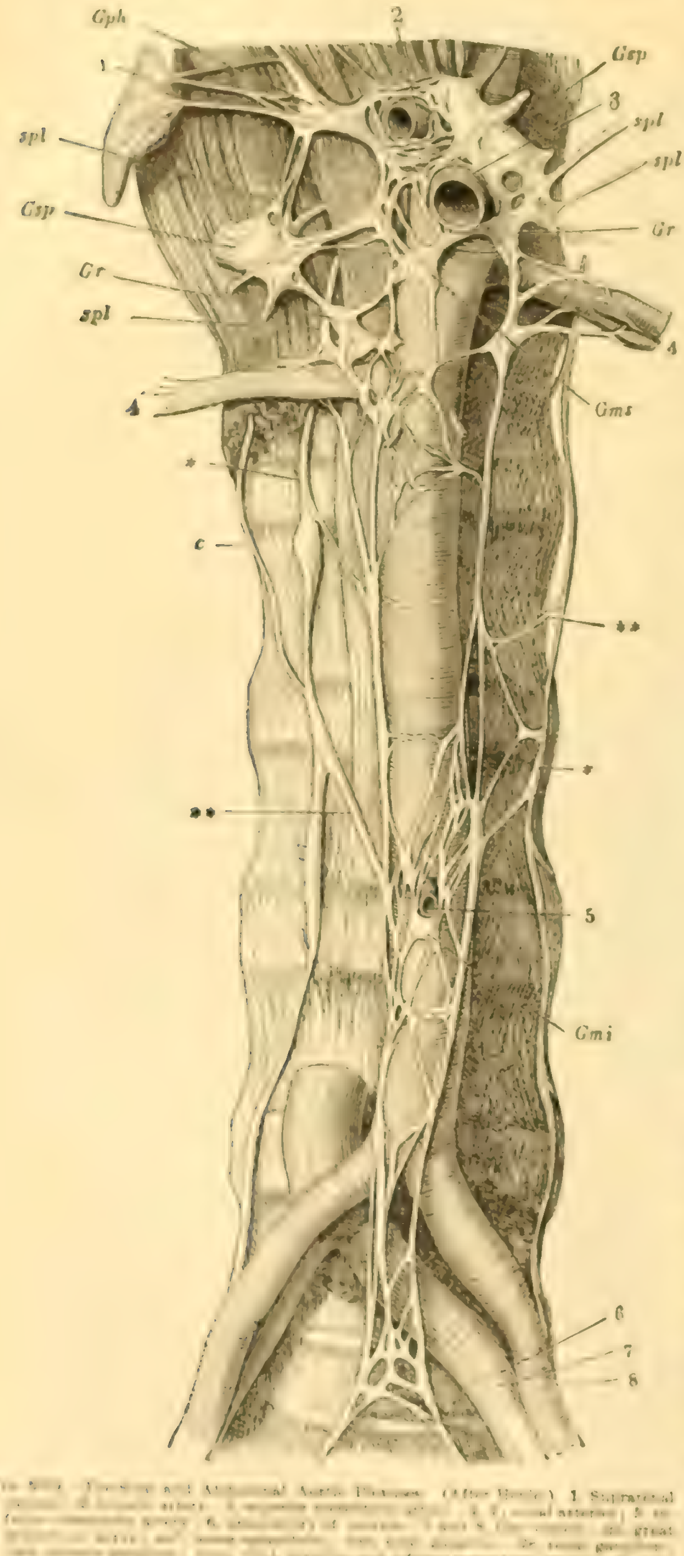

Fig. 5079.—Thoracic and Abdominal Aortic Plexuses. (After Henle.) 1, Suprarenal [illegible] renal arteries; 5, in[illegible] great [illegible]

The thoracic ganglia usually equal in number the body segments in this region. The upper ones give off branches which reinforce **the aortic, pulmonary,** and œsophageal plexuses (aortico-pulmonary branches). From the lower nerves are given off the great branches known as the splanchnic nerves which penetrate the diaphragm and supply the abdominal viscera. In appearance they resemble the cerebro-spinal nerves, being white rather than gray, owing to a predominance of medullated fibres.

The great splanchnic nerve is formed by peripheral branches derived from the sixth, seventh, eighth, and ninth thoracic ganglia. The lesser splanchnic is derived from the tenth, eleventh, and twelfth thoracic ganglia. The lower root sometimes remains independent and is then known as the renal splanchnic (nervus splanchnicus imus inferior or tertius—posterior renal nerve of Walter). Occasionally a splanchnic nerve is formed from the upper thoracic ganglia or from the cardiac plexus (nervus splanchnicus supremus). **These nerves penetrate the diaphragm** through either the crura or the aortic opening, and pass to a large, wide-meshed plexus situated in front of the aorta immediately under the diaphragm.

This, known under various names as the solar plexus, cœliac plexus, epigastric plexus, nervous centre of nutritive life, cerebrum abdominale, is by far the most considerable plexiform structure in the body, forming by its connections interlacements which embrace **all the great** vascular trunks of the abdomen and supply all the viscera therein contained. Fig. 5079 shows only a part of it that is in immediate relation with the aorta and its branches. Many ganglionic masses are collected at the points of intersection of the meshes. These, known as the solar ganglia, are quite irregular and variable in size and volume. Two principal masses can usually be made out on either side of the cœliac axis, having a somewhat crescentic shape, and hence known as the semilunar ganglia.

Secondary offsets proceed from this plexus upon all of the **principal trunks of the** abdomen, receiving names according to the trunk upon which they are situated. Thus we have phrenic, gastric, hepatic, splenic, superior mesenteric, renal, suprarenal, spermatic, and ovarian plexuses. Ganglionic masses within these sometimes receive special

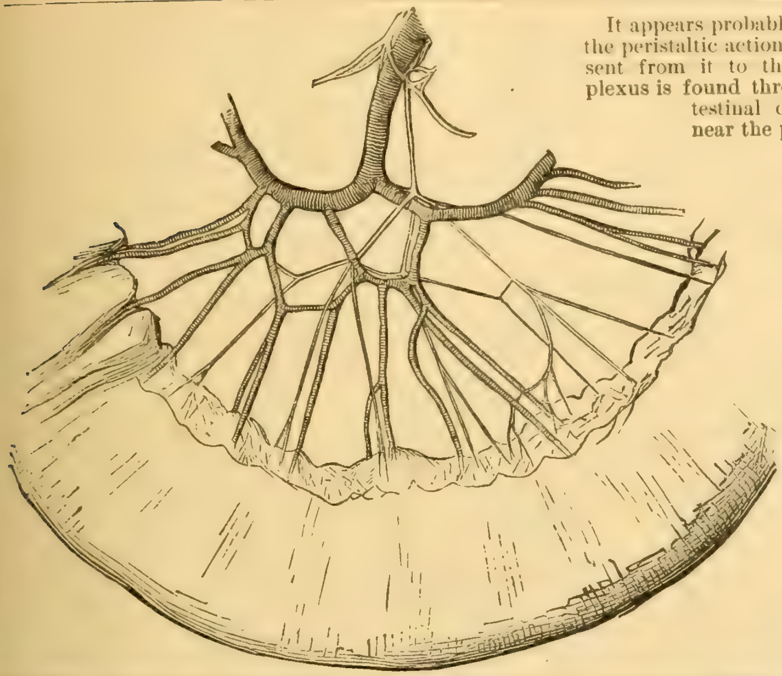

FIG. 5080.—A Portion of the Small Intestine, showing the Distribution of a Twig from the Mesenteric Plexus. (Henle.)

names, as the phrenic, superior mesenteric, and renal ganglia.

The solar plexus is continued downward along the aorta as the abdominal aortic plexus, plexus lumbo-aorticus or intermesentericus, and from this an offset proceeds to the inferior mesenteric artery. Still farther downward, in front of the last lumbar vertebra, the aortic plexus is known as the hypogastric plexus; and continued downward into the pelvic cavity in front of the sacrum, as the inferior hypogastric; it gives offsets along the branches of the internal iliac artery, receiving from them distinctive names.

These latter plexuses are exceedingly close-meshed, and abound in minute ganglia. Being intimately connected with the genito-urinary organs they play a very important rôle in the phenomena of generation and nutrition. Many of the protean symptoms of pregnancy are caused by pressure upon these nerves or interference with their functions.

Peripheral branches proceed from the abdominal and pelvic plexuses to the viscera. Those for the intestine usually pass within the folds of the peritoneum in the manner shown in Fig. 5080. While within these folds many of the branches have upon them Pacinian corpuscles, which is thought to be evidence as to their sensory character. Within the walls of the intestine the nerves again unite to form intricate plexuses. One lying between the layers of longitudinal and circular muscular fibres is known as the plexus myentericus externus (Auerbach's plexus). A clear idea of this curious structure can be had on consulting Fig. 5082. It appears probable that to this plexus is mainly due the peristaltic action of the intestines. Fine fibrillæ are sent from it to the muscle fibres themselves. This plexus is found throughout the entire extent of the intestinal canal, commencing in the stomach near the pyloric orifice.

Another plexus is found within the intestinal wall, communicating with Auerbach's plexus and lying under the submucosa (see Fig. 5081).

This was discovered by Meissner, and is known frequently by his name, but also as the plexus myentericus internus, or plexus intestinalis submucosus. It is wider meshed than Auerbach's plexus, and has collections of ganglionic cells at the intersections. It also extends throughout the small and large intestine. It apparently controls the small vessels and the smooth muscle fibres of the mucous membrane.

The nervous supply of the uterus has been very carefully investigated. The offset of the inferior hypogastric plexus that extends along the uterine and vaginal vessels is known as the plexus utero-vaginalis. At the fundus of the vagina there is found a considerable ganglionic mass, surrounding the cer-

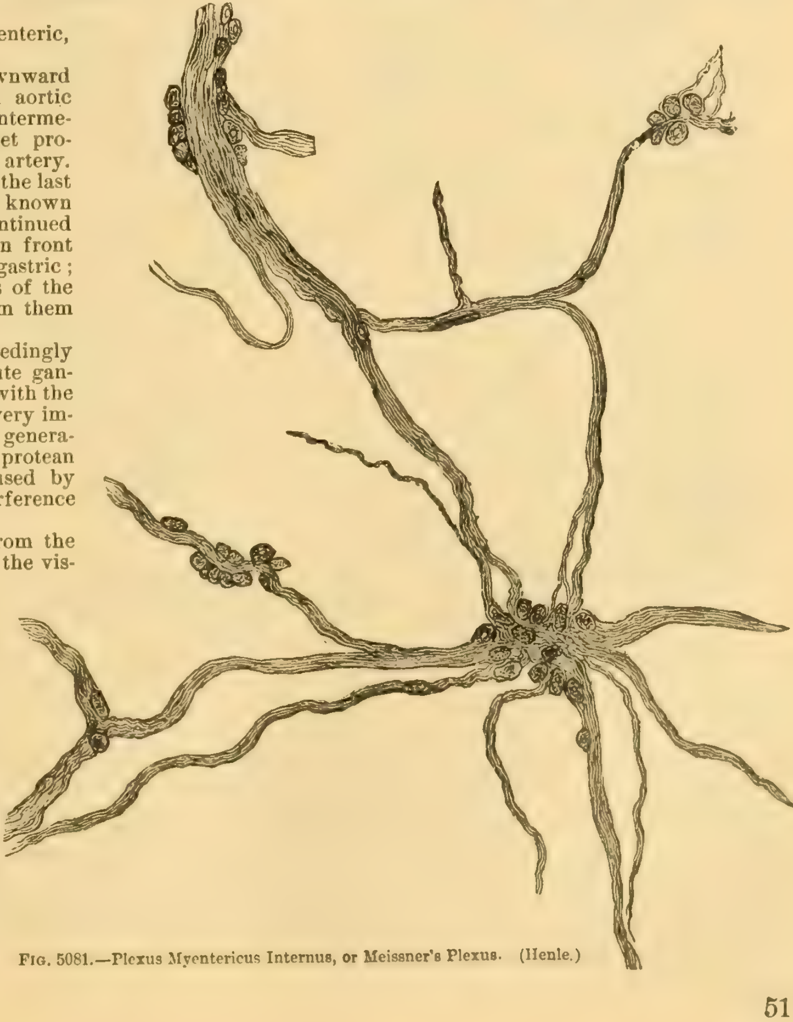

FIG. 5081.—Plexus Myentericus Internus, or Meissner's Plexus. (Henle.)

vical portion of the uterus, and known as the cervical ganglion. From this are derived all the nerves supplying the lower portion of the organ. While they form plexuses within its mass between the muscular sheets no ganglia are found there. During pregnancy they greatly increase in length and thickness. *Frank Baker.*

SYRINGO-MYELIA.

SYRINGO-MYELIA. Syringo-myelia (Ger. and Fr., Syringomyelie, from the Greek σύριγξ, a cavity, and μυελός, marrow, or pith) means, literally, any abnormal cavity in the spinal cord; it has, however, acquired a narrower meaning, and is now only used to designate cavity formation which is pathological, and accompanied by a growth of new tissue; there is in lesions of this kind such uniformity in seat and mode of development as suffice to give in most cases a well-defined symptom-complex.

Pathological Anatomy.—The lesion in syringo-myelia consists of a new growth of tissue, having the structure and attributes of the normal supporting substance of the central nerve tissues; that is, it is essentially glia tissue, and as the new growth may properly be classed with the tumors, the lesion is really a glioma, which by breaking down causes the cavity formation from which the disease is named.

The process may begin in the white or in the gray matter, and is in either case central; it reaches the pia mater, if at all, late in the course of the disease. In the majority of cases the point of origin is in the neighborhood of the central canal, which latter may remain separate from the new cavity during the whole course of the disease, or, more often, sooner or later unites with it as a result of a breaking down of the intervening tissue; it differs in this respect from hydromyelus, a condition found early in life, which consists in a distention of the central canal; the latter is the result of a congenital defect of development.

The new tissue is formed through a considerable extent of the spinal cord, and does not result in a transverse lesion; it may form in places enlargements of well-defined proportions, but has, as a rule, the characteristics of an infiltrating growth, and this hyperplastic appearance has led some observers to class the disease with the chronic inflammations. The growth may begin in any part of the vertical extent of the cord, but in most cases originates in the lower cervical and upper dorsal segments, and may extend as far as the medulla oblongata.

In some cases there are curvatures of the spinal column, which, except in cases in which there has been a trauma, seem to be due to muscular abnormalities rather than to disease of the vertebra.

The cord, on removal from the canal, may appear normal; it is often enlarged in the affected portions; if the process has extended to the periphery the pia mater may be adherent; there are rarely gliomatous masses in connection with the meninges.

On section, the cord at the affected part is soft, and contains a cavity of greater or less extent, which may, late in the disease, extend entirely across the cord in the lateral direction, so as to separate the anterior and posterior portions. The contents of the cavity are serous or gelatinous, and usually escape as soon as the cord is cut into. The preserved portions of nervous tissue have approximately a normal appearance.

On microscopical examination the cavity is seen to be bordered by tissue consisting of a fine fibrous net-work abundantly supplied with nuclei; the cell bodies are very delicate, and not easily seen. The tissue is well supplied by blood-vessels with thin walls, and there are often hæmorrhages and blood-cysts which may be of considerable size. There is no sharp line between the new growth and the normal tissue, but along the edges there is an infiltration of the nervous elements with cells, which do not differ in appearance from those of ordinary glia tissue.

The nerve-structures undergo the usual changes consequent on pressure, that is, atrophy, disintegration, and absorption; they often exhibit considerable tolerance of the presence of the new tissues, as in a case described by Schultze, in which the ganglion cells of an anterior horn were flattened out so that they lay with their axes all in a transverse direction, but otherwise appeared normal. (How much of this was really due to the disease process is somewhat doubtful; the ganglion cells of the cervical portion of the normal cord are often seen to be arranged in this way, possibly from the same cause which produces a flattening of the whole cord in this region.) The ganglion cells finally lose their processes, become shrunken, undergo pigment degeneration, and are absorbed. The axis-cylinders may become swollen and varicose, or may simply atrophy; granule-corpuscles are often abundant.

Secondary degenerations are frequent, being especially common in the lateral pyramidal tracts; they present the usual histological alterations; in some cases system degenerations have been described, which could not be due to cutting of the tracts by the new growth; thus, in a case described by Strümpell, the lateral pyramidal and direct cerebellar tracts were degenerated, but at no point affected by the primary lesion; unfortunately the medulla was not examined, so that it remains uncertain whether or not the pyramidal fibres were in this case affected above the level of the neoplasm.

Symptoms.—These depend on the location of the new growth, and on the extent and duration of the process. The first variations from the normal are noticed, in most cases, in the upper extremities, and vary according as one or another set of nerve-fibres or cells is first involved; but the cavity may be situated so as to give no symptoms, at least such as to make a correct diagnosis possible. It was first pointed out by Schultze, of Heidelberg, that many of these cases may be recognized during life.

The motor symptoms consist in progressive paralysis, accompanied in the upper extremities, if the disease is in the cervical region of the cord, with atrophy and the reaction of degeneration, diminished or abolished reflexes, and often with fibrillar twitching; as a rule, groups of muscles which habitually act together are affected at the same time; no special group of muscles is affected by preference. Somewhat later there is apt to be progressive weakness of one or both legs, with exaggerated reflexes, differing in no way from spastic paraplegia due to other causes. If the disease extends to the medulla, the face, tongue, and pharynx may be wholly or partially paralyzed. All of these paralyses are usually slowly progressive in character, but in exceptional cases power may be entirely lost in a particular group of muscles very rapidly, even within a few hours, as if from a sudden breaking down of tissue.

Sensory symptoms consist of pricking and burning sensations and formication, rarely, if ever, true lancinating pains. Much more important is anæsthesia, which is almost invariably found; the loss of sensation does not usually extend over a very large area, but occurs in patches on the body or limbs, or occasionally a whole limb may be anæsthetic; the loss is almost always to impressions of pain and of temperature, with tactile sensibility almost or quite normal. The affected area of skin may be entirely insensitive to heat or cold, receiving only a tactile impression from a hot or cold object; in some cases there is added a peculiar kind of hyperæsthesia, so that a very moderate degree of heat or cold may cause the patient great pain, without his being able to distinguish it from other painful impressions; this paræsthesia may be combined with delayed sensation, so that the patient may cry out with pain some time after the offending object has ceased to be in contact with the skin. The anæsthetic areas do not usually coincide in nerve-supply with the paralyzed muscles.

Trophic changes are noticeable, and may be the first symptoms to attract attention; there are often spontaneous and painless fractures of bones, erythematous and phlegmonous inflammations, œdema either of the skin alone or also of the deeper structures, and ulcers; in addition, increased sweating, local coldness and cyanosis, and sometimes attacks of dizziness, which, as well as the preceding symptoms, are to be attributed to vaso-motor disturbances.

When the disease extends toward the medulla, there are apt to be sensory disturbances in the area supplied by the trigeminus; diabetes insipidus has been noted in some cases. Paralysis and anæsthesia may in any case be preceded by transient spasm and hyperæsthesia, respectively. Sexual activity is apt to be lessened or abolished. The bladder and rectum may suffer either from involvement of their centres in the lower part of the cord, or more often by the severing higher up of the fibres which connect these centres with the brain. Optic atrophy and transient paralyses of the eye muscles have sometimes been observed; to what these are due is not clear. Other cerebral symptoms are usually absent.

Course and Duration.—The progress of the disease is slow, often requiring from two or three to ten years before death ensues; there are in many cases marked remissions, during which the general health improves, and the motor and sensory symptoms cease to progress, and even sometimes become much less marked. Death, however, inevitably results, and may be caused by any of the ordinary complications of spinal-cord disease, pneumonia, œdema or gangrene of the lung, paralysis of the muscles of respiration, bed-sores, cystitis, and pyelitis, or from exhaustion with heart failure.

Diagnosis.—It should be remembered that none of the symptoms of syringo-myelia are in any sense pathognomonic; they simply furnish an indication that there is a slowly progressive lesion of the central tissues of the cord. Experience has shown that such a lesion is almost invariably gliomatous, with cavity formation, just as it is found that a lesion confined to the posterior columns is almost certainly sclerotic, and so on.

A good deal of confusion has been caused in nomenclature of diseases of the cord, by the publication of cases the diagnosis of which has not been verified by autopsy. In this way many anomalies have been described, especially in cases referred to the group of progressive muscular atrophies, from the fact that sensory symptoms were not given sufficient weight in forming a diagnosis.

There are a few diseases of the nervous system which are of protean type, and may appear in almost any guise. Of these hysteria was the earliest to attract attention, and formerly most nervous cases whose symptoms could not be accounted for in any other way were brought under this head. It may be taken for granted that syringomyelia, except in the very earliest stages, will present objective symptoms which indicate organic disease with certainty; in most cases there is paralysis with atrophy and the reaction of degeneration; if this is not found, there are trophic changes much more marked in character than are those which accompany a purely functional disturbance; several cases without paralysis are recorded, in which the diagnosis was made simply from the occurrence of painless spontaneous fractures of bones, and sensory disturbances of the kind indicated above; in one of these cases, reported by Schultze, the diagnosis was verified by autopsy.

Multiple sclerosis has of late years been studied very carefully, and the infinite variety of its lesions in position and extent recognized; it is conceivable that a sclerotic patch might occupy the central portion of the cord, and so cause the symptoms which are regularly found in syringo-myelia; at the same time I know of no such case on record, and the chances against its occurrence would in any particular case be very great.

The habit of omitting examination of the peripheral nerves at the autopsy of cases of suspected disease of the central nervous system is in great part the reason why we know so little of primary and secondary nerve affections; a routine naked eye and microscopical examinathat of the different nerve-trunks in cases of this kind cannot be too strongly insisted on. Multiple neuritis has but lately attracted the attention it deserves. In typical cases it is readily differentiated from syringo-myelia by its rapid course, marked pain and tenderness along the nerve-trunks, paralysis coinciding in distribution with the areas of sensory disturbance, and equal involvement of the tactile with the other varieties of the sense of touch. At the same time it must be said that affections which are now classed with the neuritic processes may give only motor symptoms, as in lead palsy, or only sensory symptoms, as with some of the neuralgias of organic origin, so that there would seem, in mixed nerves, to be a selective action in disease analogous to that which is found in system diseases of the spinal cord. Again, some of the neuritic processes are doubtless subacute or chronic, and may correspond to the primary degenerations in the cord and brain. Until the different forms of nerve disease have been more carefully studied and classified it will be impossible to lay down fixed rules for their differentiation; but it will be possible to distinguish syringo-myelia from most of these forms of disease on the general principles already laid down, and especially from the somewhat striking fact that the motor and sensory symptoms in this affection are apt to be dissociated, and not to occur in the distribution of the same nerve.

Against confusion with the diseases mentioned above a careful routine examination is the only safeguard, as some important symptoms, especially anæsthesia, may be unknown to the patient and unsuspected by the physician. It is somewhat easier to distinguish the disease in question from those affections which have a definitely located lesion. Of these the progressive muscular atrophies form a distinct class, and may readily be excluded in any doubtful case by establishing the existence of sensory symptoms. Under this head may properly be brought the various forms of pseudo-hypertrophy, which are without doubt varieties of the same disease, progressive muscular atrophy of spinal type, amyotrophic lateral sclerosis, and acute and chronic polio-myelitis anterior. Without discussing here the relation which these diseases bear to one another, we will observe that they are alike in one respect: in any uncomplicated case sensory symptoms must, from the position of the lesion, be entirely absent.

A mistaken diagnosis of locomotor ataxia could hardly be made, except in those cases of syringo-myelia in which the new growth begins in the posterior columns; in this case, however, the columns of Goll are affected sooner than are the root zones, and the typical character of the anæsthesia, origin of the disease in the cervical region, and lack of eye symptoms, will serve to distinguish the case from one of tabes. In general, such disease processes as tumor, and cavity formation, and ordinary inflammatory action have a certain irregularity of development, no matter where they begin, and differ markedly from the system diseases, which, beginning in certain tracts of fibres, run almost or quite their entire course without overstepping the limits of these tracts; so that it is possible to give of the system diseases a clinical picture which shall much more accurately correspond to the features of any particular case. At the same time, even with such a process as the one under discussion, there is a strong tendency for the lesion to occupy a definite position, and it is this fact which makes its diagnosis possible.

Hypertrophic pachymeningitis and meningeal tumor are distinguished by the early occurrence of marked pain and tenderness over the affected region, and absence of the symptoms which are caused by lesion of the central part of the cord; but in cases of syringo-myelia with gliomatous masses in the meninges, the diagnosis may be difficult or impossible.

Frequency and Causation.—This disease was formerly considered quite rare, because unrecognized; it was usually diagnosed as progressive muscular atrophy, tumor of the cord, or spastic paralysis. It is said by Schultze to be as common as multiple sclerosis. While this may be true in Germany, it can hardly hold good in this country; the diagnostic features of the disease are moderately well known here; the only case yet on record in the United States was described by Dr. M. Allen Starr in the *American Journal of the Medical Sciences* for May, 1888; while not verified by autopsy, the diagnosis is conceded to have been a correct one. Twice as many men as women are said to be affected by the disease. It occurs most often between the ages of thirty and forty years.

Little is known of the causation of syringo-myelia; in a moderate proportion of the cases there is a history of preceding trauma, with injury of the spinal column or of the cord itself. It has been thought by some writers that the disease invariably develops in a cord predisposed by congenital defects; this is denied by Schultze, who holds that the changes may commence in an originally healthy cord, and as well in the white as in the central gray matter. Exposure to cold, and venereal and sexual excesses may probably be excluded as causative agents in this disease.

The prognosis is absolutely bad. No case of recovery is on record.

Treatment is confined to the relief of symptoms and sustaining of the general health; no specific against the disease process is known.

Henry S. Upson.

TEA (*Thé*, Codex Med.). The prepared leaves of *Thea sinensis* Linn. (*Camellia Thea* Link, etc.), Order, *Ternstrœmiaceæ*. This includes as varieties *Thea (Camellia) viridis*, *Th. Bohea* and others, as well as the wild Assam Tea tree supposed to be the origin of them all. The Tea plant as seen under cultivation is a shrub a metre or so in height (from two to five feet), but in the wild state it becomes a small tree of from five to ten metres. It has bushy, very leafy branches and smooth, brown bark. The leaves are alternate, evergreen, rather thick and leathery, smooth when mature, short petioled, lanceolate, of varying bluntness, serrate, feather-veined, the veins not reaching the margins, and from five to ten, or in the much larger wild plant, from fifteen to twenty centimetres long (Fig. 5083).

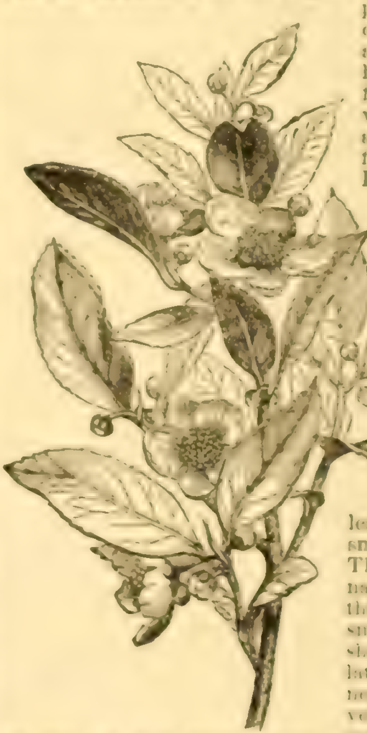

FIG. 5083.—Tea plant. Flowering Branch. (Baillon.)

Flowers axillary, one, two, or three together, on short recurved peduncles, about the size and shape of cherry blossoms, creamy white. Sepals five, petals five or more, cohering at the base. Stamens numerous, filaments cohering at the base, and also slightly attached to the bases of the petals. Ovary superior, three-celled, with several ovules in each cell (Figs. 5084 and 5085). Fruit, a slow-ripening, fleshy capsule, finally loculicidal, three-celled, with two or three oily, albuminous seeds in each cell.

Tea is a native of Asia, and grows in a semi-wild state in many of the districts where it is cultivated, but has only been found in an unquestionably indigenous condition in Assam, where it was discovered some fifty years ago by Mr. Robert Bruce, as a good sized tree, with very large leaves. It is now cultivated in many parts of the world; first in importance in China, where it is said to have been domesticated more than a thousand years ago, also in great quantity in Japan, Java, and India, to a slight extent in South America and elsewhere, and finally in the United States, experimentally. Although it grows pretty well in many places, and is comparatively hardy, the higher price of labor is a bar to its profitable production in most civilized countries.

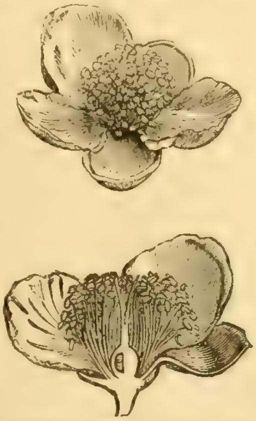

FIG. 5084.—Flowers of Tea-plant, with Section. (Baillon.)

The earliest knowledge of the use of Tea is from the Chinese, to whom it was familiar one thousand and perhaps two thousand years ago. It was introduced into Japan in the thirteenth century, A. D., and into Java and India in recent times. It was first used in Europe near the middle of the seventeenth century.

Tea is planted in gardens and tended without gathering until two or three years old, then the leaves and buds are plucked for two or three successive crops each season. If green tea is to be made, they are immediately dried over a heated stove, and afterward colored more or less. For black tea the leaves are pressed in little heaps, and allowed to wilt and ferment a little before drying, which is effected in the same way as above; by this process some of the tannin is decomposed, and the essential oil altered so as to modify the taste and smell a little; its color is also very much darkened, as well as that of the infusion made from it. The principal varieties of tea are: Black—flowery pekoe, orange pekoe, souchong, congou, bohea, etc. Green—gunpowder, imperial, hyson, young hyson, etc. The Teas of our market are nearly always "blends," made by mixing several grades together.

The usual shape of Tea is attained by compressing and rolling the leaves in the hand, or upon a table until they are crumpled into the little rolls or wads of which commercial tea consists; in the nicer sorts each leaf is rolled by itself.

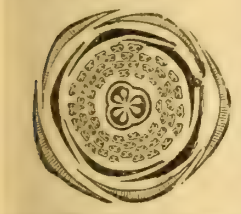

FIG. 5085.—Plan of Flower. (Baillon.)

COMPOSITION.—In the proportions of the ingredients there is considerable variation, but the following are the principal ones: *Essential Oil* from one-half to one per cent., which is the source of its flavor; *Caffeine* (Theine) from one-half to two or three per cent., which gives it bitterness. This alkaloid is found in half a dozen other plants, most of which are used somewhere as stimulating food adjuncts (see Caffeine, Guarana, Cola Nuts, etc.). It is also related to Cocaine and Theobroma. The amount of *tannin* in tea is large (from twelve to seventeen per cent.).

ACTION AND USE.—The large amount of tannin found in Tea makes it an active astringent, especially to those unaccustomed to its use. It constipates the bowels, impairs the digestion, and reduces intestinal secretion when taken in large quantity; locally it makes tea a mild hæmostatic, and a useful wash for indolent ulcers, exuberant granulation, etc. The essential oil gives to Tea its agreeable flavor, and a good part of its exhilarating character; it relieves fatigue, stimulates thought, postpones sleepiness, and cheers the mind. The *caffeine* is also a mental and nervous stimulant and cardiac tonic of considerable importance. By long-continued, habitual use neither of the above effects is much felt, unless carried to the extent of diminishing the appetite and developing dyspeptic troubles.

The least desirable of the constituents of Tea is the *tannin*, it is also one of the slowest to dissolve out, and can, therefore, with a little care, be largely left with the dregs. The quicker an infusion of Tea is made the more fragrance and less bitterness and astringency it has, and the more slowly, the more tannin. Tea for drinking should be made by pouring *boiling* water into a suitable vessel containing the tea and allowing it to stand from five to ten minutes, no longer. A better way is to rinse the cup in boiling or very hot water until it is heated through, then put in a teaspoonful of dry tea, fill the cup with boiling water and allow to stand a few minutes. Tea should never be boiled, or stand long unless the *tannin* is wanted. If made in an iron vessel or in a tin one which has begun to wear, it will become dark from the formation of a bitter tannate of iron. On account of its almost universal use over the entire world, Tea is not often available as a medicine; its effects are identical with those of coffee, but perhaps more astringent and less stimulating than that article. As is the case with coffee, the commercial value of Tea depends more upon its aroma than on the amount of caffeine it contains.

ALLIED PLANTS.—There are a dozen or more species of *Thea*, one of which is *Thea Japonica*, the beautiful Camellia of the gardens. Besides this there is nothing of economic importance in the order.

ALLIED DRUGS.—Caffeine, Coffee, Theobroma, Guarana, Coca, etc. *W. P. Bolles.*

TERMINOLOGY, ANATOMICAL. § 1. DIVISION OF THE SUBJECT.—Current anatomical terms are fairly represented in the following selections, from Huxley's "Vertebrated Animals" (1873*), and from a paper by the same author (1881):

A. "The red corpuscles of mammalia are usually circular."

B. "The clavicles of the dog are always rudimentary, and are generally represented by a gristly intersection of muscles."

C. "In a human fœtus the manus and pes are very similar in size and form."

D. "Speaking broadly, the back of the arm corresponds with the front of the leg."

E. "In the latter part of the period of gestation the legs gain on the arms, and the proximal segments of the limbs on the distal ones."

F. "The cornua come to lie somewhat dorsad of them."

§ 2. The terms included in the foregoing sentences may be grouped primarily as follows:

I. Such as designate parts; *e.g.*, *arms*, *manus*, *cornua*, *clavicles*.

II. Such as indicate the attributes or relations of parts; *e.g.*, *circular*, *red*, *similar*, *represented*, *corresponds*, *proximal*, *dorsad*.

Among the terms in group II., those referring to size and color need not be specially considered. Those that indicate relations of similarity or identity are enumerated in § 81. The terms which express form, location, and direction are discussed under Toponymy † (p. 533). The terms embraced in group I. are the names of parts, organ-names or *organonyms*, and their consideration constitutes *organonymy*.‡

§ 3. Historical Note.—Aside from dictionaries of realized and adequate terms which naturally and prudently (although not, as elsewhere intimated by the writer,* with the highest possible effect upon glossary) are confined to a somewhat indiscriminate presentation of existing terms, useful treatises upon anatomical terminology date back little more than a century (Vicq d'Azyr, 1786), and those writers who have given serious and extended attention to the subject are far from numerous. Among these, Whewell (1840) discusses mainly general principles, and Barclay (1803), while presenting the whole subject, elaborates especially a set of topographic (descriptive) terms. The two most helpful papers upon nomenclature proper are Owen's immortal "Report" (1846), and Pye-Smith's "Suggestions" (1877). After a recent reperusal of these two papers, the writer regrets that space will not permit even more extended extracts than are given in the following pages (§ 43, Appendixes XXVII., XXXII., etc.). He cannot refrain from expressing the opinion that no one is fully qualified to deal with the general subject of Anatomical Terminology without an acquaintance with the views of the four writers last named. Others who have contributed to the subject, directly or indirectly, are named in the Bibliography or quoted among the aphorisms, § 43.

---

* See list of publications at the close of this article.

† This division is by S. H. Gage, the remainder by B. G. Wilder; their views upon both divisions of the subject are, however, nearly identical, as may be seen from their joint publication, "Anatomical Technology" (especially the Introduction, and the Preface to the second edition).

In this connection acknowledgment may be made of valuable assistance upon linguistic matters rendered the writers by their colleagues, past and present, T. F. Crane, Isaac Flagg, W. G. Hale, W. T. Hewett, Tracy Peck, and B. I. Wheeler; the last-named especially has kindly answered a very large number of queries.

‡ These terms are from the Greek ὄνυμα (a name), and the words for part (ὄργανον) and position (τόπος). In the writer's earlier papers, and in the first edition of "Anatomical Technology," the words were spelled *organonomy* and *toponomy*, as if from ὄνομα, the other form of ὄνυμα. The change is made for the sake of uniformity with *synonym*, etc., and in accordance with the considerations offered by Coues (1884). The adjective should be *onymic*, as in *patronymic*, rather than *onymal*, used, perhaps without reflection, by Coues and J. A. Allen.

ORGANONYMY.

§ 4. Most of the kinds of organonyms (names of organs or parts) in common use are represented in the following passages, mainly selected from the account of the development of the brain in Huxley's "Vertebrated Animals," 1871.† The words in brackets are taken from the writings of well-known anatomists for the sake of including more varieties of terms. These names constitute good illustrations of existing nomenclature, and any criticism to which they are justly subject would apply with greater force to the less well chosen terms in the less perfectly constructed writings of less eminent anatomists.

Here and elsewhere in this division of the article, encephalic terms will be commonly selected, partly because of the writer's greater familiarity with them, and partly because, as remarked by Pye-Smith, "the nomenclature of the brain needs revision more than that of any other part."

§ 5. A. "The hind-brain is differentiated into the medulla oblongata behind, and the cerebellum with the pons Varolii (Lat., also pons;‡ Eng., pons or bridge; Ger., [illegible] or Brücke; Fr., pont; It., ponte; Sp., puente), in front."

B. "The components of the mid-brain or mesencephalon are the optic lobes (corpora bigemina or quadrigemina), the crura cerebri, and the interposed cavity which is reduced to a mere canal, the [aqueductus Sylvii or] iter a tertio ad quartum ventriculum [passage from the third to the fourth ventricle]."

C. "The sides of the anterior vesicle thicken greatly and become the optic thalami, which are connected by a gray, soft commissure; transverse fibres developed in the lamina terminalis [§ cinerea] constitute the anterior commissure."

D. "A few fan-shaped gyri are developed upon the insula."

E. "The pia mater dips into these sulci."

F. "The ventral face of the metencephalon presents on each side a flattened rectangular area, the corpus trapezoides [or trapezium]."

G. "The calcarine sulcus ("posthippocampal fissure" of Owen) causes a projection into the floor of the posterior cornu which is the hippocampus minor [later called by Huxley, calcar]."

H. "There is, in man, no diastema, though the summits of the canines project slightly beyond the level of the other teeth."

I. The paragraph (Huxley's "Vertebrated Animals," p. 60) respecting the spinal portion of the central nervous system is headed "myelon," but this word, so far as the writer is aware, does not occur elsewhere in the volume; "spinal cord" is commonly used, but "cord" alone in the paragraph indicated.

J. The cerebral surface becomes "complicated by ridges and furrows, the gyri and sulci." The first to be recognized is the "Sylvian fissure," and the second the "fissure of Rolando," the latter being called (see explanation of Fig. 21) "sulcus of Rolando."

§ 6. Groups of Organonyms.—Names of parts may be grouped in several different ways, viz., as to parts of speech (§ 7), syllabication (§ 8), derivation (§ 9), form (§ 40), authority (§ 19), degree of comprehensiveness (§ 21), nature of the attribute implied (§ 12), personal sense which they convey (§ 16), constancy and consistency (§ 16), euphoniousness (§ 20), etymological accuracy (§ 66), reference to individuals (§ 18), number of component words (§ 24), kind and degree of equivalency to other terms (§ 32).

§ 7. Parts of Speech.—Anatomical terms consist for the most part of substantives or adjectives, although some polyonyms comprise also prepositions (as in iter a tertio, etc.), and certain obsolete phrases contain pronouns, adverbs, verbs, and conjunctions so as in fact to constitute nearly complete sentences, e.g., fissura medullaris, qui intercedit inter thalamum et corpus striatum (Burdach, 1822).

§ 8. Number of Syllables.—Anatomical names may consist of a single syllable (e.g., pons), of two (e.g., [illegible]), of three (e.g., cerebrum), of four (e.g., cerebellum), or of five (e.g., infundibulum). Words of four or more syllables are polysyllabic; those of less than four (trisyllables, dissyllables, and monosyllables) are oligosyllabic.

Monosyllables are apt to be abrupt and undignified, while anything beyond a quinquesyllable is difficult to pronounce or even to grasp at sight as a single word. In fact, with any series of six or more objects, even if separated by distinct intervals, the exact number is not commonly recognized at a glance as with five or less.

§ 9. Diminutives.—Cerebellum (a small brain) is the regular diminutive of cerebrum, the brain; but, like most other diminutives, the word itself is longer than the original; this is the case with pes (a foot) and pedunculus (a little foot), and with falx (a sickle) and falcicula (a small sickle)—the latter, by the way, being employed in the article Gross Anatomy of the Brain as a mononym for falx cerebelli. The inverse ratio between the size of the objects and the length of the names which characterizes diminutives, is in harmony with the general rule that words or phrases designating a part are longer than those which represent the whole, e.g., arm, upper arm, forearm; America, North America, South America.

§ 10. Metaphorical Names.—In designating parts of the brain, e.g., pons and insula, the names are transferred from the original object to something that has, or is supposed to have, some resemblance thereto; this transfer constitutes a metaphor, as when we call a man a "fox" or a "lion"; the comparison is implied. Other metaphorical encephalic names are aqueduct, thalamus, hippocampus, [illegible], etc.

§ 11. But with some names the comparison is directly expressed, commonly by a dionym consisting of a common noun (corpus, pars, lamina, etc.), with an adjective ending in the Latin formis or the Greek oides, denoting likeness. Such a term is corpus trapezoides, signifying a body resembling a trapezium. The conversion of the polyonym, simile name, into one which is mononymic and metaphorical may commonly be effected, as it has been in the example above given, by omitting the common noun and reducing the adjective to the substantive from which it was derived.

§ 12. Attributive Names.—Most organonyms refer, at least in part, to some real or fancied attribute, as, e.g., size (hippocampus major), consistence (corpus callosum,

§ [illegible]

soft commissure) ; color (*substantia nigra*) ; shape (*hemisphere, medulla oblongata*) ; function (*aqueduct of Sylvius*) ; course (*vagus*) ; distribution (*pneumogastric*) ; location (see § 13).

§ 13. Locative Names.—Names indicative of position are very common—*e.g., anterior vesicle ; mesencephalon ; lamina terminalis ; ectoglutæus* and *paracentral lobule.* Locative names form two groups : (*a*) Such as indicate the position of a part relative to another part, larger, more important, or earlier designated, with which it has merely a general association in other respects ; *e.g., paracentral lobule* indicates the topographical relation of a mesal area of the cerebrocortex to a fissure on the other (lateral) aspect of the hemicerebrum ; *lamina terminalis* and *filum terminale* indicate the locations of the parts in question at the extremities of the entire neuraxis ; *adrenal* signifies the neighborhood of the body formerly called *supra-renal capsule* to the kidney (*ren*) ; *precuneus* indicates that the cortical area lies cephalad of the cuneus. (*b*) Such as indicate the relative positions of parts constituting a natural or conventional series ; for example, *anterior vesicle* implies the existence of a posterior ; *posterior commissure* implies the existence of an anterior ; *mesencephalon* (middle brain) would have no appropriateness unless there were two extremes of a series. The advantages of locative names will be presented farther on (§ 54).

§ 14. Order.—*Seventh cervical vertebra, first rib; last costal cartilage,* and *fifth cranial nerve* imply the existence of a series of comparable parts. Such names might be called *ordinal,* but they are practically only a variety of locative names, since the general consent of anatomists has established the rule that, of two or more parts forming a cephalo-caudal series, that nearest the head is to be taken as first. This is applied likewise to the fingers and toes, which, in the normal position of the arms and legs, form a cephalo-caudal series, the thumb (pollex) and the great toe (hallux) being reckoned as first in the hand and the foot ; on this group of names, see also the toponymic division of this article, § 94.

§ 15. Correlation.—The adjective *calcarine* (as applied to a sulcus [fissure]) is evidently derived from the noun, *calcar,* and the stated collocation of the ectal depression with the ental elevation is implied in the correlation of the two terms. Similar instances are *hippocampal* from *hippocampus.*

§ 16. Consistency.—As appears in § 5, I., the same part is designated in different passages as *cord, spinal cord,* and *myelon,* with no direct intimation that the three terms are equivalents. In J., it is implied that all cerebral depressions are *sulci,* but the first two named are called *fissures,* and one of these again is called *sulcus.* Within fifty pages of a standard neurological treatise, in addition to the Latin *crus fornicis,* there occur the following vernacular equivalents : *Fornixschenkel ; Gewölbschenkel ; Fornixsaülchen.* Terminological variety, such as occurs in the passages quoted, may be expressed by the single word, *pœcilonymy* ;* § 72.

§ 17. Indirect Pœcilonymy.—The examples given above are of what may be called *direct pœcilonymy ; i.e.,* two or more substantives are applied to the same part ; but perhaps even more frequent is indirect pœcilonymy, or pœcilonymy by implication, where one substantive is applied to the part itself, but to the same or a related object is applied either a name or an adjective derived from another and totally different word. In the translation of a well-known article the great cerebral commissure is called, as usual, *corpus callosum,* but in one passage occurs the adjective "*trabecular*" (=callosal) ; *trabal* (Latin, *trabalis*) would merely recall the obsolete name for the callosum, *trabs cerebri ;* but *trabecular* implies *trabecula,* the diminutive of *trabs.* The former case would be simple, the latter is *compound, indirect pœcilonymy.*

§ 18. Reference to Individuals.—*Pons Varolii* and *aquæductus Sylvii* imply some relation between the parts so named and the anatomists, Varolius and Sylvius ; such terms, derived from the names of persons, are called *eponyms ;* there are many of them in anatomy, and their merits will be considered later ; § 59.

§ 19. Authority.—This may depend upon one or more of three distinct factors, viz., (*a*) antiquity ; (*b*) general use ; (*c*) employment by one or more eminent anatomists. *Cerebrum* and *cerebellum* are strictly ancient terms. *Spinal cord* is in almost universal use among the laity and anatomists alike. Robin's suggestion of *neuraxis* (in the Galloparonym, *neuraxe*) entitles it to consideration (see the article, Gross Anatomy of the Brain, § 6) ; while *myelon* (also, in fact, an ancient term), proposed by Owen and adopted by Huxley, requires but few influential adherents to supersede *spinal cord* entirely. How far priority and authority may justly be disregarded, will be considered later ; § 44.

§ 20. Explicitness.—The verbal representations of objects differ widely in this respect, *i.e.,* as to their completeness. For example, the brain might be represented either (1) by a full description of all its parts ; or (2) by the statement that it is the intra-cranial portion of the neuraxis ; or (3) in place of *brain,* might be used *encephalon* (ἐν, in, and κεφαλή, head), referring to its location ; or (4) any other word in any language might be substituted, provided the substitution were announced ; or (5) any abbreviation might be employed ; or (6) a wholly artificial and conventional sign or number might serve as the written or spoken symbol of the complex organ. These grades of representation are contrasted in the following table :

Tabular arrangement of the grades of verbal representation of organs :

A.—Descriptions.
    a. Complete, or approximately so.
    b. Partial, constituting a definition or characterization.
B.—Designations.
    a. Natural or indicative.
    b. Artificial or arbitrary.
        α. Names or abbreviations.
        β. Symbols ; signs or numbers.

From the above table it will be seen that the primary distinction is between names that are *descriptive* and those that are *designatory ;* between those that make, as it were, an attempt to offer an account of the parts, and those that are content with pointing out some general feature without entering into details. *Pons, fornix,* and *encephalon* are good examples of designatory terms, while a typical descriptive term is the following, from Burdach : *Corpus pyramidale striatum inferius, externum, posticum.*

§ 21. Idionyms.—Among organonyms some are restricted in their application to particular organs ; *e.g., cerebellum, lamina terminalis ;* these are comparable to what are called proper names, and may be termed *idionyms* (Gr., ἴδιος and ὄνυμα). Other organonyms, like common names, may refer to any one of many parts ; *e.g., canal, sinus, cavity, side, roof, floor, segment ;* others, again, are intermediate in comprehensiveness, and are applied often to either of several similar parts constituting a series ; *e.g., muscle, nerve, artery. Ventricle* designates only certain cavities (of the heart, brain, and larynx) ; *commissure* is nearly confined to the neuraxis ; *cœle* is used by some for the encephalic cavities (§ 80). Owen's names for the elements of a typical vertebra, *centrum, neurapophysis, hæmapophysis,* etc., are examples of this group of idionyms.

Certain classical terms that had originally a more or less general application, have come to be restricted to special parts. For example, with both the Greeks and Romans, διάστημα, *diastema,* signified any kind of interval, more particularly in music ; this latter meaning seems to be retained for the English form (Angloparonym), *diastem ;* but in anatomy, *diastema* refers specifically to an interruption of the dental series in either jaw for the intrusion of the crown of the canine belonging to the opposed jaw. In this restricted, idionymic, sense it is used without definition by Huxley (see above, § 5, H.).

§ 22. Homonyms.—In anatomy there are words which, identical in pronunciation or spelling, or both, are applied to two or more dissimilar objects. *Os*, a bone, and *os*, the mouth, are familiar homonyms. In most of these cases there is really no more probability of misapprehension than when the word *radius* is used in its mathematical or anatomical sense; or, when Huxley applies the phrase *mental prominence*—which certainly *might* signify intellectual superiority—to a bony projection corresponding to the chin.

---

* From ποικίλος, various, changeful, inconstant ; cf., ποικιλόβουλος, of changeful counsel ; *pœcilopoda*—various footed. The unfamiliar term is perhaps the less objectionable, in that it stands for a habit which may ere long be eradicated.

§ 23. Polychrestic Words.—The same word may do duty in many different connections, either by application, unchanged, to members of more or less extensive classes of parts, or by composition, becoming portions of distinct names. Such words, useful in so many ways, may be called *polychrestic*, although this adjective is commonly applied to drugs of various utility. A good example is *occipital*. This adjective distinguishes from the others of the same general group, an artery, a bone, a crest, a fissure, a fossa, a groove, a lobe, a protuberance, a region, a sinus, a triangle, and a vein; united with the prefixes *ad*, *basi*, *ex*, *mid*, *par*, *pre*, *prepar*, *postpar*, *sub*, and *super*, it serves to designate as many parts, fissures, gyres, and bones. Compounded with *atlad*, *axiad*, *frontal*, and *parietal*, it is applied to joints, a muscle, and a fissure. A certain fissure is commonly known as the "transverse occipital." Deducting one (since one fissure is designated by *occipital* and *occipito-parietal*), there remain twenty-six parts which the single word *occipital* aids to designate. In greater or less degree, polychresty is predicable of many other words, *e.g.*, *frontal*, *dorsal*, etc.

§ 24. Mononyms and Polyonyms.—In the writer's opinion the most radical and far-reaching of all distinctions between anatomical terms is this: Some consist of but one word each; others of two or more; the former are *mononyms*, the latter, *polyonyms*.*

§ 25. There are two methods of securing mononyms from pre-existing polyonyms. A. By the omission of unessential words. The omitted word or words may be special and particular, as, *e.g.*, when *Societas de Propaganda Fide* is reduced to *Propaganda*, which is used as a collective noun like *army* or *convention*; or they may be common and general, as when *filtrate*, *precipitate*, *distillate*, etc., are used without the understood *substance*, *material*, *part*, or *portion*. Among encephalic terms, the reduction of *aqueduct of Sylvius* to *aqueduct*, of *corpus callosum* to *callosum*, of *foramen* [illegible] to *foramen*, are examples.

B. By the compounding of two or more of the separate words, *e.g.*, *postfrontalis* from *frontalis posterior*; *supraoccipitalis* from *occipitalis superior*; *postpeduncularis* from *pedunculus posterior*.†

§ 26. Mononyms by Association or Implication.—With series of parts having the same general constitution, *e.g.*, the vertebræ, ribs, muscles, nerves, arteries, veins, metacarpal and metatarsal bones, and the cerebral fissures and gyres, it would be wellnigh impossible to apply to each a distinctive mononym like *atlas*, *axis*, [illegible], and a few others; hence the entire designation is at least a dionym, consisting of the common noun (*vertebra*, *nervus*, *fissura*, etc.) with a more or less distinctive adjective ([illegible], [illegible], *ventralis*, etc.). In nearly all cases, however, the context so far indicates the group of parts that the common name may be omitted, and the adjective may be employed alone without ambiguity. When there is but a single adjective the term, although theoretically a dionym, becomes practically a mononym. In a few cases the adjective is applied to no other part, and is therefore distinctive or idionymic, *e.g.*, *phrenicus*.

The substantive *cord* is an example both of polychresty (§ 23) and of mononymy by implication. Combined with appropriate adjectives it designates at least five organs of entirely distinct structure; but in many cases the context warrants dispensing with the adjective, and the "cords" of the laryngologist, the neurologist, the obstetrician, the surgeon, and the embryologist may thus refer to the vocal bands, the myelon (spinal cord), the funis (umbilical cord), the spermatic cord, and the notochord (dorsal cord) with little risk of misapprehension.

§ 27. Reducing Polyonymic Qualifiers to Mononyms.—Usually these may be treated as if they were partly substantive and partly adjective, and reduced according to the methods named in § 25. For example, for *glutæus major*, *medius*, and *minor*, Owen has proposed *ectoglutæus*, *meso-* and *entoglutæus*; for *external* and *internal carotid*, *ecto-* and *entocarotid*; for *vena cava anterior* and *posterior*, *precava* and *postcava*; all of the same author's fissural and gyral names are mononymic adjectives (1868, pp. 136, 137). With these precedents the writer proposed, in 1873, *ectopectoral* and *entopectoral*; in 1882 ("Anatomical Technology," p. 207), *latissimus*, *coracodeus*, *indicator*, etc.; in 1884, a series of mononymic simplifications of the common names of the larger encephalic arteries (*e.g.*, *medicerebral* for *middle cerebral*, etc.);* the fissural and gyral names employed in the article, Gross Anatomy of the Brain, are substantially those which were proposed by the writer in 1884, modelled largely after those of Owen.

§ 28. Source.—Most of the words in § 5 are classical in origin, *i.e.*, derived from the Latin or Greek; *e.g.*, *pons*, *cerebrum*, *hemisphere*, *hippocampus*. Others are vernacular, *i.e.*, English (used in the most comprehensive sense as equivalent to non-classical), *e.g.*, *brain*, [illegible], and *sides*. Vernacles or vernacular terms would include also words of German origin, and such French and Italian words as have no immediate Latin or Greek antecedents.

§ 29. In this connection, notice may be taken of the fact that a large number of apparently Latin words do not occur in ancient Latin writings, or in lexicons based thereon. For example, while *quadrigeminus* (four-fold) is true Latin, *bigeminus* is a modern combination perfectly legitimate and acceptable. There are also words from various modern, and even barbarous, languages which have been Latinized, and some of these (*e.g.*, [illegible]), have all the appearance of genuine Latin words.

§ 30. Form.—Irrespective of their source, certain terms are obviously English, *i.e.*, they are Angliform, *e.g.*, *forebrain*, and *posterior cerebral vesicle*; others are Latiniform, *i.e.*, *crura cerebri*, and [illegible]; these latter are recognized as Latin because of the regular forms of cases, the genitive (*cerebri*), ablative ([illegible]), and accusative ([illegible]), which do not (as yet) occur in English. With other terms the presumption is that they are English (*e.g.*, *posterior cornu*), or Latin (*corpora bigemina*), because the adjective precedes the substantive in the former case, but follows it in the latter. But the general rule as to the relative position of the substantive and adjective has many exceptions, *e.g.*, *Hotel Brunswick*, and *notary public*, in English, and *pia mater*, *alma mater*, etc., in Latin.†

§ 31. Besides the words above mentioned, which are recognizable as Latin or English from their spelling or their relative position in polyonyms, there are some which are either Latin or English according to circumstances; *i.e.*, the question of their Latinity is determined by their environment. *Cerebellum*, for example, is a Latin word; but it is also English by adoption; it occurs in English lexicons, is used in ordinary speech, is pronounced as any English word would be, and is not usually italicized; the same may be said of *medulla*, taken alone, and even of *thalami*, although the form of the Latin plural is retained (instead of the regularly English *thalamuses*), and although in the dionym, *thalami optici*, it is unquestionably a Latin word.

---

* [illegible]

† [illegible]

* These are adopted in the article Vessels of the Brain.

† In the opinion of Professor B. I. Wheeler, the relative position of the substantive and adjective [illegible]

§ 32. Equivalency.—Among the terms at the end of § 5, A, all refer to the same part of the brain and are therefore equivalent terms. But, if *pons Varolii* be taken as the basis, they differ in this respect, *viz.*, most of them are in another language than the Latin, while *pons* is in that language; strictly speaking, *pons* and *pons Varolii* are *synonyms*, while *bridge*, *Brücke*, *pont*, *ponte*, and *puente* are not, but may be called *isonyms*, from the Greek **ἴσος**, equal. In like manner *trapezium* and *corpus trapezoides* are Latin synonyms.

§ 33. Paronyms and Heteronyms.—Among the equivalents of *pons Varolii* other than the Latin synonym *pons*, it will be noted that the French *pont*, the Italian *ponte*, and the Spanish *puente* are derived from *pons*, directly or indirectly; while the German *Brücke* and the English *bridge* have no such Latin antecedent. The former are *cognate* with the Latin, the latter are not. The former are *paronyms* of the Latin *pons;* the latter are *heteronyms* or vernacular translations. In general terms the relation between the Latin *pons* and the French *pont* is one of *paronymy;* but between *pons* and the English *bridge* it is one of *heteronymy*.

Other familiar illustrations are the following:

Canal is derived from the Latin *canalis*, constituting in fact the stem of that word without its case-endings. The difference between the two is merely that the one is English and the other Latin; *canal* is *canalis* Anglicized; it is its paronym. But *tube, passage, trough, water-course*, and *aqueduct*, while they may *mean* the same as *canalis*, are totally different words; they have no etymological relationship, direct or indirect; they are *heteronyms*.

Vesicle is a paronym of the Latin *vesicula; lobe* is a paronym of *lobus*, but *mid-brain* is a heteronym of *mesencephalon. Sylvian aqueduct* and *aqueduct of Sylvius* are both paronyms of *aquæductus Sylvii; ventricle* is a paronym of the Latin *ventriculus*, but the phrase "passage from the third to the fourth ventricle," is a heteronym of the Latin polyonym, *iter e tertio ad quartum ventriculum*.

§ 34. Paronymy and heteronymy among words are comparable with the relations of homology and analogy among organs. An organ which is the same as another in essential structure, is its homologue; but its analogue when it merely subserves the same function; see § 81.

§ 35. So far, there have been mentioned only Latin words and their English equivalents; but there are paronyms and heteronyms in all languages. For example, the Greek **ἀταξία** means disorder or irregularity, and these two English words are its heteronyms. But the word itself occurs in all modern languages with such slight modifications as adapt it to what is called the "genius" or "spirit" of each tongue. The complete series is as follows: Greek, **ἀταξία**; Latin, *ataxia;* English, *ataxy* (or *ataxia*)*;* Spanish, *ataxia;* Italian, *atassia;* French, *ataxie;* German, *ataxie*. Each of these is a geographical variety, so to speak, of the original; it is as if one and the same individual were simultaneously an inhabitant of seven different lands, and in each adopted the distinctive costume of the people.

§ 36. Paronymization.—The application of the principle of paronymy in a given case is *paronymization*, or the word is said to be *paronymized*. The several forms of the process are indicated in the following table:

Table of the names of special forms of paronymization.

To convert into English is to Anglicize.
" " " French " " Gallicize.
" " " German " " Germanize.
" " " Italian " " Italianize.
" " " Latin " " Latinize.
" " " Greek " " Hellenize.

Proper names offer familiar examples of paronymy. The English, *John, Charles*, and *William;* the German, *Johann, Karl*, and *Wilhelm*, and the Latin, *Johannes, Carolus*, and *Guilielmus*, are all paronyms of one another.

Paronyms, then, are like naturalized foreigners; they are words that have been adopted into another than their original tongue; and the process of paronymization (including the several specific forms, Latinization, Anglicization, etc.), may be defined as word-adoption, word-appropriation, word-assumption, or word-borrowing.

§ 37. Although the term *paronymy* was published only a few years ago (in the writer's paper (1885 *), and in "Anatomical Technology" (1886), preface to second edition), the process of paronymization dates back to the time of the first conversion of a Greek word into a Latin,† and there are more or less distinct recognitions and even designations of it in various writings. In Webster's dictionary the words in brackets are commonly paronyms, while the definitions are more often heteronyms. In the preface to his translation of the "Iliad," William Cullen Bryant remarks, "The names have become naturalized in our language for centuries, and some of them, as Mercury, Vulcan, and Diana, have even been provided with English terminations." Haldeman notes (1843, 20) that "the similarity of some words is so great in different languages, that they look like old acquaintances, upon seeing them for the first time." A recent writer (Hutchinson, New York *Medical Record*, October 25, 1885, 471) declares that "Latin names should be reduced to English," although neither he nor, so far as the writer is aware, any other has described or designated the process by which the reduction is to be accomplished.

§ 38. Holoparonymy and Meroparonymy.—When a Latin or Greek word has been adopted or naturalized into all modern languages, then it is an example of holoparonymy (Gr. **ὅλος**, complete). Such is the series from the Greek **ὄργανον**; Latin, *organum;* English, *organ;* French, *organe;* Italian, *organo;* German, *organ. Ataxia* has been mentioned (§ 35); others are *anatomy*, and *mulus*. Some lack but one of the series; *e.g., agonia, fibra, stella;* but these, with the host of cases (easily found in any large English dictionary) in which two or more possible forms are wanting, may be accepted as illustrations of partial paronymy or meroparonymy (Gr. **μέρος**, partial).

§ 39. Paronyms other than Nouns.—Literally, of course, only *names* (substantives) can be paronyms, but the multiplication of terms may be avoided by applying the word and its derivatives to other parts of speech. The Latin adjective, *vitalis*, for example, becomes *vitale* in Italian, but *vital* in English and French; the German would probably be *vitalisch*. The English *organic*, and the French *organique*, are paronyms of the Latin *organicus*. The English verb *move* is paronymized from the Latin *moveo*, and the adverb *nobly* from *nobiliter*.

§ 40. Paronymic Dimorphism.—In some cases more than a single form has been adopted in a given language. Sometimes both of these refer to the same part, *e.g., pedunculus* and *peduncle;* sometimes to distinct parts, *e.g., ligula*, and *lingula*, both primarily diminutives of *lingua*. Besides *canal, channel* and *kennel* are paronyms of *canalis*.

§ 41. Anaparonyms.—In a few cases, a word which had already been adopted from one language into another has been readopted into its original source, with a second change of form; *e.g.*, the English *beef* is a paronym of the French *bœuf*, and this in its turn has been anaparonymized in French restaurants as *bif*. For the word, *anaparonymized*, warranting *anaparonym, anaparonymy*, and *anaparonymization*, the writer is indebted to his colleague, Professor B. I. Wheeler, who cited **ἀναβαπτίζω**—rebaptize; other words in which *ana* has the

---

* Paronymy versus Heteronymy, etc., Jour. of Nervous and Mental Disease, July, 1885.

† As compactly described by Campbell: "When a convenient Latin word was wanting, in making their translations, the Romans never stopped to coin one of their own, but took the Greek word and dressed it in Roman type and terminations."

[illegible] [illegible] are [illegible]; [illegible] [illegible] or [illegible].

§ 42. Unrealized Words.—These are words that have not as yet come into actual use, but are, so to speak, only potential. Every noun suggests the possibility of a corresponding derivative adjective; so, likewise, does every adjective imply the existence, actual or potential, of the noun from which it has been or might have been derived. In some cases, however, an adjective may be in actual use before the corresponding noun has been employed; e.g., *basicranial* obviously justifies *basicranium*, or even *basicrania*; but so far as known to the writer, neither of these has been actually used, *base of the skull* or *basis cranii* having been found sufficient. There is no separate Latin word *cele*, but the Latin compound *hydrocele* shows that such a term might have been used had there been need of it; at present it is the latinized paronym of the Greek κήλη. *Onym* (§ 2, *note*) occurs much more frequently in derivatives than by itself. Other examples are [illegible], [illegible], and [illegible] (the supposed adjective from which [illegible] is derived). The case is analogous to that of the assumed chemical element, *fluorine*, now known only in its compounds. The writer's *enteron*, for the entire alimentary canal (see p. 110, § 8), is warranted by the common adjective *enteric*, as well as by the compounds, *mesenteron*, etc.

§ 43. Aphorisms Respecting Nomenclature.—Under this head are collated extracts from various authors, with occasional contributions from the writer. Many of the paragraphs are not strictly aphoristic in length or in other respects, but they constitute, upon the whole, a compact summary of the history and principles of the subject, and may at least serve to show that the writer's views are in close accord with the general tendency of terminological modification; indeed, that so far from proposing numerous and radical innovations, he has confined himself mainly to crystallizing and formulating those already published, and has simply been somewhat more persistent and consistent than others in their advocacy and application.

Aph. I. "The first requisite for the accurate discussion of any subject is an appropriate nomenclature." (A. Agassiz.)

Aph. II. "Every calling has its technical terminology, and every artisan uses terms of art which sound like gibberish to those who know nothing of the art, but are exceedingly convenient to those who practise it." (Huxley.)

Aph. III. "The best workman uses the best tools. Terms are the tools of the teacher; and only an inferior hand persists in toiling with a clumsy instrument when a better one lies within reach." (Owen.)

Aph. IV. "While the name of any article is one of its most trivial and artificial attributes, laxity in the use of nomenclature causes endless perplexities and hindrances in the progress of knowledge." (Flower.)

Aph. V. "Half the difficulty of anatomy is inherent; the other half is in wordiness. The trouble with the student is more in the names of things than in the things themselves. He mistakes one for the other, his head swims, and then he founders in a Latin storm at sea." ([illegible].)

Aph. VI. "It is well known to all how much terminological appliances have accelerated and facilitated science." (Gill.)

Aph. VII. At the present time it is the fashion to extol the importance of improved methods, of mechanical devices by means of which facts are ascertained and verified; but if these same facts are to be intelligently and profitably described and discussed, surely whatever facilitates verbal and mental operations is not without value.

Aph. VIII. "Much confusion has been occasioned by importing into comparative anatomy [descriptive] terms employed in human anatomy; but the efforts of Owen, Huxley, and others to introduce terms of general applicability to vertebrate animals have resulted in a great improvement of anatomical nomenclature." (R. Ramsay Wright.)

Aph. IX. It is certainly possible to overrate the importance of nomenclature, just as one may spend too much time upon chirography, to the neglect of the subjects written upon; but those who take [illegible] stand upon the epigram "to need a new terminology is a sign of mental poverty," are in danger of [illegible] some anatomical writers; they may carry their laxness so far as to use several terms for the same object, to employ English, French or German indifferently, and even to introduce new words without apology or explanation; their affectation may be compared with the indifference to legibility in writing exhibited by eminent writers and cultivated by modern would-be geniuses.

Aph. X. "Stereotyped formulas are repeated by each succeeding generation of the unthinking multitude, in whose mouth the inheritance receives no increment." (Super.)

Aph. XI. Of many anatomical terms, the chief characteristics are antiquity, macrology, and unintelligibility.

Aph. XII. "Nomina . . . sesquipedalia, enunciatu difficilia vel nauseabunda, fugienda sunt." (Lacaze Duthiers.)

Aph. XIII. "All terms are, or ought to be, defined, and their signification in anatomy ought to be extended no further than these definitions allow of." (Barclay.)

Aph. XIV. "Ancient words are, by common consent, not necessarily used in scientific nomenclature with their precise original meaning." (Editor *New York Medical Journal*.)

Aph. XV. "The human mind wearies of too many names, and much more readily assimilates a new meaning for an old one." (W. H. Dall, letter to the writer.)

Aph. XVI. "Scientific truth must cease to be the property of the few. It must be woven into the common life of the world." (L. Agassiz.)

Aph. XVII. "The names which come nearest to be [illegible] accuracy of expression . . . are longest, most complex, least convenient, and least euphonious, and therefore are least adapted to common use." (Dr. E. R. Squibb.)

Aph. XVIII. Nothing is at once more desirable and more difficult than for the learned anatomist to revert, so to speak, to his long-past state of ignorance, and put himself in the place of one who undertakes to learn facts about unfamiliar organs and finds each new word an obstacle, and each needless synonym a pitfall.

Aph. XIX. "Every organ should have one name and but one only; and to that name the allusions contained in the names of its muscles, nerves, arteries, etc. [of its appended or distinctly collocated parts], ought to refer." (Barclay.)

Aph. XX. "Enfin, il a l'avantage de permettre de désigner sans changement d'adjectif les parties qui se rattachent à la description de cette circonvolution; [illegible] [illegible] [illegible]." (Broca.)

Aph. XXI. For the student or general reader, in one and the same publication, a single poor term is better than two good ones.

Aph. XXII. What is worth stating at all, is worth stating clearly.

Aph. XXIII. The four chief requirements of scientific writing should be clearness, consistency, correctness, and conciseness.

Aph. XXIV. Obscurity of style, in so far as it may be avoidable by devoting more time to composition, is a very offensive form of literary egotism.

Aph. XXV. "The best excuse . . . for the numerous terms of art [technical terms] actually used in anatomy . . . is that by the help of these, discourse is shortened by expressing in one word what must otherwise have been expressed in several, and for such things as must be mentioned very often such a liberty is not only allowable, but necessary." (Douglas.)

Aph. XXVI. "Those terms may surely be retained which are just and accurate, and not too long; those which assist us in discriminating objects; and those likewise, however absurd their original allusions, that, course of time, have laid aside their primary sense, and begun to be used as arbitrary names" (Barclay).

Aph. XXVII. "It is an old maxim accepted by the best logicians, that no name is so good as that which signifies the total idea or whole subject, without calling prominently to mind any one particular quality, which is thereby apt to be deemed, undeservedly, more essential than the rest" (Owen).

Aph. XXVIII. "The practice of anatomists of the soundest judgment has usually been, to transfer the anthropotomical name or phrase to the answerable part when detected in other animals. The objection that the original descriptive or otherwise allusive meaning of the term seldom applies to the part with equal force in other animals, and sometimes not at all, is one of really little moment; for the term borrowed from anthropotomy is soon understood in an arbitrary sense, and without regard to its applicability to the modified form which the namesake of the human bone commonly assumes to suit the ends required in the lower species. No anatomist, for example, troubles himself with the amount of resemblance to a crow's or other bird's beak in the 'coracoid' bone of a reptile, or with the want of likeness of the kangaroo 'coccyx' to the beak of a cuckoo; or of the whale's 'vomer' to a ploughshare; or ever associates the idea of the original mystic allusion of the anatomical term *sacrum* with his description of that bone in the megatherium or other monster. Common sense gratefully accepts such names when they become arbitrary, as *cat* or *calomel*, and when such concretes or adjectives as coccygeal, vomerine, and sacral can be employed to teach the properties or accidents of their subjects" (Owen).

Aph. XXIX. "The chief improvement which the language of anatomy, based upon that of anthropotomy, must receive in order to do its requisite duty, is the substitution of names for phrases and definitions; and this is less a change of nomenclature than the giving to anatomy what it did not before possess, but which is absolutely requisite to express briefly and clearly, and without periphrasis, propositions respecting the parts of animal bodies. Such names should be derived from a universal or dead language, and when Anglicized, or translated [adopted or paronymized ?] into other modern equivalents, ought to be capable of being inflected adjectively" (Owen).

Aph. XXX. "In proposing a definite name for each distinct bone, . . . I have sought earnestly to reduce the amount of reform to the minimum allowed by the exigencies of the case" (Owen).

Aph. XXXI. "In substituting names for phrases, I have endeavored, conformably with another of Dr. Whewell's canons (Aph. XVII., Op. cit., p. cxvii.) [see § 52], to approximate the sound of the name as nearly as possible to those of the leading terms of the definition or phrase, as *e.g.*, *alisphenoid* for '*ala media*, etc., *sphenoidalis*,' and for '*grande aile du sphénoïde*;' *orbitosphenoid* for '*ala superior seu orbitalis*, etc., *sphenoidalis*,' and for '*aile orbitaire du sphénoïde*'" (Owen).

Aph. XXXII. "I fully admit the inconvenience of any change in itself, and the mischief which ensues when affectation of precision of language takes the place of accurate knowledge of the objects of language. For the accomplished anatomist and physiologist names are scarcely of even secondary importance. But for the learner it is otherwise; and experience of the difficulties which ambiguous or misleading names occasion to students has led me to note down, from time to time during the last ten years, those points which I have found most troublesome, and which may be improved with the least amount of change" (Pye-Smith).

Aph. XXXIII. "The most important characters which nomenclature in anatomy, as in any other branch of science, ought to possess are *clearness and convenience*. Each object should have only a single name in use, and each name should be sufficiently distinctive" (Pye-Smith).

Aph. XXXIV. "A name should first, if possible, consist of a *single word*, for the reason just given, as well as for the practical advantage of brevity. Many anatomical terms, as *foramen lacerum medium basis cranii* and *iter e tertio ad quartum ventriculum cerebri*, are explanatory phrases which become intolerable when quoted habitually. Secondly, it should also be *capable of forming an adjective*. This is an additional reason against a binominal nomenclature. In the third place, every name should have its *Latin* as well as a vernacular equivalent. Besides euphony and flexibility in forming adjectives and compounds, the community of scientific interest among civilized nations makes this an indispensable rule. It is scrupulously followed by zoologists and botanists, with the best results, and its neglect by anatomists is always inconvenient" (Pye-Smith).

Aph. XXXV. New terms are, at best, necessary evils, hence their formation must be justified by something more than their logical or etymological correctness. They should present some advantage over existing terms in respect to brevity, or accuracy, or correlation, or capacity for inflection or euphony; and even all these should not warrant their introduction unless it were apparent that they were likely to be used somewhat often.

Aph. XXXVI. "Words—so innocent and powerless are they, as standing in a dictionary; how potent for good and evil they become to one who knows how to combine them" (Hawthorne).

Aph. XXXVII. "The Greek and Latin are both sanctioned in our present nomenclature; I should be inclined, notwithstanding the opprobrium attached by some to certain connections and intermarriages among harmless vocables, not to reject the co-operation of the two languages in any form, where experience shows it to be convenient, useful, or necessary" (Barclay).

Aph. XXXVIII. "Meaning does not exist in a word by virtue of its root or its history. The question is not what the word has stood for in the minds of persons long since dead, but what it stands for now in the minds of the living" (*Popular Science Monthly*).

Aph. XXXIX. "It is full of Latinisms, Gallicisms, Germanisms, and all isms but Anglicisms" (Lord Chesterfield).

Aph. XL. "The improvement of scientific speech thus far has been made under compulsion, for the most part by persons caring little, perhaps knowing little, of the rational laws of language; and has spawned a myriad of linguistic monstrosities that cannot live in the mouths of Christian, Pagan, or Jew. . . . What should be done is to make the technical terms grateful to the cultivated literary sense. . . . Then no one can read anything worth reading at first hand without learning these technicalities, and then the technicalities will be drawn into the popular speech and displace the old names and forms" (March).

Aph. XLI. "The happy facility for combination which the German language enjoys has long enabled the very eminent anatomists of that intellectual part of Europe to condense the definitions of anthropotomy into single words; but these combinations cannot become cosmopolitan; such terms as "*zwischenkiemendeckelstück*," are likely to be restricted to the anatomists of the country where the vocal powers are trained from infancy to their utterance" (Owen).

Aph. XLII. "By persons who commonly speak the English language, many of the commoner Latin words have ceased to be considered as foreign, and, except when combined with other Latin words or inflected according to Latin forms, are treated as English by adoption [paronyms]" (Dr. F. P. Foster).

Aph. XLIII. Either classicalism or vernacularism, either exoticism in nomenclature or esoticism, may be indulged so inconsiderately as to become a "fad." Nomenclature demands care and attention; but one must avoid becoming a *doctrinaire*. The "happy mean" should be maintained.

Aph. XLIV. It would be obviously unfair to ask the anatomists of other nationalities to adopt the vernacular names of any one modern tongue; but none of them can seriously object to technical terms derived from the dead languages, which are the source of so many of their common words.

Aph. XLV. "Technical terms of science should remain unaltered [essentially, i.e., should not be replaced by [illegible] heteronymes] in every translation" (Barclay).

Aph. XLVI. "Translation [heteronymy] blunts the [illegible]" (Charles Reade).

Aph. XLVII. "Scientific names, like the names of persons, should be available [by paronymy] in all languages" (Dal[illegible]).

Aph. XLVIII. In terminology, as in law, possession counts nine points. That which is may not be ideally perfect, but it is, *ipso facto*, endurable.

Aph. XLIX. All innovations are in some degree objectionable.

Aph. L. "Nowhere is prudence more necessary than in our attempts to innovate on habits and established customs" (Barclay).

Aph. LI. "Unfortunately, imagining that a principle, if right, could not be carried to too great a length, some anatomists seem to have forgotten the old, though just, observation of the poet, that

"'Est modus in rebus; sunt certi denique fines,
Ultra citraque nequit consistere rectum'"

(Barclay).

Aph. LII. "The question of encephalic nomenclature is of the highest importance. . . . The necessity of greater precision in our nomenclature is now recognized in all directions, and various special memoirs have been published upon the subject" (Duval and Keller).

Aph. LIII. "The older anatomists exhausted their ingenuity in inventing fanciful names for every feature of the brain, and as treated by the usual method of descriptive anatomy the mass of details has no more organic connection than a pile of jack straws has structure" (F. Baker).

Aph. LIV. "Die Anatomie hat es schon öfter anhören müssen dass sie eine arbitrare und prinziplose sprache spricht" (Hyrtl).

Aph. LV. "The nomenclature of the brain stands more in need of revision than that of any other part" (Pye-Smith).

Aph. LVI. "Il est bien certain qu'une nomenclature régulière est un grand moyen de simplification, dont l'utilite se manifeste surtout dans une étude aussi compliquée que celle du cerveau" (Broca).

Aph. LVII. "My object is not so much to get my own or any other set of terms adopted, as to urge the necessity for a reform in the nomenclature of the central nervous system and its cavities, a necessity which no comparative anatomist, especially if he be a teacher, can fail to see" (T. Jeffery Parker).

Aph. LVIII. "Whoever will carry out the application of [illegible] substantive terms [mononymns] to the homologous parts and structures of the encephalon, as they may be successively determined, will perform a good work in [illegible]" (Owen).

Aph. LIX. "I have no hesitation in saying that the labor of the anatomical student will be diminished fully one-half when this nomenclature shall have been [illegible] adopted" (Spitzka).

Aph. LX. "Are we to consider primarily the men who have worked . . . . or the men who are working now and who will work after we are gone?" (Bessey).

Aph. LXI. "A little present labor and the example of adoption, where the reasonableness and necessity of the reform are plain and undeniable, will much accelerate the future progress of anatomical science" (Owen).

Aph. LXII. "The medical profession is conservative, and no reasonable expectation can be entertained that the nomenclature now in use—with all its absurdities and imperfections—will be materially modified until a congress of teachers, convened for the purpose, agree upon a list of terms which will be introduced into the textbooks and which will be employed in teaching"* (H. Allen).

Aph. LXIII. "A new nomenclature is not to be classed with those important and brilliant discoveries . . . . It promises no immortality to its author, nor secures to his name any enviable mark of distinction. It is nothing more than what anatomists have long wished for, a desideratum which they have often attempted to supply by partial amendments. . . . It cannot pretend to instruct the learned or to give them new ideas of the animal structure . . . . and yet if it should facilitate the progress of study, and remove only a part of the rubbish that obstructs the journey, the author will consider his object as attained" (Barclay).

§ 44. The Merits of Organonyms. Aside from the aphorisms the foregoing pages are intended to present simply *facts* respecting nomenclature and etymology. In considering the relative advantages of names or sets of names the question naturally arises, How far should the adoption of a term depend upon the number or eminence of those who use it? Were we merely chronicling the past or providing for the present, it might well be claimed that the majority should prevail; that is, that a selection should be made of those terms that are in actual use by the largest number of leaders in anatomy; but, first, we are—or should be—thinking rather of the future, of the time indeed when our personalities shall have been forgotten, and when our memories shall be honored or the reverse, according to the evidence of disinterestedness in our action of to-day. In the second place, great anatomists may be poor linguists, and therefore be no real authorities excepting as mechanics are governed by tradition and rule of thumb. Thirdly, even though they may be linguistically accomplished, they may be careless or deliberately ignore the just claims of a correct terminology. Finally, they may have some "exclusive dogma," some nomenclatural whim or fancy which renders it almost impossible for them to take an unprejudiced view of matters.* In short, "witnesses are to be weighed, not counted," and the weight is to be assigned after a deliberate and impartial consideration of the subject from all sides.

§ 45. The writer asks a careful consideration of his plans for terminological improvement: because they are based upon an unbiased study of nearly all previous publications; because—as he has reason to think—during the last ten years he has given to the subject more time than has been given by any other anatomist, living or dead; because the linguistic principles involved have been approved by philological authorities; because the actual disturbance of the existing order of things is kept at the minimum; and because the practical availability of the terms has been demonstrated with hundreds of students in both a university and a medical school.

As contrasted with the vocabulary in common use (at least up to 1889), that which seems to the writer best calculated to facilitate the advancement and dissemination of accurate anatomical knowledge would consist of terms which are:

Designatory rather than descriptive.
Conservative rather than eradicating.
Impersonal rather than personal (eponymic).
Idionymic rather than homonymic.
Correlate rather than irrelate.
Coordinate rather than inco-ordinate.
Classical rather than vernacular.
Dissyllabic or trisyllabic rather than monosyllabic or polysyllabic.
Mononymic rather than polyonymic.
Monoglot rather than polyglot.
Paronymic rather than heteronymic.
Constant rather than varied.

---

* At the meeting in September, 1888, [illegible] of American Anatomists [illegible] by the American [illegible] [illegible] Alexis [illegible]

* The following are examples of what may be [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] anatomy in fifteen [illegible] of two hours each.

§ 46. Advantages of Mononyms over Polyonyms.*—A. From the former, adjectives may be regularly derived; *e.g.*, from *callosum*, callosal; from *hippocampus*, hippocampal; from *thalamus*, thalamic. Notwithstanding the occasional introduction of verbal monstrosities like *pia-matral*, it is generally admitted that polyonymic adjectives are undesirable; indeed some writers, who still adhere to the polyonymic nouns, employ the mononymic adjectives.

B. Mononyms are readily compounded with other words; *e.g.*, *calloso-marginalis; subthalamicum;* such compounds could not well be formed from *corpus callosum* and *thalamus opticus*.

C. Mononyms are constant in form, excepting for the regular derivatives, numbers, cases, adjectives, and paronyms; whereas polyonyms are subject to variations of several kinds:

(*a*) By the omission of words; *e.g.*, *thalamus nervi optici* is commonly written *thalamus opticus*. The compound, *opto-striated body*, which occurred first in its French form, is ambiguous because the definite noun, *thalamus*, has been omitted, leaving the indefinite adjective *opto*, itself contracted from *optico*.

(*b*) By the conversion of qualifying words into other parts of speech; *e.g.*, the English translation (heteronym) of *pons Varolii* is *bridge of Varolius;* but *Varolian bridge* has also been employed.

(*c*) By the substitution of wholly different words for one or more of the components; *e.g.*, *commissura thalamorum*, *commissura mollis*, and *commissura intermedia* are liable to be used interchangeably; *medicommissura* is invariable.

(*d*) When a term comprises three or more words it is subject to permutation, *i.e.*, to the transposition of its components; *e.g.*, *Fissura occipito-parietalis* and *F. parieto-occipitalis;* these transpositions are, of course, more frequent among lengthy German combinations; the subject is also considered under the head of Pœcilonymy (§ 72).

(*e*) Polyonymic adjectives are subject to intentional, and even accidental, variation. The gyre designated by Owen as *subfrontal*, has been named *inferior frontal*, *infero-frontal*, and *inferofrontal*, *lower*, *first*, and *third*, as well as *Broca's*.

D. Mononyms may be more uniformly abbreviated. According to present methods, one and the same part, the *commissura anterior*, might be indicated upon figures by *c.a.* (Latin or French), *a.c.* (English), and *v.c.* (German); a single word like *præcommissura* would always have an abbreviation beginning *prc.* With the middle commissure, which is also known as the *soft*, the *gray*, and the *thalamic*, the opportunities for abbreviational diversity would be correspondingly numerous.

E. Aside from systematic abbreviation, polyonyms are subject to irregular and often inelegant abridgement. In one and the same paper occur *corpus callosum*, *corp. callosum*, *corp. callos.*, and, finally, *corpus*. In another, *corpus quadrigeminum*, *corp. quadrigem.*, *corp. quadrig.*, and *corp. quad.*; in a third, *tractus peduncularis transversus* is not merely abbreviated to *tr. ped. tr.*, but variously abridged to *tractus peduncularis trans.*, *tractus peduncl. tr.*, *tractus ped. trans.*, and *tractus ped. tr.*

F. Mononyms are usually shorter than the corresponding polyonyms. The prepositions *præ*, *post*, *sub*, *super*, *intra*, *extra*, *ento*, *ecto*, *medi*, *meso*, etc., are all shorter than the adjectives having the same force, viz., *anterior*, *posterior*, *inferior*, *superior*, *interior*, *exterior*, *ental*, *ectal*, *middle*, or *intermediate*. Hence there results from composition with them, not only the advantage of a mononym, but also the actual reduction in the number of letters and syllables. The following are examples of this reduction: *Præpedunculus* for *pedunculus anterior; postgeniculum* for *geniculum posterius; medicommissura* for *commissura media; subfrontalis* for *frontalis inferior; superoccipitalis* for *occipitalis superior*.

In this connection three points are to be observed:

1. The length of a term may be affected by (*a*) the number of words; (*b*) the number of syllables in each word; (*c*) the number of letters in each syllable.

2. One or two of these elements may be counteracted by the others; for example, although *corpus callosum* is a longer term than *callosum*, and *hippocampus* a longer word than *hippocamp*, and *bough* a longer word than *bow*, yet *indefatigability*, a mononym, is longer than the dionym *corpus callosum*, and the monosyllabic *though* is longer than the dissyllabic *also*. Hence, in any generalization respecting the length of terms, it is necessary to add, or understand, the qualification, "other things being equal," *ceteris paribus*, which may be abbreviated as *c.p.*

These generalizations are then as follows: Polyonyms are, *c.p.*, longer than mononyms. Polysyllables are, *c.p.*, longer than oligosyllables, *i.e.*, monosyllables, dissyllables, and trisyllables.

3. The written length of a term is affected by all three of the elements above named; but its spoken length is practically dependent upon only the number of words and syllables; *e.g.*, as written, *bough* and *eight* are longer than *bow* and *ate*, but as spoken they are equal.

G. A mononym is capable of adoption into any other language, either unchanged, or with so slight a modification as not to prevent its ready recognition. With most polyonyms, the transfer to either English or German involves either a change in the order of words; *e.g.*, when *thalamus opticus* becomes *optic thalamus;* or a change in the words themselves; *e.g.*, when *substantia cinerea* becomes *gray matter*. On this point see § 30.

§ 47. Between longer and shorter words there is merely a difference of degree, *e.g.*, *crus* and *pedunculus;* between a Latin word and its vernacular equivalent or heteronym (*e.g.*, *pedunculus* and *footlet*); or its paronym (*peduncle*) the choice might depend upon individual preference; but mononyms and polyonyms, terms of one word each and terms of two or more (*e.g.*, *pedunculus* and *pedunculus cerebelli*) differ in *kind;* it is not a question of size or euphony, but of essential endowment and capacity. The mononym is to the polyonym as is the water to the earth, or as is the bird to the tortoise.

§ 48. The desirability of replacing polyonyms by mononyms is in direct ratio with the frequency with which the part is mentioned, and with the need of employing corresponding adjectives. *Hypophysis* (formerly *pituitary body*) and *conarium* (formerly *pineal gland*) are much more frequently named since the discovery that the former has peculiar developmental relations with the pharynx, and the latter even more remarkable connections with a vestigial organ of sight. So long as the thin sheet of nervous tissue just dorsad of the chiasma was regarded as insignificant, and as occasionally absent, either *lamina cinerea* or *lamina terminalis* might not be so objectionable; but its now-admitted morphological importance as the cephalic boundary of the encephalic cavities justifies the use of the mononym, *terma*. The orifice left by the removal of the hypophysis and infundibulum had apparently received no name up to 1880; *foramen infundibuli* was a sufficiently appropriate descriptive term; but the frequency of its mention in notes respecting the preservation of the brain led the writer to discard it in favor of *lura*, at the same time that *alcohol-injection* was reduced to *alinjection* (after the analogy of *aldehyde* from *alcohol dehydrogenatus*).

§ 49. A good illustration of the principle that onymic improvement commonly attends any awakening of interest in parts, so that they are discussed by more persons or more frequently by some, is afforded by the prompt acceptance of Broca's arbitrary and sometimes Greek names, mostly unfamiliar and non-suggestive, for the various points on the head and skull which have to be recognized in operations involving the brain. In the last edition of "Gray," the editor gives very compact definitions of the mononyms *nasion*, *ophyrion*, *bregma*, *obelion*, *lambda*, *inion*, *basion*, *asterion*, *gonion*, *stephanion*, and *pterion*. Nor is it any valid objection to these new terms that, although only eleven in number, nearly one hundred words are required to define them.

The first two cervical vertebræ alone have mononymic titles; but were there similar anatomical, physiological, or aliquot occasions for specifying any other member of the vertebral series, a mononym would probably soon be proposed and generally adopted.*

---

* For convenience, it is assumed that these are Latin, or in Latin form.

Mononymization seems to be hastened by the length of the principal word; e.g., of *membrana conjunctiva* the principal word is polysyllabic and the modifier *membrana* has been long and commonly dropped; but *pia* and *dura* are so short that the equally needless *mater* has not as yet proved burdensome to most writers. The case is analogous to the retention in English of the entire word *ultima*, while the longer *penultima* and *antepenultima* are abridged to *penult* and *antepenult*.

The following serves as a somewhat striking and nearly complete illustration of the comparative brevity of mononymic paronyms and polyonymic heteronyms: the phrase "*central gray substance of the aqueduct of Sylvius*" (employed by a distinguished experimental neurologist) might be reduced to *aquæductal cinerea*; nor is the marked diminution in length counteracted by any lack of intelligibility, for the term can be interpreted in only one sense.

§ 50. Increasing Use of Mononyms.—Whether consciously or unconsciously, there has been, during the present decade, a marked increase in the employment of single-word terms. Among the mononyms which may now be said to be in somewhat common use are *pons*, *thalamus*, *chiasma*, [illegible], *aqueduct*, [illegible], [illegible], *dura*, [illegible], [illegible], *hypophysis*, *striatum*, *callosum*, *fimbria*, [illegible] and *hippocampus*. In some cases also the appropriate adjectives are employed, e.g., *pial*, *dural*, *callosal*, [illegible], *hippocampal*, [illegible], and *pontile* (sometimes, incorrectly, *pontine* or *pontal*).

In a few encouraging instances, the introducer of a polyonym has himself been timely impressed with its undesirability, and has proposed an equivalent mononym. William Patten (*Journal of Morphology*, I., [illegible]) regards his [illegible] as "unsatisfactory on account of its length," and substitutes [illegible] therefor.

§ 51. Some of the new muscle names proposed by Coues and Shute (1887†) are truly mononyms (e.g., [illegible] and [illegible] for [illegible] and [illegible]); the majority (e.g., [illegible] for [illegible] [the writer's [illegible]]) are merely hyphenated dionyms. Besides attempting to simplify the names and reduce their length, the authors have grouped the muscles according to their nerve-supply, a basis of classification that commends itself theoretically, and proves practically available. But in undertaking to give all the members of a given group names of a special pattern, they have, as it seems to the writer, illustrated the disadvantages of "exclusive dogmas" in nomenclature. For the term [illegible] is [illegible] by the [illegible], [illegible] is retained, [illegible] is haplologized, and [illegible] is transposed into [illegible]. The writer cannot help feeling that this is a different [illegible] from his own [illegible], and [illegible] (W. and G., p. [illegible]), and that it is particularly unfortunate to encumber the often mentioned and only "popular" muscle, [illegible], especially if, as proposed by the authors, the biceps of the leg can be distinguished by a slight change of title.

§ 52. In reducing polyonyms to mononyms the retained word should be as distinctive as possible. Since any adjective may be used as a substantive, the choice should be determined by the desirability of retaining the word least likely to be misunderstood. For example, with [illegible], since the adjective is very common ([illegible], § [illegible]) and the noun does not occur in any other connection, the latter is retained as the mononym; but with [illegible] the noun is very common, and the adjective is retained and used as a noun. Where the choice is between two adjectives or other modifiers, that should commonly be retained which is [illegible] the more often used alone; e.g., [illegible] should be mononymized as [illegible] rather than as [illegible].

§ 53. When the noun and the adjective are equally distinctive, the choice may be made upon other grounds. With *appendix vermiformis* either part of the term would be sufficiently distinctive; the former is more commonly employed, although the latter occurs in a recent paper (Biggs, 1888); since, however, inflammation of the part has come to be designated quite generally as *appendicitis*, the noun will probably be retained.

§ 54. Locative Names.—As defined in § 13, these are terms indicating the location of organs; e.g., *posterior commissure*, *mesencephalon*, *precentral lobule*. As may be seen from the index of any anatomical manual, a very large number of organonyms indicate position.

Their advantages.—Most of the desirable information respecting an organ would be covered by the headings, *adult structure*, *development*, *function*, *discoverer*, *date of discovery*, *likeness*, *location*. Of course the first three are of the greatest intrinsic importance, but the information is seldom fully gained until long after the necessity for some kind of designation has led to the adoption of a name not altogether appropriate. Names commemorating a discoverer (eponyms, § 18) are undesirable (§ 59). There remains to be indicated the location or position of the organ; this is definite and suggestive as compared with the date or discoverer, and also much more readily determined than points of structure, development, or function. Furthermore, the location of an organ is a general and comprehensive attribute, and names which indicate it are commendable in accordance with the following opinion of Owen: "It is an old maxim accepted by the best logicians, that no name is so good as that which signifies the total idea of whole subject, without calling prominently to mind any one particular quality, which is thereby apt to be deemed, undeservedly, more essential than the rest."

Many geographical names are locative, the prefixes usually indicating the points of the compass. Most of them are polyonyms, e.g., *South Boston*, *East Boston*, etc.; but country names are sometimes combined as mononyms giving a complete series, like *Middlesex*, [illegible], *Sussex*, *Essex*, and *Wessex*. Among encephalic names these are nearly paralleled by *medicommissure*, *precommissure*, *postcommissure*, and *supracommissure*, *subcommissure* only being wanting.

§ 55. Locative Mononyms.—Most locative terms in common use consist of two or more words, the adjective indicating position being separate from the substantive or from the other adjective; e.g., *frontalis anterior*, *frontalis posterior*, [illegible]. In 1842 a large number of such polyonyms were mononymized by Owen, and terms like *postorbital* and *postfrontal*, *basisphenoid*, etc., were soon generally employed. Later, in the "Comparative Anatomy of Vertebrates," he introduced [illegible], [illegible], [illegible], [illegible] and [illegible], and a complete series of mononyms, largely locative, for the fissures and gyres. The classical names of the encephalic segments, *mesencephalon*, *metencephalon*, etc., are locative mononyms. Following these precedents, in 1873, the writer proposed to replace [illegible] and [illegible] by the locative mononyms [illegible] and [illegible],† and in 1881 formulated the general method of conversion as follows: "When two or more parts are similar, or have similar relations, to distinguish them by joining to some common title already in use prefixes indicative of their relative positions" (*Science*, p. 121, March 19, 1881). In all these terms *pre* and *post* signify, respectively, toward the head and toward the tail.‡

---

* [illegible]

† [illegible]

* [illegible]

† [illegible]

‡ In most instances of the confusion caused by the employment of [illegible] [illegible] Vertebrates, [illegible].

§ 56. Formation of Locative Mononyms.—Two distinct questions are involved: (*a*), the selection of the substantive;[*] (*b*), the choice of the prefix. For example, the cerebellum is connected with other parts of the brain by three fibrous bundles at each side, continuous respectively with the pons, the mesencephal, and the postoblongata. How may they be most conveniently distinguished from other parts and from one another? Each has received many names; that which connects the cerebellum with the postoblongata has been known by at least twenty-three distinct Latin titles, besides many in other languages.

The Latin names are as follows: *Corpus olivare posterius; cp., pyramidale anterius; cp., pyramidale inferius; cp., pyramidale laterale; cp., pyramidale posterius; cp., restiforme; crus cerebelli ad medullam oblongatam; crus cerebelli descendens; crus cerebelli posticum; eminentia posterior bulbi rhachidici; eminentia pyramidalis; pars trunci medullæ cerebelli, qui pertinet ad partem posteriorem medullæ oblongatæ; processus a cerebello ad medullam oblongatam; prc. cerebelli ad medullam oblongatam; prc. cerebelli inferior; prc. cerebelli posterior; prc. cerebelli tertius; radix cerebelli; pedunculus chordæ spinalis; pdcl. medullæ oblongatæ; pdcl. cerebelli tertius; pdcl. cerebelli inferior; pdcl. cerebelli posterior.*[†]

§ 57. Among the substantives in the above list, *corpus* is so vague and common that it means nothing, and should be eliminated from all terms.[‡] *Eminentia* and *processus* more commonly refer to elevations with a free apex. The choice lies, therefore, between *crus* and *pedunculus*, which, also, are more commonly employed than the others. The latter is preferred on the following grounds:

1. It is more generally used in this sense; while *crus* is more commonly applied (as the Latin plural, *crura cerebri*) to the fibrous tracts between the pons and the chiasma.

2. There are two diverging crura, as the human legs form a pair; but there are three pair of peduncles, and the word less directly suggests the actual limbs.

3. Locative mononyms indicative of relative position, *præcrus*, *medicrus*, and *postcrus*, are less euphonious than *præpedunculus*, etc.[§]

§ 58. If the "pedunculus cerebelli posterior" be called *postpedunculus*, two corollaries naturally attend: 1, The other two "footlets" become respectively *medipedunculus* and *præpedunculus*; 2, the general name, *pedunculus*, should not be applied to other encephalic parts; *habena* is already replacing *pedunculus conarii*, and it is probable that a suitable mononym will be found for *pedunculus corporis callosi*. Even, however, without the above restriction, so that absolute explicitness might require the three cerebellar parts here under consideration to be named collectively *pedunculi cerebelli*, each of the three locative mononyms becomes a definite name or idionym; there may be many pedunculi, but only one pair of parts can now be called *postpedunculi*; the word has become an idionym, or name with a restricted application (see § 21).

3. *Crus* being no longer applicable to either of the cerebellar peduncles, it may be reserved as a mononymic substitute for *crus cerebri*; this latter is not merely a dionym, but actively misleading, inasmuch as it implies a direct connection with the cerebrum. When first introduced (in 1671, by Wharton), *cerebrum* included the thalami, and even the gemina, representing two other segments of the brain; but its present restriction to the prosencephal leaves the crura, the mesencephalic floor, connecting the epencephal with the diencephal. *Crus* is no longer needed for the columns of the fornix, and the less frequently mentioned supports of the olfactory bulbs may be called *olfactory crura* or *rhinocauls*. There will be many advantages in restricting *crus*, as an encephalic term, to the large and important fibrous tracts in question.

§ 59. Eponyms and Descriptive Terms.—These two groups of terms usually consist of more than one word, and may properly be considered here.

Disadvantages of eponyms. A. Anatomical names derived from the names of individuals are always polyonyms, and hence are objectionable on that score. Two other objections are mentioned by Pye-Smith: B. They are sometimes confusing; "the lymph-follicles of the spleen and the acini of the uriniferous tubules are alike called *corpora Malpighiana*."

C. Their meaning may be historically incorrect; "*Galvanism* is as unjust to Volta as *America* is to Columbus."

D. The association of an individual with some part discovered or described by him may be far from an honor that he would covet, since the tendency is to regard that as his only or at least principal achievement. This objection is recognized in the following comment in the London *Lancet*, November, 1882, upon *Listerism*: "It is unjust to so great a man for us to use his name in connection merely with a special means of dressing wounds. We consider Mr. Lister's work as far too great to be narrowed down to a mere matter of spray and gauze."

E. In some cases there may be an unjust, though inevitable, discrimination by reason of the length or cacophony of the discoverer's name.[*] Probably their most ardent admirers would hesitate to call parts after certain anatomists, who, nevertheless, have ample title to be so remembered.

F. Certain eponyms are needless, that is, the name of the individual is not required in order to render the term as a whole distinctive. So long, for example, as there is in the brain but one pons,[†] one insula, one aqueduct, and one torcular,[‡] there is no more need of adding the names of their discoverers or describers, than there would be of saying the *brain of Jones*, the *liver of Brown*, and the *cæcum of Robinson*, supposing those organs to have been discovered or named by those individuals.

From § 78, it will be seen that the writer has replaced the dionymic eponyms, *foramen Monroi*, *sulcus Monroi*, and *foramen Magendie*, by *porta*, *aulix*, and *metaporus*, respectively, these being mononyms of appropriate signification.

Among encephalic eponyms, however, there is one which no one thinks of discarding, viz., *fissura Sylvii*, the *Sylvian fissure*. This may be due partly to the doubt as to which Sylvius is referred to, so that the name has no distinct personal association, but mainly to the large number of compounds that have been applied to adjoining parts, *e.g.*, *presylvian*, *subsylvian*, *ectosylvian*, *supersylvian*, etc.; see especially, Owen, 1868, iii., pp. 136, 137.

---

[*] With certain large groups of parts, fissures, gyres, arteries, etc., the entire name cannot be a mononym: a polyonymic adjective, however, may be mononymized by selecting a main adjective and combining it with a prefix (see § 25).

[†] Two other mononyms for the part in question have been suggested, though not insisted upon, by Spitzka. *Restibrachium* (*Science*, April 9, 1881, p. 165) is an admirable compound, and the same may be said of its correlatives, *pontibrachium* and *tegmentibrachium*; but *brachium* seems to have become well fixed upon parts of an adjoining segment, one of which (*brachium posterius = postbrachium*) is connected with the same (postgeminal) lobe as the tegmentibrachium, constituting a source of ambiguity. To *myelobrachium* (New York *Medical Record*, October 11, 1884, p. 395) there pertains the same objection as to *brachium*, and also there is the undesirable implication of an immediate macroscopic continuity with the myel, rather than with the oblongata.

[‡] There are about one hundred Latin encephalic names beginning with *corpus*; rid of them, neuronymy is relieved, lightened, literally disembodied.

[§] To offset these, there seems to the writer but one argument in favor of retaining pedunculus for the mesencephalic crus, viz., the existence of Gudden's name, *tractus pedunculi transversus*, for a band crossing the part; but even if this polyonym is not replaced by the writer's mononym, *cimbia*, it could easily become *tractus cruris transversus* with no lack of explicitness.

[*] Even had Ludovic Muggleton been inspired as he claimed, it is doubtful whether a sect of "Muggletonians" could have survived long in any cultivated community.

[†] *Pons Tarini* is an altogether obsolete synonym.

[‡] In this connection the writer desires to express his regret at having proposed (*New York Medical Journal*, March 21, 1881) to replace *torcular Herophili* by the obsolete synonym, *lenum*. Were the part newly observed, the latter term would be preferable on account of its brevity; but since the phrase has become familiar, the desired mononymization is best attained by merely dropping the superfluous genitive. Respecting the abandonment of *preoptic* and *postoptic lobes* for *pregeminum* and *postgeminum*, there may be some question; but a somewhat mature and unprejudiced consideration of the matter from all sides has induced the change: perhaps the most cogent reason is the willingness to perpetuate the essential element of the very common names, *corpus quadrigeminum* and *cp. bigeminum*.

§ 60. The objections to descriptive terms are two:

1. *Length*; e.g., *pneumogastricus*, [illegible] [illegible].

2. *Incompleteness*. It seems possible for chemists to indicate in a single word the entire composition of a substance; thus, for example, the full title of sulfonal is said to be *Diethylsulphondimethylmethan*; similarly, some surgical terms may be said to almost describe the procedure; an operation on the testicle is called [illegible]. In anatomy, excepting perhaps in German writings, names of such unwieldy lengths do not occur; one of the longest Latin names is incomplete as a descriptive title; *pneumogastric* is more than twice as long as *vagus*, the designative name of the same nerve, yet it falls of perfection as a descriptive term; it indicates only two of the six organs to which the nerve is distributed; to include them all the name should be *Nervus laryngo-pharyngo-pneumo-gastro-cardio-[illegible]*; which is as if antipyrine were known only as *dimethyloxyquinizine*. This matter is well stated by Barclay (1803, 161), referring especially to the proposition of Chaussier and Dumas to name all the muscles in accordance with their origin and insertion. "Such names are admirably calculated for muscles that have only a single origin and a single insertion; but where the origins and insertions are numerous, the name that pretends to enumerate the whole must run out to the length of a sentence;" e.g., for *Trapezius* we should have *Occipito-dorsi-clavi-acromi-scapularis* (this being a Latinization of Chaussier's descriptive term).

The most fatal objection to such descriptive names does not seem to have been considered by either of the French anatomists or by Barclay, viz., few if any muscles have the same attachments in other animals as in man; the biceps, for example, would be *coraco-gleno-radialis* in man, but *gleno-radialis* in the cat, where it has but one origin and thus but one head.* The ordinary name is accepted in a conventional sense, but a descriptive name would be at once remarked upon as not in keeping with the facts.

§ 61. It will be remarked that *postperforatus* (§ 58), although reduced from a polyonym to a mononym, is not only obviously a Latin word, but somewhat obtrusively so; upon an English page or in an English lecture its frequent recurrence has a savor of pedantry. In the writer's earlier terminological papers and in the first edition of "Anatomical Technology," this feature was noted in respect to the components of [illegible], etc.; but in the effort to accomplish the mononymization of a large number of polyonyms less attention was given to this aspect of nomenclature.

In the paper "Paronymy versus Heteronymy" (see § 5, note), this subject was fully discussed, and the conclusions are stated briefly in the preface to the second edition of the "Technology."

Admitting that certain Latin mononyms are so evidently Latin as to appear incongruous among ordinary English words, there are two alternatives, viz.: (1) to translate the objectionable words into the vernacular, to [illegible] them, [illegible] words be *heteronyms*; (2) to retain them essentially unaltered, but change their endings so as to appear less un-English; to convert them into *paronyms* (§ 59).

§ 62. *Objections to most Heteronyms*. Certain vernacular translations of Latin words are either inelegant in themselves or inappropriate to scientific writing; such are "tree of life" for *arbor vitæ*, "striped body" for *corpus striatum*, "bridge" for *pons*, "worm" for *vermis*, "little tongue" for *lingula*. An extreme example of heteronymic inappropriateness is offered by the name of a great French naturalist which might be translated "Baron [illegible]." If heteronymy is to be extended, there may be expected in time a treatise upon [illegible], with a peculiar [illegible] of the hinder [illegible] of the little brain."

But a much more vital objection to many heteronyms is that they unavoidably obtrude the literal sense and thence become more or less misleading or at least disturbing to the mind. As remarked by Whewell (Aph. XII., p. xv.), we may apply the term *cirrus* to a cloud composed of filaments even if those filaments are straight; but to call such a cloud a "curl-cloud" would be much less acceptable. "Great commissure" (as used for the callosum in Quain, II., 343) is sufficiently appropriate for the human brain; but the corresponding part in the opossum and some other marsupials is so small that its very existence has been denied in past years. The fifth digit of a pterodactyl supports most of the wing and is larger than all the rest together; hence "little finger" is strikingly inapplicable, but *minimus* much less forcibly suggests size. *Pia mater* is readily accepted, but the English heteronym, "kind" or "tender mother," like the German "fromme mutter," impresses one as needlessly literal.

Technical terms in science are comparable with certain conventional phrases in society; for example, "not at home" is commonly accepted as indicating either of several conditions which frustrate an intended call; but everyone has heard of embarrassments resulting from the literal rendering of the phrase, by ignorant servants, into "away from home," "not in the house," "has gone out," etc., all of which purport to state particular facts.

§ 63. Certain heteronyms are, however, unobjectionable, or, at least, practically ineradicable from most languages; e.g., *head*, *brain*, *hand*, *foot*, *kidney*, *heart*. Respecting most of these, it may be noted that they refer to parts either so exposed or so vital as to have claimed popular attention. They are like the domesticated animals, dog, cow, sheep, and some others whose vernacular names persist. But while *brain*, *Gehirn*, etc., are wholly unobjectionable by themselves, it does not follow that compounds, adjectives, and other derivatives should be formed therefrom. Conceding that this may be a matter for individual taste, after mature reflection, the writer concludes that *encephalic* is a convenient and appropriate adjective, and that *prosencephal* is preferable to *forebrain*. On this point Campbell comments as follows: "In Germany there is now a tendency to abolish Latin and Greek terms and substitute pure German words. In the German language this is possible, though, perhaps, not advisable. In English, however, *windpipe-head* [larynx], *woman-healing-art* [gynecology], and *straightgut-[illegible]* [illegible], would certainly be no improvement upon the technical terms now employed."

§ 64. The principal advantage of paronymization is, as it seems to the writer, that, while maintaining the general character of the modern language, the technical terms are, for the most part, so little changed from the Latin as to be at once recognizable, whether in the substantive or adjective form. With the Latin tongues, the change is very slight; *postperforatus* becomes *postperforé* in French and *postperforato* in Italian; in English it is *postperforate*; the German terms, [illegible] and [illegible], justify the retention of the Latin form; but *Postperforat* would have analogical precedent. Whichever form be used, the word never can be mistaken for any other, and the anatomist of every nationality may employ the form characteristic of his own language, with the certainty that it will be recognized by all other anatomists as equivalent to the common parent form, the Latin *postperforatus*.*

Correctly formed, paronyms also constitute a natural bond of continuity between the language of science and the language of every-day life, between the learned anatomist and the unprofessional, yet educated, man. The former uses certain vernacular nouns, *brain, heart, kidney, liver;* the latter can appreciate the significance of the technical adjectives, *encephalic, cardiac, renal,* and *hepatic,* only by becoming acquainted with the classical stems from which they are derived. Each makes a certain concession to the other.

---

* [illegible]

* [illegible] "Paronymy versus Heteronymy," see § 5, note.

§ 65. Tendency to Brevity in Paronymization.—It will be noted that English paronyms often differ from their Latin originals in the less number of letters or of syllables, or both. As might be expected, however, these reductions have been applied more commonly to longer words.

§ 66. Methods of Paronymization.—The following are brief formulations of more common modes of converting Latin words into Anglo-paronyms.*

A. *Stomachus* = stomach. The ultima is dropped from the nominative, leaving the stem entire. Of this simple and common method of Angloparonymization, the following are familiar examples: *Organum* = organ; *cella* = cell; *oviductus* = oviduct; *canalis* = canal; *palpus* = palp; *tractus* = tract. The following have been employed by the writer as justified by the foregoing: *Hippocampus* = hippocamp; *myelon* = myel; encephalon = *encephal.*

B. *Nervus* = nerve.—The ultima becomes a silent *e.* Other familiar examples are *commissura* = commissure; *oliva* = olive; *fissura* = fissure; *polus* = pole. By analogy with the above the writer employs *gyre* from *gyrus; cœle* (especially in composition) from *cœlia; tele* (in composition only) from *tela; e.g., metacœle, metatele.*

C. *Musculus* = muscle.—A dissyllable is reduced to a monosyllable by the elision of the penultimate vowel, and the replacement of the ultima by a silent *e.* Also, *pedunculus* = peduncle; *diverticulum* = diverticle (used by Günther); *receptaculum* = receptacle.

D. *Decussatio* = decussation.—The ultima is dropped from the genitive (*decussationis*), leaving the stem, which is longer than the nominative. Also, *positio* (*positionis*), position.

E. *Ovarium* = ovary.—The three letters *ium* are replaced by *y;* a dissyllable by a monosyllable. *Aviarium* becomes aviary; *insectarium,* insectary,† etc.

F. *Eminentia* = eminence.—The termination *tia* becomes *ce.* Also, *absentia* = absence; *diligentia* = diligence; *substantia* = substance.

G. *Diaphragma* = diaphragm.—The ultima is dropped from the nominative, leaving less than the stem. (The word is from the Greek, the genitive is *diaphragmatis,* and the stem *diaphragmat.*) Other examples are *epigramma* = epigram; *programma* = program.

H. *Organismus* = organism.—A part of the ultima is dropped, and the rest is attached to the stem as what may be called a *hemisyllable.* Other examples: *chasma* = chasm; *aneurysma* = aneurysm; *columna* = column; *chiasma* = chiasm.

I. *Fibra* = fiber.—The ultima *ra* or *rum* becomes *er* (or *re?*). Also, *sternebra* = sterneber; *spectrum* = specter; *metrum* = meter. Notwithstanding its frequent use, the termination *re* is French, and should, so far as possible, be left to distinguish the paronyms in that language. There is no more reason why the regular English form, *meter*, should be discarded in favor of *metre*, than that we should use the German or Latin *metrum*, the Greek *μέτρον*, or the Italian *metro.*‡

J. *Præmaxilla* = premaxilla.—The diphthong *æ* becomes *e.* As stated in the Imperial Dictionary, the retention of the Latin form, *præ*, indicates that the word is "scarcely naturalized," *i.e.*, paronymized; *e.g.*, *fæces, cæcum.*

K. *Fœtor* = fetor.—The dipthong *œ* becomes *e.* This conversion is less well established than that of *æ* into *e.**

§ 67. In selecting the illustrations of paronymy, care has been taken to include only such as present but a single kind of modification. But many Angloparonyms, especially derivatives, present two changes; *e.g.*, *crista* = crest; *præcommissura* = precommissure; *aquæductus* = aqueduct.

§ 68. With all the above examples of Angloparonymy the English word is not identical with the Latin; there is a difference of orthography, a *literal* distinction between the two; the nominatives are obviously unlike.

But with many others which are commonly regarded as Latin words adopted or naturalized into English, the evidences of such adoption are less apparent, and may even be altogether absent, at least so far as regards the nominative singular, which is commonly regarded as the representative of a verbal form.

With the following, the nominative singular remains unchanged, but the plural has a distinctly English character; hence not only the plural, but also the singular nominative, may properly be regarded as Angloparonyms. Nominative singular (Latin or English), *animal;* plural, Latin, *animalia*, English, animals; *cadaver, cadavera*, cadavers; *enema, enemata*, enemas; *lens, lentes*, lenses; *hernia, herniæ*, hernias; *corolla, corollæ*, corollas; *pendulum, pendula*, pendulums; *atlas, atlantes*, atlases; *simile, similia*, similes. In the New York *Medical Record* for November 3, 1888, occurs *neurasthenias* for *neurastheniæ.*

With the following, not only the singular but also the plural nominative has practically been adopted from the Latin with no change in spelling, although the pronunciation may differ somewhat (see § 69, E):—*Cilium*, pl. *cilia; dictum*, pl. *dicta; memorandum*, pl. *memoranda* (or memorandums); *stratum*, pl. *strata.*†

§ 69. Other Evidences of Paronymization.—A word which is spelled exactly like the Latin may nevertheless be indicated to be a paronym, *i.e.*, an adopted word, in either of the following ways:

A. By simple declaration. B. By non-italicization. Were the rule that foreign words are to be italicized strictly followed, the non-italicization of a Latin term would show that the author regarded it as an unchanged paronym. C. By combination with words that are unmistakably of the author's language. This is most common with German writers. For example, *pedunculus* is primarily a Latin word, but in the compound *Pedunculusbahn* (Schwalbe, 1869, 614) it is obviously accepted as German. The following are analogous terms: *Quintuskern, Thalamusstiel, Cerebellumgebiet, Haubentractus.* Sometimes the two components are hyphenated. D. By the use of an oblique case or compound form. For example, instead of [illegible] it would be possible, though very unusual, to say the cerebellum's [illegible]; the use of a [illegible] would be [illegible] the cerebellum was considered as an unchanged paronym of the Latin. F. By pronunciation.—According to the Roman method of pronunciation the Latin c has the force of k before e and i as well as before a, o, and u; and the vowels a, e, i, and o have essentially the force of the English ah, â, ē, and ō. Hence, when employed as Latin a word may sound very differently from the same word employed in English. For example, in the Latin [illegible], the first word is pronounced in a certain way, but in the English [illegible] the same word has a different sound. In each case the language is indicated by the accompanying adjective, its form, and its position. The subject of what may be called *pronunciatio-paronymy* is admirably presented in the following extract from the preface to Foster's "Medical Dictionary" (p. xi): "The Roman method [illegible] is the one now taught in the leading universities of this country, and it will doubtless be adopted everywhere within a very few years. [illegible] Many of the commonest Latin words have ceased to be considered as foreign, and except when connected with other Latin words or inflected according to Latin forms, are treated as English by adoption [i.e., as unchanged paronyms]. [illegible] In some instances, e.g., *Abdomen*, a Latin or Latinized Greek word is so thoroughly adopted into English as in common use to have come to be pronounced as if it had a distinct English form." *Abdomen* is an instructive illustration of several points in paronymization, but, not being an encephalic term, need not be considered in this connection.

---

* Certain etymological terms are here defined: *Ultima*, the last syllable. *Penult*, the syllable just before the last; the last but one. *Antepenult*, the syllable just before the penult; the last but two. For example, with *commissura*, *a* is the ultima; *sur*, the penult; *mis*, the antepenult. *Base*, the main or principal part of a derivative word; that which is neither prefix nor suffix, but which is qualified thereby. In the following words the basal element is italicized: *Dors*ad; post*nares;* medi*cornu;* pre*commissure;* ali*sphenoid.* (This use of the word *base* is suggested by Professor B. I. Wheeler.)

† This term was introduced by the writer's colleague, Prof. J. H. Comstock, in order to designate the first building erected for the experimental study of noxious or beneficial insects (*American Naturalist*, December, 1888, p. 1129).

‡ From the above it will be understood that the occurrence of the termination *re* in this article and in the others by the writer, is for the sake of conformity with the rules applying to the entire work.

* The learned editor of the *New York Medical Journal* and of Foster's "Medical Dictionary" (preface, p. x.) retains the diphthong, but the conversion into *e*, more common Latin form, is advocated by Professor Skeats (*Notes and Queries*); his remarks are approved and reinforced by the *British Medical Journal*, and quoted without adverse comment in the New York *Medical Record* for April 30, 1887, p. 500. Economy (from *œconomia*) and solecism (from *solœcismus*) are now never written *œconomy* or *solœcism*, and there seems to be no good reason why *diarrhœa* and *fœtus*, as English words, should not be written *diarrhea* and *fetus* (the latter, indeed, being the more common Latin form). In the writer's opinion, the *œ* should be retained only when it is desirable to distinguish two paronyms that otherwise might be confounded, as with those of *κήλη*, a tumor, and *κοιλία*, a cavity. The former can be Angloparonymized only as *cele* (at any rate, the perhaps permissible *kele* does not occur), *e.g.*, *varicocele, bronchocele*, etc.; *κοιλια* also *might* become *cele*, but the necessity for distinguishing the two (which had not occurred to the writer when his Cartwright lectures, *New York Medical Journal*, and *Medical Record*, February 9, 1884, *et seq.*, were reported, but was admitted a year later, *New York Medical Journal*, March 21, 1885, p. 326, note), justifies the retention of the diphthong. *Encephalocele*, then, is a tumor of the brain; *encephalocœle*, the brain cavity.

† Although the above Latin plurals may fairly be regarded as having been adopted into English, there is one reason for employing the regular English plural form, *ums*. In English the context does not, as in Latin, indicate the case; hence one sees not infrequently *septa, strata*, and *cilia* used as singular nouns of the first declension, and their plurals made *septæ, stratæ* and *ciliæ.*

When the changed paronym has already been adopted in common language, it is often better to employ the unchanged word in a desired special or technical sense. *Crest*, *pore*, and *hall* are changed Anglparonyms of *crista*, *porus*, and *aula*, but the latter words, as applied to special parts of the brain, are used unchanged, as English words without italicization.

§ 70. Homonyms (§ 22).—In most cases confusion from the use of homonyms is obviated by the context or by mental adjustment; the mind is set, as it were, at a particular level, and words are interpreted accordingly; it is comparable with the fact that in music one and the same symbol may stand for three sounds, D, D sharp, and D flat, according to the "key" in which the composition is written. There is, for example, no real danger of mistaking *brachium* (upper arm) for *brachium* (a ridge of the mesencephalon), or *pelvis* (a part of the skeleton) for *pelvis* (the cavity of the kidney); the parts are so distant or so different as to be unmistakable.

But homonyms applying to parts of a single organ, or to closely adjacent organs are highly objectionable, and should be disposed of either (a) by rejecting all of them, or (b) by adopting and confirming one to the exclusion of the rest.

For example, at least a score of encephalic parts have names into which *peduncle* enters; the writer proposes (§ 57) to restrict the word to the three fibrous connections between the cerebellum and other parts, viz., *prepeduncle*, *medipeduncle*, and *postpeduncle*. *Trans-* occurs in at least a dozen encephalic names; the writer would confine its application to the *fissura transversa*. *Rima* [illegible] and *rima* [illegible] constitute the "rima transversa" of Bichat; but the writer desires to employ *rima* alone for the [illegible].

Cornu.—This word has three distinct neuraxial applications: (A) To the hippocamp ("*hippocampus major*"); (B) to the medicornu ("middle or descending horn of the lateral ventricle"); (C) to the ventricornu (ventral or "anterior" extension of the myelic cinerea). The first is a curved elevation; the second is the curved cavity into which that elevation projects and a cast of which would be horn-shaped; the third is neither an elevation nor a cavity, but merely a curved area which appears upon transection of the myel. Since there are other parts of the body (thyroid bone, uterus, etc.) with which the same word is associated, it is desirable to restrict the encephalic applications, if possible. *Cornu Ammonis* is objectionable because it resembles an eponym and no beginner can be expected to know that Ammon, instead of an investigator, was an Egyptian deity with a ram's head; and because it is a dionym; so, of course, is *hippocampus major*; but if the postcornual ridge, formerly called *hippocampus minor*, be designated as *calcar*, then the "Ammon's horn" is adequately distinguished by *hippocampus* (Eng. *hippocamp*), a mononym.

The myelic cornua are strictly dorsal and ventral, and should be so named, rather than posterior and anterior; appropriate mononyms are *dorsicornu* and *ventricornu*, permitting the adjectives *dorsicornual* and *ventricornual*.

The three divisions of the paracœle ("lateral ventricle"), known commonly as anterior, middle, and posterior, may now receive the locative mononyms *precornu*, *medicornu*, and *postcornu*. These latter names, as mononyms, now become also idionyms, i.e., restricted in application. *Cornu posterius* might refer to either the dorsal ("posterior") horn of the myelic cinerea, or the caudal extension of the paracœle, to a surface or a cavity, to a part of the myel or a part of the brain; but *postcornu*, as introduced and defined by the writer in 1882 can hardly be applied to any other part of the neuraxis.

§ 71. Sinus.—This has had a very wide application, from a mere furrow on the ventral aspect of the pons to the pericardium, a closed cavity; at present so far as the head is concerned its use is restricted to three sets of cavities: (a) Spaces in the bones, e.g., the frontal sinuses, lined by mucosa and communicating with the air (Fig. 4684); (b) veins with relatively rigid walls, the longitudinal sinus, etc. (Fig. 4711); (c) irregular spaces between the pia and the arachnoid, the subarachnoidal spaces. The writer sees no way out of the existing ambiguity, and commends the considerate explanation offered in the last edition of Gray's "Anatomy," p. 167, note.

§ 72. Poecilonymy was contrasted in § 16 with terminological consistency. It may be defined as the use, in a given publication, whether by intent or through carelessness, of two or more terms, whether etymologically related or not, for one and the same object, attribute, or idea. Such discrepancies ("distinctions without differences") almost surely perplex the beginner, and may occasion doubts in the minds of even advanced students. The remark (from a neurological text-book) that certain fibers are called "*peduncular* because they are destined to pass into the *crusta cerebri*," is an explanation which explains nothing, to the student who has not learned that *crus* and *peduncle* are often employed interchangeably; the term appears simply as a *lucus a non lucendo*. Had Huxley, in the passage quoted (§ 5, *d*), gone on to speak of the elevation at the bottom of the Sylvian fissure as the "insula" in one place, as the "island of Reil" in a second, and as the "central lobe" in a third, and then defined a certain area as the paracentral lobule because it was opposite the central fissure, without stating that by *central fissure* was meant what he had called *fissure of Rolando* on one page, and *sulcus of Rolando* on another, and without adding that neither *central fissure* nor *paracentral lobule* implied any relation to the "central lobe," there would have resulted simply an unusually complete combination of poecilonymic ambiguities. Nor will such instances fail to occur until, before completing a given paper or treatise, the author decides what terms he will consistently employ as *the* names, all others being, so far as that publication is concerned, simply synonyms.*

§ 73. There seem to be two explanations of poecilonymy, viz.:

A. Intentional magniloquy, i.e., a style designed to impress the hearer or the reader with a sense of the speaker's or writer's mastery of the subject; this is so unworthy a motive that it may be dismissed with the commentary made in § 75 respecting the employment of ponderous Latin phrases.

---

* As an example [illegible] the present [illegible] for the article on the [illegible] of the brain was prepared a printed alphabetical list of all the terms that were to be used.

B. The conscious or unconscious importation into science of a style which is justified, if at all, only by the generally accepted canons of what is called "literature," and thence the avoidance of that kind of repetition which renders (perhaps needlessly) legal documents so tedious.[*]

§ 74. In order to avoid what the writer calls "indirect pœcilonymy" (§ 17), adjectives, other inflectives, and compounds, referring to a part, should, in the same publication, be derived from the name employed for the part itself. If, for example, *epiphysis* is adopted as the substantive, *pineal* and *conarial* should be avoided; while if *conarium* is adopted as the substantive, *pineal* and *epiphyseal* should be introduced as synonyms only.[†]

§ 75. Magniloquy.—Akin to pœcilonymy is the employment of lengthy terms, especially in the Latin language, where shorter would suffice. Sometimes this is due merely to habit, but too often it seems to be intentional. A distinguished anatomist is portrayed at his lecture-desk, pointing to a diagram bearing one of the least commendable of encephalic polyonyms. Is not the persistence of certain ponderous names due to the willingness of some teachers and writers in human anatomy to impress their hearers or readers with a sense of their profound erudition? Is there not something here of the "*omne ignotum pro magnifico?*"[‡]

The phrase, *medical esotery*, is said to have been used by Simon for the mystery and secrecy supposed by ancient (and perhaps some modern) physicians to be necessary for the proper management of patients;[§] is it not possible that a kindred spirit of anatomical esotery induces some anatomists to employ needlessly long and impressive terms?

Astronomers have set an example in micronymy that anatomists might well follow; the first asteroid discovered was named *Ceres*, and many of its successors have dissyllabic or, at most, trisyllabic names. This is the more noteworthy, because, in the first place, these bodies are not, and are hardly likely to become, objects of popular discussion; and, secondly, each has its assigned numeric symbol, so that the professional astronomer need not employ the names at all. Now that the choice is offered, the anatomist who deliberately says *aponeurosis* for *fascia*, *anfractuosity* for *fissure*, and *convolution* for *gyre*, runs the risk of association, in the minds of others at least equally well-informed, with the "penny-a-liner," or the village orator who distinctly prefer *conflagration* to *fire*.[*]

§ 76. Perissology, or Needless Amplification.—The following is not, as might be supposed, from an elementary account of the nervous system for beginners, but from a special article by a distinguished neurologist, in a leading metropolitan medical journal: "The anterior column of gray matter extends throughout the spinal cord and the upper enlarged intra-cranial end of the spinal cord, which is known as the oblong cord or medulla (medulla oblongata)." Could not all of this information have been conveyed in something like the following sentence: "The ventral column of cinerea extends throughout the whole length of the myel and oblongata?" Here are fifteen words in place of thirty-two.[†]

§ 77. Linguistic Uniformity.—The interlarding of ordinary English writing or speech with needless French phrases is justly regarded as an affectation; is there not something of the same in the employment by scientific writers of ponderous Latin phrases when single words in English form are available? To a well-trained literary scholar, almost any page in existing neurological literature would be apt to suggest the bills of fare in second-rate hotels, a most unsavory compound of bad French with worse English, with this difference, that the steward has usually to mention an article but once upon the same occasion, whereas the anatomist has often to name the same part several times in the course of a few pages; hence, from a real need of condensation, and from a fancied need of an elegant style, there occur barbarous abbreviations and a use of synonyms which in no wise suggest each other.

§ 78. Absolute Innovations.—The following terms have been introduced by the writer[‡] with no direct precedent, ancient or modern, and solely for the sake of substituting mononyms for polyonyms: *torus* for *tuber cinereum; cimbia* for *tractus peduncularis transversus; lura* for *foramen infundibuli; aula* for the prosencephalic portion of the "third ventricle;" *porta* for *foramen Monroi; aulix* for *sulcus Monroi; metaporus* for *foramen Magendie.*

With the exceptions named above, all of the apparently new terms employed in the article Gross Anatomy of the Brain are justified by ancient or modern usage of either the terms themselves (*e.g.*, *cœlia* for an encephalic cavity) or some derivative, *e.g.*, *lamina cribrosa* and *lame criblée*, which suggest the metaphorical use of *cribrum* itself.

§ 79. Ventricle versus Cœle.—To the continuance of *ventricle* in the encephalic sense, there seem to the writer to be two serious objections, and two others which, although real, are not of much weight.[§]

The serious objections are: 1, The word cannot be compounded with prefixes distinctive of the encephalic names, so as to form mononyms, without a very undesirably prominent hybridism; *prosoventricle* is as harsh as *prosocœle* is acceptable; 2, the word is indissolubly asso-

---

[*] The following verses (source unknown to the writer) are of course a gross caricature of literary pœcilonymy, but on that account they serve to illustrate the point in qnestion more completely:

Behold the mansion reared by dædal Jack.
See the malt stored in many a plethoric sack,
In the proud cirque of Ivan's bivouac.
Mark how the rat's felonious fangs invade
The golden stores in John's pavilion laid.
Anon with velvet foot and Tarquin strides,
Subtle Grimalkin to his quarry glides,
Grimalkin grim, that slew the fierce rodent,
Whose tooth insidious Johann's sackcloth rent.

* * * * *

Here stalks the impetuous cow with crumpled horn,
Whereon the exacerbating hound was torn,
Who bayed the feline, slaughtered beast, that slew
The rat predacious, whose keen fangs ran through
The textile fibres that involved the grain
Which lay in Hans' inviolate domain.

* * * * *

The loud, cantankerous Shanghai comes at last,
Whose shouts arouse the shorn ecclesiast,
Who sealed the vows of Hymen's sacrament
To him, who, robed in garments indigent,
Exosculates the damsel lachrymose,
The emulgator of that horned beast morose,
That tossed the dog, that worried the cat, that kilt
The rat, that ate the malt that lay in the house that Jack built.

[†] It is possible, however, to carry terminological correlation too far; the not unnatural use of *thalamencephalon* and *thalamocœle* for the shorter *diencephalon* and *diacœle*, in order to connect the segmental and cavitary names with the names of the chief masses, may lead some apostle of absolute consistency to insist upon *cerebellencephalon* and *cerebellocœle*, or upon *quadrigeminal ventricle.*

[‡] "While words of learned length and thundering sound
Amazed the gazing rustics ranged around."

[§] See the naïve remark respecting *neurasthenia* reported in the New York *Medical Record*, November 3, 1888, p. 547.

[*] There seems to be no reason why *habena* should not replace *habenula* and *sclera*, *sclerotica*; on the same grounds the cerebellar interval now called *vallecula* (properly *vallicula*, although the former occurs in the article Gross Anatomy of the Brain) may well be named *vallis*.

[†] Some of our anatomical writers would do well to heed the following vigorous commentary upon verbiage in another profession, reported to have been uttered by Hon. David Dudley Field, after showing that more than nine hundred words are used in a deed where two hundred would answer all purposes:—"They beget and confirm our dreadful habits of verbosity; they make the young lawyers think that these words and phrases mean something, and thus teach falsehood: they lead the minds of old and young to run in grooves: they encumber, and because they encumber, they tend to hinder, obscure, and confuse; they make it necessary to write, read, and record, in the course of a year, millions upon millions of useless words, all of which cost a great deal of time and a great deal of money."

[‡] The locative mononym, *intercalatum*, for *locus niger*, is used in the article Gross Anatomy of the Brain, but it was suggested by Spitzka.

[§] It is longer than *cœle*, whether letters or syllables be considered; it applies also to cardiac cavities and to a laryngeal recess, and has been sometimes used for stomach; but, as discussed under § 70, ambiguities of this kind are unavoidable, and are not, as a rule, practically confusing.

The following Table contains a sufficient number of representative, complete terms to enable the reader to estimate the degree and kind of modification involved (1) in substituting mononyms for polyonyms and (2) in framing from the Latin mononyms paronyms conforming to the "genius" of each modern language. The Latin polyonyms and the French, German, and Italian paronyms are in italics. The preferred Latin mononyms are in heavy-faced type. The preferred English paronyms are in small capitals. The English heteronyms are in ordinary type. The section numbers refer to general remarks in the text of this article. The other references are to footnotes upon page [illegible]. For all errors the writer alone is to be held responsible.

LATIN. (Polyonyms in upper line.) Mononyms	Genitive	Plural nominative	Adjective	ENGLISH. (Heteronyms in upper line.) Singular	Plural	Adjective	French, German, Italian
	Substantia alba (§ 12).			White (or medullary) matter.			
Alba	Albæ		Albalis	ALBA		ALBAL	[illegible]
	Membrana arachnoidea (§ 8).			Arachnoid membrane.			
Arachnoidea.	Arachnoideæ.	Arachnoideæ	Arachnoidalis.	ARACHNOID.	ARACHNOIDS.	ARACHNOIDAL.	[illegible]
	Arbor vitæ cerebelli (§ [illegible]).			Tree of life.			
Arbor	Arboris	Arbores	Arboreus	ARBOR	ARBORS	ARBOREAL	[illegible]
	[illegible] (§ [illegible]).			Cephalic part of third ventricle (p. [illegible]).			
Aula	Aulæ.	Aulæ.	Aulicus	AULA (§ [illegible]).	AULAS	AULIC	[illegible]
	Hippocampus minor, Calcar avis (§§ [illegible]).			Lesser hippocampus.			
Calcar	Calcaris.	Calcaria.	Calcarinus	CALCAR.	CALCARS.	CALCARINE.	[illegible]
	Corpus callosum (§ [illegible]).			Hard body (§ [illegible]).			
Callosum	Callosi.	Callosa	Callosalis.	CALLOSUM	CALLOSUMS.	CALLOSAL.	[illegible]
	Nucleus caudatus (§ [illegible]).			Caudate body or nucleus.			
Caudatum.	Caudati.	Caudata	Caudatalis	CAUDATUM	CAUDATUMS.	CAUDATAL.	[illegible]
	Tractus transversus pedunculi (§ [illegible]).			Transverse band of cerebral peduncle.			
Cimbia	Cimbiæ	Cimbiæ	Cimbialis	CIMBIA	CIMBIAS.	CIMBIAL.	[illegible]
	Substantia cinerea (§ [illegible]).			Gray matter.			
Cinerea	Cinereæ		Cinerealis	CINEREA		CINEREAL.	[illegible]
	Corpus pineale (§ [illegible]).			Pineal body.			
Conarium	Conarii	Conaria	Conarialis	CONARIUM	CONARIUMS.	CONARIAL.	[illegible]
	Crus cerebri, *Pedunculus cerebri* (§§ [illegible]).			Cerebral crus.			
Crus	Cruris.	Crura.	Cruralis.	CRUS	CRURA	CRURAL.	[illegible]
	Thalamencephalon (§ [illegible]).			Tween-brain.			
Diencephalon	Diencephali.	Diencephala	Diencephalicus	DIENCEPHAL	DIENCEPHALS	DIENCEPHALIC.	[illegible]
	Ventriculus tertius (§ [illegible]).			Third ventricle (p. [illegible], § [illegible]).			
Diacœlia	Diacœliæ	Diacœliæ	Diacœlianus	DIACŒLE.	DIACŒLES.	DIACŒLIAN.	[illegible]
	Tela choroidea ventriculi tertii (§ [illegible]).			Membranous roof of third ventricle.			
Diatela	Diatelæ	Diatelæ	Diatelaris	DIATELA	DIATELAS	DIATELAR.	[illegible]
	Plexus choroideus ventriculi tertii (§ [illegible]).			Plexus of third ventricle.			
Diaplexus	Diaplexus	Diaplexus	Diaplexalis	DIAPLEXUS.	DIAPLEXUSES.	DIAPLEXAL.	[illegible]
	Dura mater (§ [illegible]).			Hard mother (§ [illegible]).			
Dura	Duræ	Duræ	Duralis	DURA	DURAS	DURAL.	[illegible]
	Corpus fimbriatum (§ [illegible]).			Fringed body.			
Fimbria	Fimbriæ	Fimbriæ	Fimbrialis	FIMBRIA.	FIMBRIAS.	FIMBRIAL.	[illegible]
	Corpora quadrigemina (§§ [illegible]).			[illegible]			
Geminum	Gemini	Gemina	Geminalis	GEMINUM.	GEMINUMS.	GEMINAL.	[illegible]
	Corpus geniculatum (§ [illegible]).			Geniculate body.			
Geniculum	Geniculi	Genicula	Genicularis	GENICULUM	GENICULUMS.	GENICULAR.	[illegible]
	Pedunculus conarii (§ [illegible]).			Peduncle of the pineal body (§ [illegible]).			
Habena	Habenæ	Habenæ	Habenalis	HABENA.	HABENAS.	HABENAL.	[illegible]
	Hippocampus major (§ [illegible]).			Ammon's horn (§ [illegible]).			
Hippocampus	Hippocampi.	Hippocampi.	Hippocampalis.	HIPPOCAMP.	HIPPOCAMPS.	HIPPOCAMPAL.	[illegible]
	Corpus pituitarium, Glandula pituitaria (§ [illegible]).			Pituitary body (§ [illegible]).			
Hypophysis	Hypophysis	Hypophyses	Hypophysealis	HYPOPHYSIS.	HYPOPHYSES.	HYPOPHYSEAL.	[illegible]
	Insula Reilii (§ [illegible]).			Island of Reil.			
Insula	Insulæ	Insulæ	Insularis	INSULA.	INSULAS.	INSULAR.	[illegible]
	Commissura mollis (§§ [illegible]).			Middle commissure (§§ [illegible]).			
Medicommissura.	Medicommissuræ.	Medicommissuræ	Medicommissuralis	MEDICOMMISSURE	MEDICOMMISSURES	MEDICOMMISSURAL.	[illegible]

Latin. (Polyonym in upper line.)				English. (Heteronym in upper line.)			French. German. Italian.
Nom. singular.	Genitive.	Nom. plural.	Adjective.	Singular.	Plural.	Adjective.	
Nucleus lenticularis s. Corpus lentiforme (§ 11).				Lens-shaped body.			
Lenticula.	Lenticulæ.	Lenticulæ.	Lenticularis.	LENTICULA.	LENTICULAS.	LENTICULAR.	*Lenticule.* *Lentikel.* *Lenticula.*
Foramen infundibuli (§ 48).				Infundibular orifice.			
Lura.	Luræ.	Luræ.	Luralis.	LURA.	LURAS.	LURAL.	*Lure.* *Lura.* *Lura.*
Foramen Magendie (§ 78).				Foramen of Magendie.

Gyrus frontalis inferior (§ 46, C, *e*).				Broca's, or lower frontal, convolution (§ 46, *e*).			
Subfrontalis.	Subfrontalis.	Subfrontales.	....	SUBFRONTAL G.	....	....	*Subfrontale.*[23] *Subfrontal.* *Subfrontale*
Lamina terminalis s. cinerea (§ 48).				Terminal lamina.			
Terma.	Termatos.	Termata.	Termaticus.	TERMA.	TERMAS.	TERMATIC.	*Terme.* *Term* (?) *Terma.*
Thalamus nervi optici (§ 40, C, *a*).				Optic thalamus.			
Thalamus.	Thalami.	Thalami.	Thalamicus	THALAMUS.	THALAMI.	THALAMIC.	*Thalame.* *Thalam.* *Talamo.*
Tuber cinereum (§ 78).				Gray protuberance.			
Torus.	Tori.	Tori.	Toralis.	TORUS.	TORI.	TORAL.	*Tore.* *Tor.* *Toro.*

---

[1] *Album* is given by Littré as a Latin word adopted into French, but *alb* would have a more Gallic sound.

[2] According to Heyse's "Worterbuch" *arachnoida* is the encephalic and *arachnoide* the ocular form.

[3] *Aule* may be regarded as the unrealized substantive of *aulique*.

[4] Although the French for *calcaire* appears to have been used already, only as if from *calcarius* (chalky), there seems to be no reason why the same word should not be derived from *calcar*, a spur.

[5] *Cimbia* may be derived from *κῦμα*, a small wave, through the Latin *cyma*. *Central* and its compounds are written by Guldberg, *zentral-furche, postzentral, präzentral*, etc.; some, therefore, may write *zimbia* and *zinerea* for *cimbia* and *cinerea*.

[6] *Conarion* is used by Chaussier and Paré, but the termination *um* occurs in the French Dictionary.

[7] The retention of the *K* is not only in accordance with the present tendency of German writers but justified by *enkephalgisch*, to which the writer's attention was called by Professor W. T. Hewett, who suggests also that the more numerous forms, *encephalgie, encephalalgie, encephalologie, encephalotomie* must have come through the French. The Germanization of the termination *alum* of *encephalum* by dropping the ultima is analagous to the reduction of *epithelium* and *diverticulum* to *epithel* and *divertikel*.

[8] The French *cœliaque* warrants *cœlie*.

[9] The Italian *celiaca* represents the Latin *cœliaca*, but the non retention of the diphthong throws upon the context the distinction between a tumor and an encephalic cavity; see § 66, K, note.

[10] The common French form is *jumel*, but there seems to be no serious objection to *géminé*.

[11] *Genicoli* was found in the plural only, but the singular is analogous to the Latin *geminum*.

[12] *Habena* is used by Inzani, and *hippocampo* by Giacomini; several other Italian words now retain the initial aspirate.

[13] The writer has withdrawn *hypocampa* (*N. Y. Med. Jour.*, March 28, 1885, p. 356, note), in accordance with Spitzka's suggestion that the frequent occurrence of *hypocampe* in Vicq d'Azyr was a typographical error.

[14] *Hypophyse* occurs in German compounds used by Schwalbe and others.

[15] The French *ile* is the result of repeated contractions; the adjective *insulaire* may be regarded as derived from an unrealized *insule*; § 42.

[16] Although the usual Italian paronym of *insula* is *isola*, Giacomini's phrases *l'insula, dell'insula*, and *all'insula* seem to indicate the adoption of the Latin word unchanged.

[17] *Medicommissure* (rather than *mediocommissure*) seems justified by *medifourche* and *mediastin*.

[18] The ordinary Galloparonym of *myelon* is *mœlle*, but *myél* seems warranted by *myélite*, and by *myélaxe* and *myélencéphale*.

[19] No German compound of *myel* has been found by the writer, but such terms as *myasthenie* and *myologisch* may be sufficient precedents for retaining the Y.

[20] *Neuraxe* is justified by *Neurorohr* and *Neuralgtaschicht*, and by *Erdaxe* and *Himmelaxe*.

[21] The prefix *post* is adopted into the French *postpéduncule*, and *postabdomen*.

[22] *Brachiale* seems to warrant *brachio*, rather than *braccio*.

[23] *Subfrontal* and other compounds of *sub* have precedents in *subalterne, substance*.

[24] *Diatela* and *diaplexus* are practically contractions of *diencephalic tela*, and *plexus*, the prefix having the force of the entire segmental name; compare *aldehyde*, § 48.

[25] *Pituitary body* is objectionable, not as based upon an error respecting the source of the nasal mucus, but because it is a polyonym, § 46.

[26] With several of these terms a second English paronym would be legitimate, *e.g.*, *diacœlia, diatele, diaplex, hippocampus, lenticle, myelon, olive*; see § 40; *lingula* and *lingule* would both be good English words.

ciated with the ordinals, *third*, *fourth*, and *fifth*, which are not only unhelpful but positively misleading.

Had it chanced that the several encephalic cavities had been enumerated like the encephalic vesicles, from first to fifth, or even (assuming that the entire oblongata, cerebellum, and pons constitute a single segment) from first to fourth, it is probable that these numerical designations would be forever left undisturbed, notwithstanding they would have had no obvious correlation with the segmental names, and would have been [illegible] and incapable of inflection.

But the current ventricular designations are as meaningless and misleading as if the cervical vertebræ were named as follows: *First* and *second* are applied to the lateral masses ("wings") of the atlas and the neural, connecting part ignored; the axis (second) is then called "third;" the actual third (supposing it to be small in the adult) is called a "process" or "isthmus;" the fourth and fifth, being fused, are called "fourth;" finally, the hyoid bone is named "fifth" because, although in no sense a vertebra or originally part of the series, it is at least a bone and must be designated in some way.

Were it possible or desirable to exclude from the minds of students at the present day all knowledge of development and comparative anatomy, teachers might, with some hope of success, continue to enumerate the encephalic cavities as *first*, *third*, etc., "ventricles;" but as it is, they are compelled, in the interests of logic and even common sense, to stop and explain that there is no true relation whatsoever between these antiquated, anthropotomical ventricular designations and the facts of embryology and comparative anatomy which, sooner or later, would be presented.

Under these circumstances, is it worth while to continue the solemn farce of affirming a thing and denying it in the same breath? Is it not actually easier to discard the old names once and for all, as having indeed scarcely a historical value, and simply combine the fairly well-established segmental prefixes with the single short word, which was indeed employed by the Greeks in the very sense now independently revived?

§ 80. In favor of *cœle* (Lat. *cœlia*, from Gr. κοιλία), in place of *ventricle* for the encephalic cavities, may be urged the following arguments, some direct, others indirect:

1. It is a word of Greek origin and thus regularly compatible with the characteristic prefixes already employed in the segmental names; mesocœle, epicœle, etc., are terms both correct and euphonious.

2. It has strictly classical authority for use in the sense of an encephalic cavity.*

3. It has been at recent times independently proposed by two anatomists, teachers as well as investigators.†

4. It has been adopted, more or less completely, by three distinguished neurologists: H. F. Osborn, E. C. Spitzka, and R. Ramsay Wright.‡

Assuming that *cœle* is gradually to replace *ventricle* as a general term for the encephalic cavities,* how shall the several divisions be distinguished? After carefully considering his own propositions and those of T. J. Parker, the writer concludes that the original and natural plan is the best, viz., to simply transfer to *cœle* the characteristic Greek prefixes by which the five commonly accepted segments are designated (see pp. 114 and 125 of this volume); this gives a series of terms which may be tabulated as follows:

Segments.	Cavities.	Ordinary designations.
Prosencephal	Procœle	[illegible]
Diencephal	Diacœle	[illegible]
Mesencephal	Mesocœle	[illegible]
Epencephal	Epicœle	[illegible]
Metencephal	Metacœle	[illegible]
Myel	Myelocœle	[illegible]

[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]			[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]		[illegible]	[illegible]
[illegible]			

§ 81. **Terms Indicating Relations of Resemblance or Identity between Organs.**—In § 1, B, C, and D, occur the phrases *similar to*, *corresponds to*, and *represented by*. In like manner it might be said that the hand of man is *represented* by the paw of the cat, but that the spots on the peacock's tail feathers are *similar* to eyes. When the resemblance is a superficial, or merely functional one, and does not involve any real, structural unity, the parts are said to be *analogous*, and the relation is one of *analogy*; but when, with or without such resemblance, the parts agree in structure, in connections, and in mode of development, they are said to be *homologous*, and their relation is one of *homology*. There are several kinds and degrees of homology; for example, the manus and pes are not only similar in form and therefore analogous, but also nearly identical in structure, and therefore homologous; but this is like the homology between the right and left hands, rather than the relation of parts of two individuals. For further discussion and definitions of these and kindred terms, see works upon Comparative Anatomy, especially Owen (1866), and Gegenbaur (1878); also Geddes' article "Morphology," *Encyclopædia Britannica*, and the writer's papers "On Morphology and Teratology," *Bost. Soc. Nat. Hist.*, *Memoirs*, I., [illegible], and "Intermembral Homologies," *Bost. Soc. Nat. Hist.*, *Proceedings*, xiv., pp. 154–242.

§ 82. **Concluding Remark.**—Aside from prejudice and lack of practical direction as to removing, preserving, and examining the organ, there is but one valid reason why every child of ten years should not have almost and somewhat extended personal acquaintance with the gross anatomy of the mammalian brain; that obstacle is the enormous and unmanageable accumulation of objectionable names under which the parts are literally buried.

The anatomists of to-day have an opportunity of providing for the future while cherishing the past; of benefiting posterity without neglecting ancestors; of lightening the burdens of generations to come, while recognizing the value of what was done by the anatomical fathers; of erecting a terminological monument in which the best of what has been is cemented by their own labors.*

TOPONYMY.

§ 83. For the definition of toponymy as referring to descriptive terms, see § 1. The present division of the article consists mainly of an enumeration of toponyms, and of their equivalents and synonyms as used by various writers. The principal difficulties arise from the not unnatural transfer of terms applicable only to the erect human body, to quadrupeds or other vertebrates having a horizontal attitude. As well remarked by Wright, "much confusion has been caused by importing into comparative anatomy terms employed in human anatomy."

Terms of description based upon the relation of an animal to the earth, *e.g.*, horizontal, vertical, longitudinal, etc., constitute an *extrinsic toponymy;* the *intrinsic toponymy* advocated and employed by the writers since 1880 includes only terms referring to the *regions of the organism, e.g., dorsal, mesal, caudal, ventrad*, etc.

§ 84. *Afferent* and *Efferent.*—Fr., afferent, efferent; Ger., afferent and efferent. These words, as applied to the nervous system, indicate the supposed direction taken by the nervous impulse; an afferent nerve conveys impulses toward the nervous centre, it is, therefore, equivalent to a sensory or a centripetal nerve, and it is said to extend *centrad.* An efferent nerve is one conveying impulses from the central nervous system. It is therefore equivalent to a centrifugal, motor, or secretory nerve, and the nerve is said to extend *peripherad.*

As applied to the lymphatic vessels, *afferent* indicates a vessel approaching a lymphatic gland, and *efferent* one leaving a lymphatic gland; both vessels extend centrad. (See article Lymphatic System, Vol. VIII., and under *central* and *peripheral.*)

Applied to blood-vessels, *afferent* indicates an artery, that is, a vessel extending peripherad to an organ, while *efferent* indicates a vein, that is, a vessel leaving an organ and extending centrad. (Klein, "Elements of Histology," p. 92.)

§ 85. *Caudal*, see under *Cephalic* and Fig. 5086, A.

Central and *peripheral* (adj.).

Central (adj.), centrad (adv.); Lat., centralis; Fr., central; Ger., central, centralwärts. Syn.: Centric, cardiac, proximal, afferent, centrally, centralward, heartward.

Peripheral (adj.), peripherad (adv.); Fr., périphérique; Ger., peripherisch, peripheralwärts. Syn.: peripheric.

Central and *centrad* designate position in, or direction toward, a central organ or system; while *peripheral* and *peripherad* designate position or direction away from the central organ or system.

Remarks: These terms are used occasionally in anatomy in their geometrical sense, referring for example to the centre or periphery of the eye; but in their proper technical sense they refer to the brain and myel (central nervous system or neuraxis), and the nerves (peripheral nervous system), or to the heart (centre of the vascular system) and the blood-vessels or lymphatics (peripheral part of the vascular system). In their purely anatomical sense these words apply to actual nearness or remoteness from the centre, as when it is said that a nerve, as the vagus, is cut and the central end stimulated, the end next the central nervous system or still in connection with it is intended, while the peripheral end is the one separated from the central nervous system, but in connection with the heart, lungs, etc. So also, in speaking of incisions in blood-vessels or lymphatics, the central side of the incision in either artery or vein is that nearest to the heart, while the peripheral side of the cut is away from the heart. Used in a physiological sense, the words indicate the direction taken by the contents of a vessel, as the veins extend centrad, the arteries peripherad; or the direction of the impulse of a nerve, the sensory nerves extend centrad and the motor nerves peripherad.

Equivalents. *Cardiac* is sometimes used for central (Allen). *Proximal* and *distal* are also used instead of central and peripheral (Chapman, 309; Foster, 222; Landois and Stirling, 117, 163). *Afferent* is equivalent to central, and *efferent* to peripheral. As used with the lymphatic vessels, both the afferent and efferent vessels of a gland extend centrad (see article Lymphatics, REFERENCE HANDBOOK, Vol. VIII.). *Above* is also used for central, and *below* for peripheral, in speaking of the valves in the veins and lymphatics (Gegenbaur (1883), 84; REFERENCE HANDBOOK, I., 591); with reference to the teeth, *central* is used to designate those next the meson, as the central incisors (REFERENCE HANDBOOK, VI., 741). Cf. remarks under *proximal* and *distal.*

§ 86. *Cephalic* and *Caudal.*—Cephalic (adj.); cephalad (adv.). Lat., cephalicus; Fr., céphalique; Ger., cephalwärts. Syn. of adverbial form: Cephalically, cephalward, headward.

Caudal (adj.), caudad (adv.). Lat., caudalis; Fr., caudal; Ger., caudalwärts. Syn. of the adverbial form: Caudally, caudalward, tailward.

Cephalic and *cephalad* are used to designate position in, or direction toward, the head end of the body. *Caudal* and *caudad* are used to designate position in, or direction toward, the tail end of the body (Fig. 5086, A). *Cephalic* and *caudal* are used with reference to the two extremities or ends of the body in exactly the same way that *right* and *left* (*dextral* and *sinistral*, with the adverbial forms) are used with reference to the sides of the body. (Comstock; W. and G.; Quain, i., 6, 128; Ranney, 35; Parker and Bellamy, 5, 16; REFERENCE HANDBOOK, I., 633; III., 1, 185, 193; VI., 209; VIII., 107–194; also in *Journal of Nervous and Mental Diseases*, in many articles; also in "Proceedings of the American Philosophical

---

* The new edition of Leidy's "Human Anatomy," published after the completion of this article, represents a distinct and considerable advance over all other treatises in respect to nomenclature, particularly that of the brain. In the following extract from the preface the interpolated numbers refer to commentaries by the writer: "As a rule, one name for an organ or part is used,[1] and that one selected which is simplest and most expressive of its character.[2] The name, also, as far as may be permitted, is rendered into English.[3] Many phrases in common use as names[4] have been curtailed of what have appeared unnecessary portions,[5] and sometimes the adjective portion of the phrase has been retained, in preference to the substantive portion,[6] where, for various reasons, it has seemed more appropriate. Where names of persons are applied to parts, they are generally avoided,[7] and others, in all respects better adapted to the purpose, are used. Some further attempts have been made to improve the nomenclature,[8] and it is hoped that the experiment may prove successful in helping the student in acquiring a knowledge of the subject.[9] While the author regards with favor the proposed improvement in anatomical nomenclature of able authorities,[10] he has not followed them completely, in apprehension that, with the prevalent nomenclature, a radical change[11] would confuse rather than facilitate the study of anatomy." It will be seen that, to employ the more technical phraseology of the present article, (1) Pœcilonymy is avoided (§ 72); (2) in the choice between names, mere etymological appropriateness is subordinated to availability (§ 20); (3) the Latin words are commonly paronymized (§ 61) rather than translated into heteronyms (§ 62); (4) certain so-called names are rightly regarded as really descriptive phrases (§ 60), and (5) are reduced to mononyms (§ 25) when practicable; (6) when the adjective element of a polyonym is more distinctive than the substantive, the latter is dropped and the former used substantively; (7) eponyms are regarded as undesirable (§ 59); commonly the personal genitive or adjective is simply dropped, leaving, *e.g.*, *torcular* for *torcular Herophili*, *pons* for *pons Varolii;* but *sinus of Valsalva* is replaced by *valvular sinus;* (8) the other modifications consist mainly in converting polyonyms to mononyms by the substitution of prefixes for adjectives (§ 56); (9) Dr. Leidy has kept constantly in mind the needs of the student, who, in the effort to familiarize himself with the parts themselves, should be embarrassed as little as possible by their names; (10) he favors the eventual accomplishment of still further improvements, but draws the line now at new or unfamiliar terms, some of which, however, are given as synonyms, *e.g.*, *terma* for *lamina cinerea*, *porta* for *foramen Monroi*, *pseudocœle* for *fifth ventricle.* Notwithstanding these limitations, it may be said that in this latest treatise on human anatomy, by one alike eminent as an investigator, successful as a teacher, and conservative in his tendencies, there are embodied the more essential features of the system which is set forth in the organonymic division of the present article.

Society," and in the "Proceedings and Transactions of the Royal Society" (Gegenbaur, Fig. 106, pp. 115, 130).

As applied to the limbs, *cephalic* indicates the radial or thumb side of the arm, when the hand is semisupinated, *i.e.*, with the radius and ulna parallel, and the tibial or great toe side of the leg. *Caudal* refers to the ulnar or little finger side of the arm, the fibular or little toe side of the leg (Fig. 5086) (W. and G., 26).

Remarks.—*Cephalic* is frequently used to designate what pertains to the head, and *caudal* what pertains to the tail; as *caudal vertebræ*, that is, the vertebræ of the tail; as *cephalic skeleton*, the skeleton of the head or skull.

Equivalents.—*Cephalic* and *Cephalad* (H. A.) superior, superiorly, above, upper, upward; (C. A. and Emb.) anterior, anteriorly, front, forward, before, and as in man.

Caudal and caudad (H. A.).—Inferior, inferiorly, down, below, lower, downward; (C. A. and Emb.) posterior, posteriorly, behind, hinder, back, backward, and as in man.*

In the arms *cephalic* is outside and *caudal* inside; in the leg *cephalic* is inside and *caudal* outside, or cephalic is pre-axial and caudal post-axial in both arm and leg (W. and G., 25, 26).

§ 87. *Dextral and sinistral* (right and left).—Dextral (adj.), dextrad (adv.), sinistral (adj.), sinistrad (adv.). These terms or their vernacular equivalents are in use everywhere and have the same significance in human and comparative anatomy and in every day life. From the universality of the use of these terms and their ready comprehensibility by everybody they serve as models for the designation of the other four aspects of the body, as was clearly pointed out by Comstock ("Laboratory Guide to Entomology"). These terms are also used in a very comprehensive sense, as when in directing a person he is told to turn to the right or to the left; hence when an organ or part is said to face or extend cephalad or dorsad the meaning should be considered exactly as when it is said that a part faces or extends to the right or the left, that is, *a general direction should be understood and not some specific point on the body*. If the terms of direction and position are used in the general sense that *right* and *left* are, to indicate relative but not absolute position or direction, then the apparent absurdity of speaking of the cephalic end of the tail, vanishes.

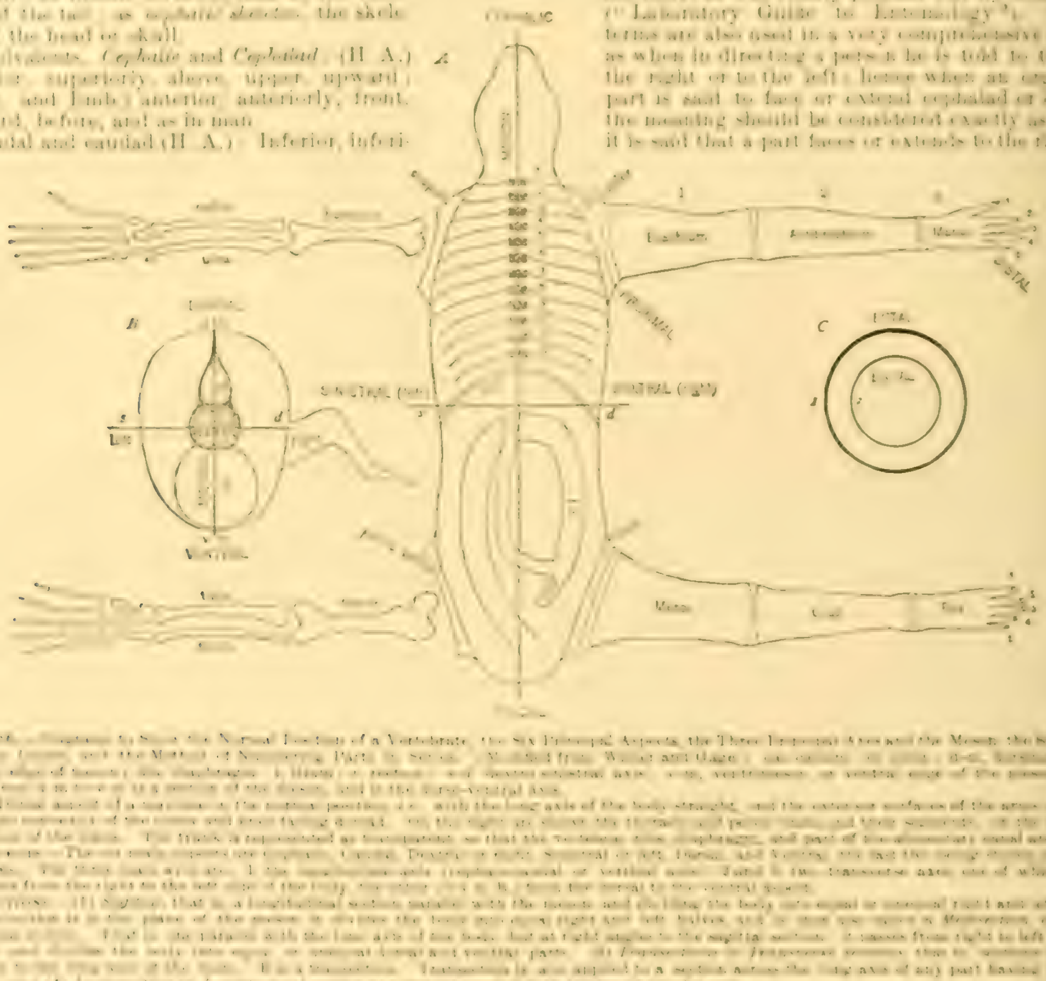

FIG. 5086.—Diagrams to Show the Normal Position of a Vertebrate, the Six Principal Aspects, the Three Principal Axes and the Meson, the Segments of the Trunk, and the Method of Numbering Parts in Series. (Modified from Wilder and Gage.) [illegible]

A. Dorsal aspect of a vertebrate in the normal position, *i.e.*, with the long axis of the body straight, and the extensor surfaces of the arms and legs [illegible]

Aspects.—The six main aspects are Cephalic, Caudal, Dextral or right, Sinistral or left, Dorsal, and Ventral [illegible]

[illegible]

B. [illegible]

C. Diagram to show the method of naming and numbering parts at different distances from the surface. [illegible]

Distal, see under Proximal and Fig. 5086, A.

Dorsimeson, the dorsal edge of the meson (Fig. 5086, B, d. m.); see also under Meson.

§ 88. *Dorsal and Ventral.*—Dorsal (adj.), dorsad (adv.), Lat., dorsalis; Fr., dorsal; Ger., dorsal, dorsalwärts. Syn., tergal, neurad, dorsally, dorsalward.

---

* Whenever it is stated in this [illegible] (C. A. and Emb.) [illegible]

Ventral (adj.), ventrad (adv.); Lat., ventralis; Fr., ventral; Ger., ventral, ventralwärts; Syn., hæmal, hæmad, visceral, viscerad, ventrally, ventralward.

Dorsal and dorsad are used to indicate position in, or direction toward the back, that is the part containing the central nervous system (Fig. 5086, B), while ventral and ventrad are similarly used to designate position in or direction toward the belly side of the body, that is, the side containing the vascular and digestive systems (Fig. 5086, B, H). These terms should be used in the same general way as *right* and *left* (*q. v.*) are.

Reference Handbook, I., 634–635; III., 178–193; V., 774, 776; VI., 380, 592; VIII., 107–194; Barclay; W. and G.; Comstock; Owen (1868), i., 2, 473; Allen, 21, 201; Gray, 846; Parker, 48, 127; Bernard, 252; Quain, i., 3, 5, 129; ii., 318; Huxley and Martin, 31, 37; Howell, 7, 36, 35; Marshall and Hurst, 259; Parker, 222, 307; Morrell, 203; Rolleston and Jackson, 13; Gegenbaur (1883), 103, 114.

With the limbs, *dorsal* refers to the dorsum of the hand and foot and to the extensor side of both arm and leg; the convexity of the knee and the elbow point dorsad when they are in the normal position (Fig. 5086, A and B). *Ventral* refers to the palm and the sole, and to the flexor side of the arm and leg. In Fig. 5086, A, it is the surface not seen, in B it is the concavity of the elbow or knee.

Equivalents: Dorsal and dorsad; (H. A.) posterior, posteriorly, back, backward; (C. A. and Emb.) superior, superiorly, upper, upward, also as in man.

Ventral and ventrad; (H. A.) anterior, anteriorly, front, forward; (C. A. and Emb.) inferior, inferiorly, lower, down, downward, also as in human anatomy.

Remarks: Dorsal and ventral have some special uses, for example the ectal aspect of the human scapula and ilium is said to be dorsal, while the ental aspect is said to be ventral (Gegenbaur (1883), 261). Dorsal has retained its original and more specific use for designating the thoracic vertebræ, and for designating parts situated in what is considered a dorsum, as the dorsal artery of the penis; its use is, however, becoming generalized like right or left, and with the tongue, foot and hand the general and specific uses coincide. In the limbs, dorsal is the back of the arm, and the front of the leg, while ventral is the back of the leg and the front of the arm.*

§ 89. *Ectal and Ental.*—Ectal (adj.), ectad (adv.). Greek, ἐκτός; Lat., ectalis; Fr., ectal; Ger., ec- or ektal, ectalwärts; Syn., of the adverbial form ectally, ectalward. Ental (adj.), entad (adv.); Greek, ἐντός; Lat., entalis; Fr., ental; Ger., ental, entalwärts; Syn., entally, entalward. *Ectal* and *ectad* indicate position on or direction toward an aspect or surface farther from an actual or supposed centre than some other part with which it is compared (Fig. 5086, C). *Ental* and *entad* indicate a position or direction comparatively nearer a real or supposed centre, or farther from the periphery than the ectal or starting-point (Fig. 5086, C), as the ectal or free surface of the skin, the ental or subcutaneous or attached surface, the ectal or subcutaneous surface of a rib, the ental or pleural surface of the same (Wilder, "Science," vol. ii. (1881), pp. 122–22, 126, 133–138; W. and G., 26–27; Reference Handbook, VIII., 107–194).

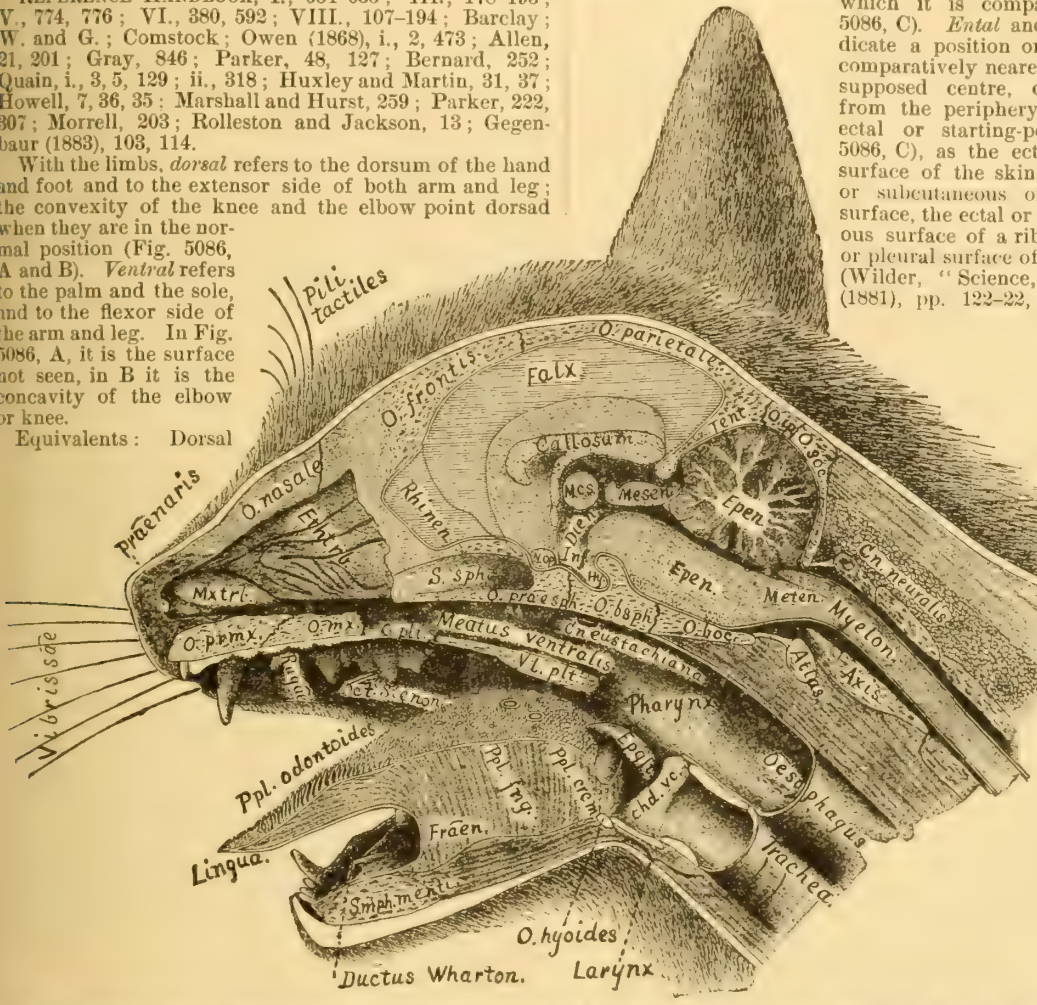

Fig. 5087.—Mesal Aspect of the Right Half of a Cat's Head for Comparison with a Similar View of a Human Head (Fig. 4684). (Wilder and Gage.) This figure is introduced to show that in many of the lower animals the mouth and nose are nearly in line with the body axis, while in man (Fig. 4684) they are nearly at right angles to the body axis. From this it results that in the head, the terms front, back, anterior, posterior, upper, and lower as used in human and comparative anatomy, agree in significance, although in the rest of the body the terms indicate position and direction differing by ninety degrees.

Remarks: These terms were introduced by Wilder in 1881, to take the place of outer, inner, external, internal, superficial, and profound. They conform readily to paronymyzation, definiteness, and general applicability to human and comparative anatomy. Note the recent embryological term, *ectental line*.

Equivalents: External, internal; outer, inner; superficial and profound, or deep.

Ental, see under *ectal*, and Fig. 5086, C.

---

* Ventral is commonly applied to the fins of fishes representing the legs, but *pelvic* would be less ambiguous and better correlated with *pectoral*.

Lateral, see under *mesal*; also Fig. 5086, A and B.

§ 90. *Mesal* and *Lateral*.—Mesal (adj.), mesad (adv.); Lat. mesalis; Fr. mésal; Ger. mesal, mesalwärts, medianwärts; Syn., mesally, mesalward, mesial, mesiad, medial, mesialward, medius, medial—position at or direction toward the meson (Fig. 5086, A and B). Lateral (adj.), laterad (adv.); Lat. lateralis; Fr. latéral; Ger. lateral, seitenwärts—position or direction away from the meson on either side of the body.

Allen, 20; Barclay; Comstock; Darling and Ranney, 10, 21; Gegenbaur (1878), 41; Gray, 145, 848; Henle, I., 10; Krause, ii., 2; Parker and Bellamy, 3, 5, 16, 230, 254; Quain, i., 3; ii., 339, 910; Reference Handbook, I., 258, 638; VIII., 107, 194; Rolleston and Jackson, 14; Sappey, i., 64; W. and G.; Parker, "Proceedings Royal Society," vol. xlix., p. 395; Stowell, "Proceedings American Philosophical Society," 1881, 1886, 1888.

Remarks: Mesal and lateral are both general terms, as there are two sides to the body and correspondingly two faces to the meson. The terms indicate position and direction applicable to both symmetrical halves. For example, if a structure is said to extend mesad, it would not be known whether it was extending from the right side of the body toward the meson, or from the left side; so with lateral. It simply means toward the right or toward the left. Usually the context gives the specific information. In some cases it is desirable to use dextral or sinistral instead of lateral in order to be perfectly definite.

These terms are not properly applicable to the limbs, for when the limbs are in the normal position, *i.e.*, a position in which homologous parts may be readily compared in man and animals, and also in the arms and legs, the mesal aspect is proximal and the lateral aspect distal (see Fig. 5086). As used in both human and comparative anatomy, the median aspect of a limb is the one in the natural position of the limb which faces mesad and the lateral aspect the one facing laterad. From this it follows that the ulnar side is median, or inner, with the arm, and the radial side lateral, or outer, while in the leg the tibial side is median or inner and the fibular side lateral or outer.

Equivalents: Mesal, internal, internally, inward, inner. Lateral, external, externally, outer, outward.

§ 91. *Meson*.—Synonyms and equivalents: Mesian (Barclay, 121); mesial plane (Quain, i., 5); median plane (Darling and Ranney, 17); median vertical plane or vertical median plane (Huxley (1873), 30; Gegenbaur (1878), 416). Fr., plan médian (Morel and Duval, 37); plan vertical antero-postérieur, plan médian (Sappey, i., 13). Ger., medianebene (Henle, i., 7; Hoffmann, i., 5); mittelebene (Krause, ii., 2). Besides these proper terms, mesial, middle or median line, is often used for the meson or median plane (Flower, 72, 10; Foster and Langley, 2; Gegenbaur (1878), 442; Gegenbaur (1883), 7; Huxley and Martin, 8; Reference Handbook, II., 179, 305; III., 172; V., 538; VI., 632; Rolleston and Jackson, 3). The meson, mesal or median plane is an imaginary longitudinal plane extending from the dorsal surface of the body to the ventral surface and dividing the body into right and left symmetrical halves (Fig. 5086). The term meson was introduced into anatomical literature by Wilder (Science, ii., 1881; W. and G., 25).

Ventrimeson and *Dorsimeson*.—These terms indicate the ventral and the dorsal edges of the meson (Fig. 5086, B, v m, d m).

Equivalents: Dorsal and ventral mid-line (Howell, 15, 30); dorsal and ventral middle line (Huxley and Martin, 41); mid-dorsal and mid-ventral line (Parker, 99, 115); median dorsal or ventral line (Reference Handbook, III., 177; V., 248). Fr., ligne médiane du ventre, du dos (Milne-Edwards, iv., 474, 476); ligne médiane postérieure et antérieure (Sappey, i., 13). Ger., Medianlinie der ventralseite, der dorsalseite (Claus, "Zoologie," 633).

Ventrimesal, ventrimesad, dorsimesal, dorsimesad.—These terms indicate direction or position in or toward the edge of the meson indicated by first part of the word (W. and G., 25).

Peripheral, see under *Central*.

§ 92. *Proximal* and *Distal*.—Proximal (adj.), proximad (adv.); Fr. proximal; Ger. proximalwärts.

Distal (adj.), distad (adv.); Fr. distal; Ger., distal, distalwärts.

Proximal indicates position at or direction toward the attached extremity of an appendage, or at some point nearer the attached extremity than some other point with which it is compared. For example, the shoulder is proximal of the elbow, but the elbow is proximal of the wrist, etc. (Fig. 5086, A). The free extremity of the organ is often called the distal when the attached end is the proximal end. Where an object is attached at both ends the more important is usually called proximal, as the vertebral attachment of a rib is called the proximal and the sternal attachment distal.

Distal and *distad* indicate direction or position in a part or appendage away from the attached or proximal end.

Barclay, 124; Ranney; Darling and Ranney, 141; Flower, 241; Gray, 1, 278; Gegenbaur (1883), 175, 287; Huxley, 19, 29, 31; Morel, 29; Owen (1868), i., 408; Quain, i., 6; ii., 863; Parker, 101, 104, 53; Parker and Bellamy, 277; Reference Handbook, I., 310; II., 827; III., 188, 209, 486; VI., 596; W. & G.

Remarks: As stated under central and peripheral, proximal is sometimes used for central and distal for peripheral.

Right, see under *Dextral*.

Sinistral, see under *Dextral*; also Fig. 5086.

Ventral, see under *Dorsal*; also Fig. 5086, B.

Ventrimeson, *Ventrimesal*, *Ventrimesad*, see under *Meson*, and Fig. 5086, B.

§ 93. In using these terms for the designation of position, or of lines, or for the indication of direct and oblique lines they may be employed as are the more common expressions, for example, the scapula of man is at the dorsal and the cephalic (upper and back) part of the thorax. A line drawn from the xiphisternum to the kidney would extend dorsad, caudad, and laterad (backward, downward, and outward). These terms may also be combined as are the words designating the points of the compass, and instead of saying the cephalic and the dorsal, the two words are combined thus, cephalodorsal; and so in the second example the line extending from the xiphisternum to the kidney is a dorso-caudo-lateral line or it extends dorso-caudo-laterad, etc.

§ 94. Numbering the Parts of a Series.—The general rule is to commence with the most cephalic, *e.g.*, the first rib is the most cephalic (Fig. 5086); 2, the most proximal is first, as the first segment of the thoracic limb is the brachium (Fig. 5086); 3, the most distal of a number of layers is first, as the first layer of muscles is next the skin; with the germinal layers the ectoderm is first. With blood vessels and nerves there is a tendency to number from the origin so that the first part of the aorta is the most central, that is the arch, but the first part of the postcava is that formed by the two iliac veins, etc.

In the limbs the most proximal of a series is first, as the first row of carpals is next the radius and ulna, but in numbering the individual elements the first is the most preaxial or cephalic, that is the scaphoid.

In numbering the fingers and toes, the thumb and great toe are first; they are most cephalic if in a natural position (Fig. 5086).

In numbering the teeth the one nearest the meson, *i.e.*, the symphysis, is number one; this is also said to be the proximal one while the last molar is the distal one (Gray, 841; Quain, ii., 847; Reference Handbook, VI., article Teeth).*

The above rules are almost universally adhered to and deviation is due rather to lack of knowledge than to design.

BIBLIOGRAPHY

In the following list the titles are arranged alphabetically. The number following the author's name is the year of publication of the whole work or of the last volume. In the text the dates are omitted [illegible] excepting for special reasons or to distinguish between two or more publications by the same author. The frequent references to the joint work of the writers of this article, Anatomical Technology, are by their initials "W. and G." In the Bibliography of that volume may be found the titles of their terminological papers up to 1886. Certain publications by them and others are named in the text of this article.

THIGH. APPLIED ANATOMY.—The thigh comprises a section of the lower extremity, bounded above and posteriorly by the gluteo-femoral crease, laterally and in front, by an imaginary continuation of this line around the circumference of the limb.

The artificial antero-lateral upper limit of the anatomical thigh is placed 12 to 15 ctm. below Poupart's ligament. Above the thigh are, behind and externally, the gluteal region and hip, in front, the subinguinal region.

Internally, the converging lines of Poupart's ligament and the upper limit of the thigh meet at the outer margin of the perineal and ischio-rectal spaces.

The lower limit of the thigh is formed by the upper boundary of the next adjoining regions, namely, the *popliteal space* behind and the *knee* in front. The capsular ligament of the knee-joint in the extended position of the thigh reaches from 3 to 8 ctm. above the upper border of the patella, and forms the lower boundary of the thigh at this point.

The general shape of the thigh is that of a cone. A grooved depression or furrow extends along the inner aspect of the limb, beginning above in the subinguinal region, and corresponding to the interval between the adductor group and the vastus internus. Along this depression course the large vessels of the lower extremity, and incisions for ligature of the femoral artery are made in this situation.

An external depression, extending nearly vertically on the outer aspect of the thigh, and more pronounced in thin subjects, marks the interval between the vastus externus and the biceps, and corresponds to the external intermuscular septum of the deep fascia (see Fascia lata, p. 538). This lateral groove serves to divide the thigh on its surface into an anterior and a posterior segment. Internally the dividing line is not so well marked. The prominence formed by the adductor gracilis muscle may be taken as such; but for practical purposes it is more desirable to include in the anterior division the entire adductor group, on account of their intimate relation to important vessels and nerves which belong to the anterior part of the thigh.

A. ANTERIOR REGION OF THIGH.—*Integument and Superficial Fascia.*—The integument of the anterior region is firm and dense, extremely retractile on transverse division, and easily separated from the deep fascia. In circular amputation of the thigh, these anatomical characteristics are of considerable aid, enabling the operator to dispense with a specially prepared and reflected cylinder of integument.

The subcutaneous areolar tissue and fat form a layer of varying thickness, usually much more developed in the female. It forms a continuous investment for the whole of the lower extremity, and can usually be divided into two or more layers, between which are situated the superficial vessels and nerves, and in the inguinal region the superficial inguinal lymphatic glands. The superficial layer is continuous above with the superficial layer of the abdominal fascia; the deep layer of the abdominal fascia becoming adherent to the fascia lata of the thigh, about three ctm. below Poupart's ligament.

Superficial Veins.—The most important is the v. saphena magna—the great or internal saphenous vein with its tributaries. This vein, ascending from the foot and leg, passes behind the internal condyle of the femur, and then along the median aspect of the thigh, corresponding pretty accurately in direction to the inner border of the sartorius muscle—close behind which it is situated,—to open into the femoral vein through the saphenous opening of the fascia lata, about one and a half inch below Poupart's ligament. A second large cutaneous vein, draining the antero-lateral regions of the thigh, joins the v. saphena magna near its termination. The veins from the inner and back part of the thigh either open into the same vessel singly, as a number of smaller branches, or unite to form a third large subcutaneous vein, which joins the saphena magna near the falciform opening. The veins corresponding to the superficial branches of the femoral artery, viz., the vv. pudendæ externæ, epigastrica superficialis, circumflexa ilii superficialis, open either into the v. saphena magna near the saphenous opening, or pass through this opening to terminate in the v. cruralis.

At times the superficial dorsal veins of the penis empty all, or in part, into the saphena instead of into the deep dorsal vein of the penis.

Frequently the saphena is double; the two trunks uniting near the saphenous opening to form a common vessel which receives the tributaries above mentioned.

As the vein usually runs somewhat behind the inner margin of the sartorius, it is readily avoided in operations for ligature of the femoral artery. If exposed by the first incision, which should simply divide the integument, the vein can be drawn to the inner side.

The *superficial lymphatic vessels* for the most part course along the inner aspect of the thigh with the saphena magna. A few run along the posterior and external aspect. All empty into the superficial inguinal glands (gl. crurales).

The superficial nerves are derived from the lumbar plexus.

1. *Ilio-inguinal*, derived from first lumbar nerve, after emerging from the external abdominal ring, or perforating the external pillar of the ring, arrives at the outer side of the spermatic cord, where it divides into its terminal branches. The more numerous (internal or transverse) branches pass to the hypogastric region. The external or descending branch is distributed to the integument of the inner inguinal region, and the upper and inner aspect of the thigh. Those thigh branches of the ilio-inguinal can be replaced by the genital branch of the genito-crural (n. spermaticus externus), which communicates with the ilio-inguinal at the external abdominal ring.

2. The external or crural branch of the *genito-crural nerve* (n. lumbo-inguinalis) is derived from the second lumbar nerve, and passes beneath Poupart's ligament to the outer side of the femoral vessels to be distributed to the integument of the anterior aspect of the thigh. A few branches become cutaneous by passing through the saphenous opening to the outer side of the saphena vein. Others perforate the fascia lata external to the saphenous opening. Their distribution is somewhat variable, as branches from the external cutaneous nerve, and cutaneous branches from the anterior crural (especially the middle cutaneous) can replace them. Usually they do not extend beyond the middle of the anterior aspect of the thigh.

3. *The external cutaneous nerve* (n. cutaneus femoris lateralis) is derived from the second loop of the lumbar plexus, receiving filaments from the second and third lumbar nerves. It passes below and in front of the anterior superior iliac spine to the thigh, lying in front of the deep circumflex iliac artery beneath Poupart's ligament, and then in front of the tendinous origin of the sartorius muscle. In the thigh the nerve lies in a canal in the fascia lata, and divides into an anterior or descending main branch, and a posterior branch, which perforate the fascia separately to become cutaneous.

a. The *posterior branch* (ramus glutaeus) passes obliquely over the tensor vaginae femoris to the integument of the posterior part of the thigh and of the lower gluteal region.

b. The *anterior branch* (ramus femoralis) is the direct continuation of the main nerve. Perforating the fascia lata 3 to 5 cm. below Poupart's ligament, the nerve becomes cutaneous and passes along the anterior surface of the vastus externus to the outer aspect of the knee. Lateral branches variable in number and size are given off, especially on the outer side. They pass obliquely outward and backward.

At times (according to Schmidt twice in thirty-three subjects) the external cutaneous nerve at first runs with the anterior crural, and, either beneath or below Poupart's ligament, turns suddenly outward to its proper distribution. The nerve can either completely replace the crural branch of the genito-crural nerve, or send branches to reinforce the peripheral distribution of the same.

4. Branches from the distribution of the *anterior crural nerve*, which arises by three branches from the second, third, and fourth lumbar nerves, and probably receives fibres from the first lumbar nerve through the first lumbar ansa. The nerve passes into the thigh through the lacuna musculorum beneath Poupart's ligament, between the psoas and iliacus muscles, and separated from the femoral artery, which lies to the inner side, by the former muscle. In the thigh the nerve divides into an anterior, chiefly sensory, and a posterior, chiefly muscular, division.

An *anterior division* gives cutaneous branches to the anterior and inner aspects of the thigh, and a muscular branch to the sartorius.

a. *The middle cutaneous nerve* (n. cutaneus femoris anterior medius) is usually composed of two branches.

(1.) *The superior branch* (ramus perforans superior) is a musculo-cutaneous nerve, supplying the sartorius muscle, along the posterior aspect of which it passes. The continuation of the main nerve usually perforates the sartorius at the junction of the upper and middle thirds, and piercing the fascia lata immediately, passes as a cutaneous nerve along the anterior surface of the thigh as far as the knee.

(2.) *The inferior branch* (ramus perforans inferior) at times is given off from a common trunk with the preceding, but is usually a separate branch from the anterior terminal division of the anterior crural. Usually it does not supply branches to the sartorius. It perforates the fascia lata to the inner side and below the preceding nerve, and passes downward as far as the knee, supplying the integument of the anterior region of the thigh.

b. *The internal cutaneous nerve* (n. cutaneus femoris medialis) usually consists of two, sometimes of three, branches. One perforates the fascia lata below the saphenous opening and runs along the saphena vein to below the middle of the thigh. This branch frequently communicates with a cutaneous branch from the obturator nerves. The second branch (sometimes double) runs down along the median margin of the sartorius, perforating the fascia a short distance above the patella to supply the integument on the inner aspect of the knee.

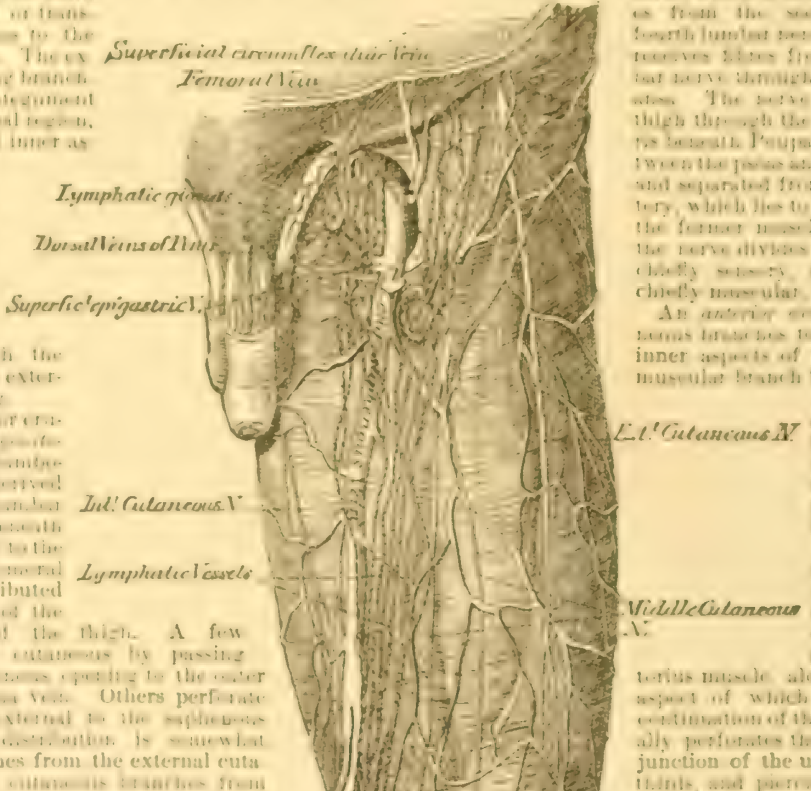

FIG. [illegible].—Superficial Veins, Nerves, and Lymphatics of Front of Thigh. (Allen.)

The fascia lata envelops the entire thigh, forming a continuous investment for the deeper structures. A division into an anterior and posterior part is therefore impracticable. The fascia is attached above and in front to Poupart's ligament, and to the body and horizontal ramus of the pubes; externally to the outer limb of the crest of the ilium, posteriorly to the sacrum and coccyx; internally to the descending ramus of the pubes, ascending ramus, and tuberosity of the ischium, joining with the lower border of the great sacro-sciatic ligament. For the formation of the saphenous opening and the relation of the fascia lata to the sheath of the femoral vessels, the reader is referred to the article on hernia and the topographical anatomy of the subinguinal region.

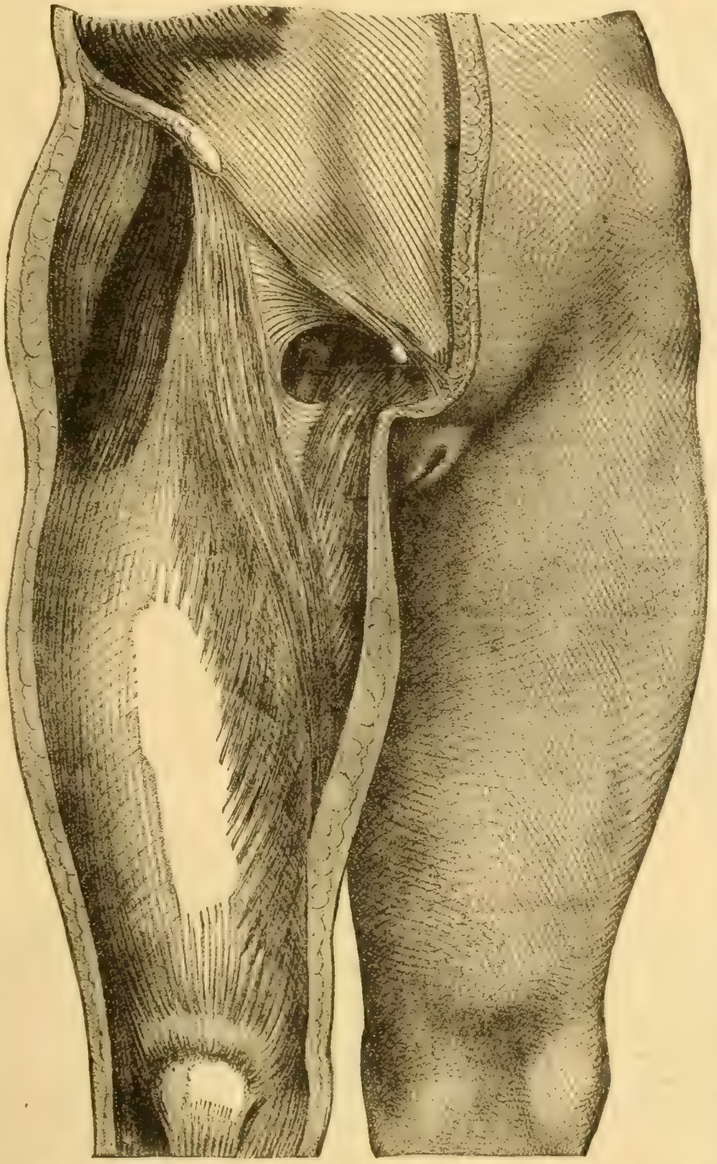

Fig. 5089.—Antero-external View of Thigh, showing Fascia Lata and Tensor Vaginæ Femoris. (Henke.)

Posteriorly this fascia covers in, above, the glutæus maximus muscle, forming a thin layer closely united to the inter-fascicular connective-tissue septa of the muscle, and composed of fibres which run nearly at right angles to the course of the muscular fasciculi. A thin layer of the fascia passes beneath the glutæus maximus, separating it from the glutæus medius, and becoming continuous with a very dense fascia which forms a firm investment for the anterior free portion of the latter muscle. The strongest portion of the fascia lata is situated at the upper and outer part of the thigh. Here it is composed of two layers of fibres which cross each other at right angles, a superficial vertical and a deep circular set. This external portion of the fascia is considerably reinforced by a fibrous expansion which passes to it from the superficial portion of the tendon of the glutæus maximus. In this situation also the tensor vaginæ femoris is inserted between its layers. Posteriorly, and at the upper and inner part, where it covers in the adductor group of muscles, the fascia is very thin. Around the knee it is strengthened by fibrous expansions from the tendon of the biceps externally, and from the sartorius, gracilis, semi-tendinosus, and quadriceps extensor cruris internally and in front. Below, the fascia lata is attached to the condyles of the femur, tuberosities of the tibia, and the head of the fibula.

The fascia surrounds all the muscles of the thigh, exerting considerable pressure on the same, so that after division of the fascia a hernia-like protrusion of the muscle takes place. Between fascia and muscle is a layer of thin cellular tissue, in which suppurative and phlegmonous processes readily become diffused.

The portion of the fascia lata arising from the forepart of the crest of the ilium, corresponding to the origin of the tensor vaginæ femoris, passes down as two layers, which include the muscle between them, and at its lower border blend together after having received the insertion of the muscle, forming a firm, dense band. This band passes down to become attached to the outer tuberosity of the tibia, and is known as the *ilio-tibial* or *Maissiat's band*. According to Maissiat, this band helps to limit adduction of the thigh.

The fascia lata sends inward from its deep surface a number of intermuscular septa, which form compartments in which the muscles of the thigh are lodged. Two of these are of especial strength, and pass inward to be inserted into the linea aspera of the femur. They are called the *external* and *internal intermuscular septa* (Lig. intermuscularia laterale et mediale). Together they limit a space in which are found the adductors of the thigh and flexors of the leg.

The external intermuscular septum arises from the entire extent of the outer lip of the linea aspera, from the trochanter major to the external condyle of the femur. It separates the vastus externus from the glutæus maximus above, and from the short head of the biceps below. It is well shown at its upper part, between the vastus externus and glutæus maximus, in Fig. 5090, which represents a transverse section at right angles to the long axis of the thigh, immediately below the lesser trochanter of the femur.

It is possible to penetrate deeply into the thigh along the external intermuscular septum, as far as the femur, without dividing any important muscles, vessels, or nerves—a fact which is of considerable importance in operations, such as sequestrotomy, or the opening of subperiosteal abscesses, etc.

The internal intermuscular septum follows the inner lip of the linea aspera, to which it is firmly attached. It arises above from the lesser trochanter, and follows

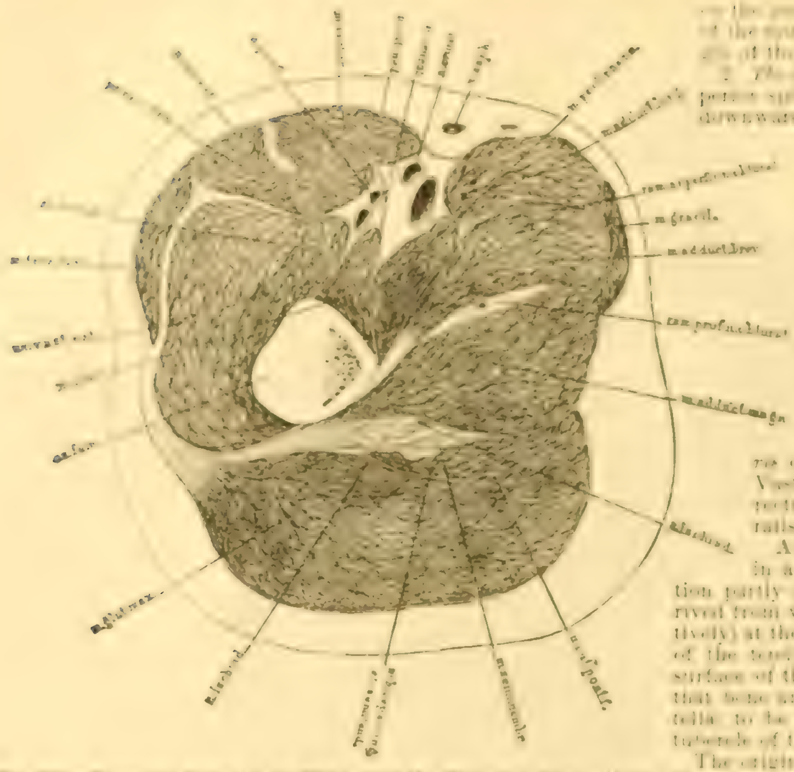

Fig. [illegible].—Transverse Section of the Thigh, below the Trochanter Minor. (After Braune.) [illegible]

on the preceding page. The posterior margin of the muscle touches above the internal margin of the gluteus medius.

2. *The sartorius* arises from the anterior superior spine of the ilium, and passes obliquely downward and inward behind the internal condyle of the femur, turning forward again, to be inserted into the inner aspect of the tibia.

Between the sartorius, adductor longus, and Poupart's ligament is situated Scarpa's triangle, or the trigonum subinguinale, in which the femoral artery and vein and the branches of the anterior crural nerve are placed. The sartorius at its upper part lies to the outer side of the femoral vessels, crosses them at the apex of Scarpa's triangle, and lies to their inner side below.

3. *The extensor quadriceps femoris* consists of four portions or heads: *a*, Vastus externus; *b*, vastus internus; *c*, rectus femoris; *d*, vastus medius or cruralis.

All four of these muscular bellies join in a common tendon, which finds insertion partly at the base, partly (the portions derived from vastus internus and externus, respectively) at the margins of the patella. A portion of the tendinous fibres passes over the anterior surface of the patella, and at the lower border of that bone unites with the strong ligamentum patellæ to be inserted into the lower part of the tubercle of the tibia.

The origin of the different portions of the quadriceps extensor is as follows:

a. The Rectus Femoris.—The median and superficial portion arises by two heads: One, the straight head, arises from the anterior inferior spinous process of the ilium; the other, called the reflected head, arises from a depression just above the acetabulum.

the origin of the vastus internus, becoming lost below in the tendinous portion of the adductor magnus.

A third important fascial layer separates the muscles situated on the posterior aspect of the thigh from the adductor group. As is well shown in the accompanying plates, this layer appears in transverse sections as a somewhat thinner fascial structure, which joins the external intermuscular septum at its insertion into the linea aspera.

The three layers just described divide the muscles of the thigh into three main groups, viz.: 1, An anterior group, comprising the tensor vaginæ femoris, sartorius, and quadriceps extensor femoris; 2, an inner group, comprising the adductors; and 3, a posterior group, comprising the biceps, semitendinosus, and semimembranosus.

A glance at Fig. [illegible] shows that the femoral vessels course between the anterior and internal of these groups, viz., between the vastus internus and the adductors.

I. MUSCLES OF THE ANTERIOR GROUP.—1. *Tensor vaginæ femoris* arises from the crest of the ilium, close to the anterior superior spine, and is inserted into the so-called "band" of Maissiat, already described

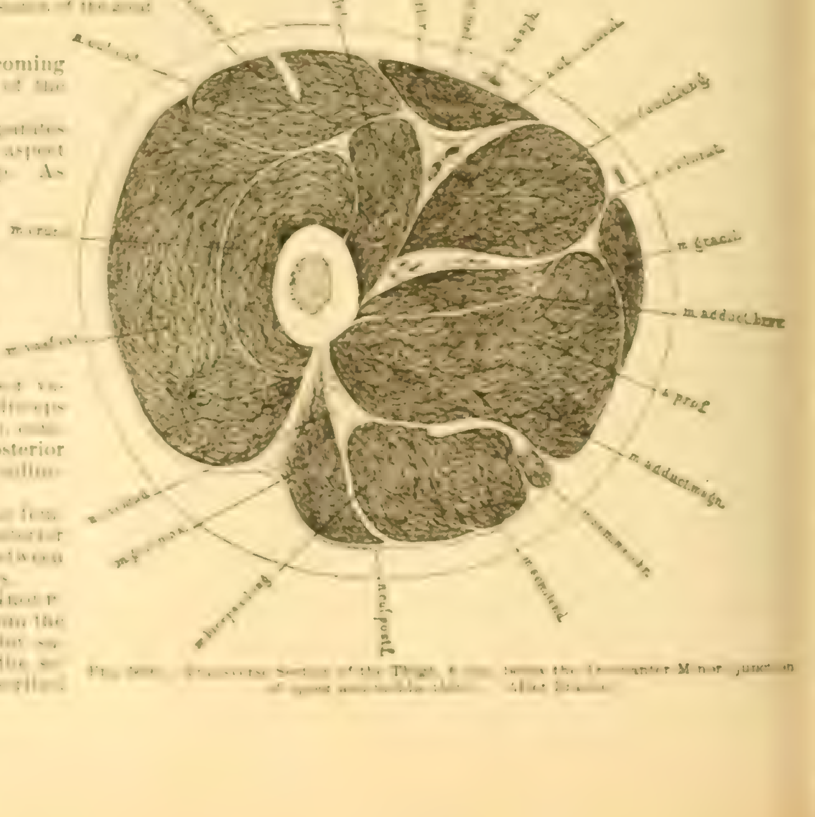

Fig. [illegible].—Transverse Section of the Thigh, 4 cm. below the Trochanter Minor; junction of upper and middle thirds. (After Braune.)

b. The vastus internus arises along the whole length of the inner lip of the linea aspera, and from the anterior and lateral surfaces of the femur. This deeper portion is at times completely separable from the vastus externus, as well as from the main portion of the vastus internus, and has, therefore, been designated by the name of vastus medius, or m. crureus s. cruralis. Usually, however, this part of the muscle is intimately blended with the vastus externus and internus, especially with the latter muscle. In Fig. 5091, representing a transverse section of the thigh just below the junction of the upper and middle thirds, the fascial septum, which at times separates the crureus from the vastus internus as well as from the vastus externus, is very perfectly shown.

c. The vastus externus arises from the whole of the external labium of the linea aspera, beginning above at the base of the trochanter major, immediately beneath the insertion of the glutæus medius and glutæus minimus. Some fibres also arise from the external intermuscular septum.

At about the middle of the thigh the vastus externus and vastus internus become united with each other, and at the beginning of the lower third the superficial and anterior fibres of these muscles join the outer and inner margin, respectively, of the tendon of the rectus femoris, which is inserted into the upper border of the patella, the superficial fibres passing across the anterior surface of the bone as a dense aponeurotic layer which joins the ligamentum patellæ. The remainder of the fibres of the vastus externus and internus terminate by a tendinous insertion into the outer and inner borders of the patella.

Beneath the crureus is found a small muscular slip, which arises from the anterior surface of the lower fourth of the shaft of the femur, and is inserted into the upper pouch of the knee-joint which passes upward beneath the extensor. It is called the *subcruralis*.

II. MUSCLES OF THE INNER OR ADDUCTOR GROUP. — 1. *Gracilis.*—A long, slender muscle arising from the descending ramus of the pubes, close to the lateral margin of the symphysis, and inserted together with the sartorius and semitendinosus into the inner surface of the tibia.

2. *The pectineus* arises from the ilio-pectineal line and surface of the pubes in front of it, between the ilio-pectineal eminence and spine of the pubes, and is inserted into a rough line passing downward from the lesser trochanter, between the outer and inner lips of the linea aspera.

Between the pectineus and ilio-psoas muscles is a deep furrow or depression, the fossa ilio-pectinea, which forms part of the floor of Scarpa's triangle, and in which are contained the femoral vessels.

3. *The adductor longus* arises by a narrow tendon from the space between the symphysis and spine of the pubes, and is inserted into the middle third of the inner lip of the linea aspera.

4. *The adductor brevis* is covered in by the adductor longus and pectineus. The muscle arises from the descending ramus of the pubes at its junction with the body beneath the adductor longus, and between the origin of that muscle and the margin of the obturator foramen, and is inserted into the upper third of the interspace of the linea aspera, somewhat above the insertion of the adductor longus.

5. *The adductor magnus* arises from the tuber ischii and the ascending ramus of the ischium. The portion arising from the ramus forms a deep layer, which finds insertion along the whole length of the linea aspera, behind the adductor longus.

The superficial portion of the muscle arising from the tuberosity of the ischium, forms the inner margin of the muscle, and terminates in a rounded tendon which is inserted into the adductor tubercle, or internal epicondyle of the femur.

In the lower third of the thigh tendinous fibres pass from this superficial portion of the adductor magnus obliquely to the vastus internus. In this way a canal (*Hunter's canal*) is formed, about five ctm. long, in which are contained the femoral vessels and the internal saphenous nerve. The anterior wall of this canal is formed by the above-mentioned oblique tendinous fibres passing from the adductor magnus to the vastus internus. The vastus internus also forms the external wall, while the posterior wall is formed by the adductor longus, which lies upon the deep muscular portion of the adductor magnus, and is intimately connected with it.

The upper opening of Hunter's canal is bounded by a crescentic tendinous fold of the adductor magnus. The lower opening is situated in the deep portion of the muscle close to its insertion, and is also surrounded by tendinous fibres. Through this so-called "adductor foramen" the femoral vessels pass into the popliteal space.

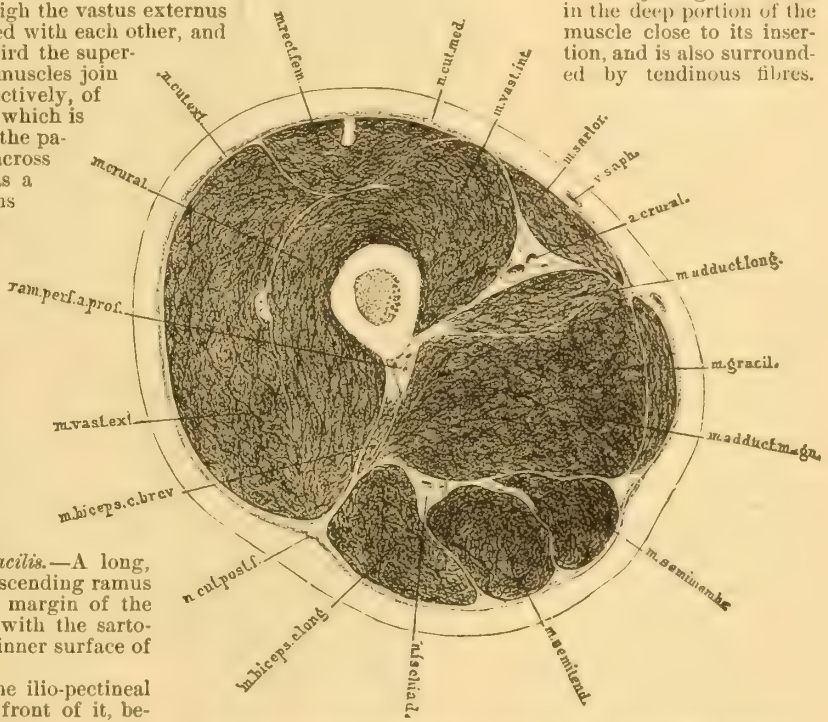

FIG. 5092.—Transverse Section of Thigh about the Middle. (After Braune.)

6. *Adductor minimus.*—Under this name a muscular bundle is known which is regarded by many authors as the uppermost portion of the adductor magnus. It arises from the ascending ramus of the ischium and descending ramus of the pubes, external to the origin of the gracilis, and is inserted into a line which descends vertically from the middle of the posterior intertrochanteric line to the linea aspera. Above this muscular bundle is the quadratus femoris; below, it overlaps the upper margin of the adductor magnus from behind. A large branch of the internal circumflex artery passes between the adductor minimus and quadratus femoris. Between the adductor minimus and adductor magnus the first perforating artery from the profunda usually passes.

The *femoral* or *crural artery* begins at Poupart's ligament and terminates at the adductor foramen, where the vessel passes into the popliteal space and becomes the popliteal artery. A line drawn from midway between the pubic symphysis and the anterior superior iliac spine to the posterior margin of the internal condyle of the femur, corresponds to the course of the artery. Superternally, the groove between the vastus internus and the adductors indicates the position of the vessel.

The artery lies at first in front of the femur, but soon comes to be situated to the inner side of the bone.

The femoral vein at Poupart's ligament, and for a short distance below the same, lies internal to the artery.

Opposite the origin of the profunda the vein passes behind the artery and continues in this situation in the middle portion of the thigh. At the lower part of the thigh the vein is behind and slightly to the outer side of the artery.

The artery and vein are enclosed in a common sheath, but separated from each other by a septum. Below Poupart's ligament this sheath of the vessels is reinforced by a process of the fascia transversalis which passes down in front, and one from the fascia iliaca which passes down behind the vessels, to become blended with the common sheath.

The anterior crural nerve at Poupart's ligament lies between the psoas and iliacus muscles, about one-fourth of an inch external to the femoral artery. The internal saphenous nerve lies superficial and external to the artery, beneath the aponeurotic covering of Hunter's canal, but not enclosed in the sheath. The muscular branch from the anterior crural to the vastus internus descends on the outer side of the artery, as far as the middle of the thigh.

According to the relations of the artery to the surrounding soft parts, and especially to the muscles, the following subdivisions of the vessels may be distinguished:

1. A superior superficial portion in the subinguinal fossa or Scarpa's triangle. 2. A middle portion beneath the sartorius. 3. An inferior portion in Hunter's canal.

1. The femoral artery in Scarpa's triangle is very superficial, being covered only by integument, superficial fascia and subcutaneous fat, inguinal glands, and the fascia lata. The direction of the vessel is indicated by a line drawn from the apex of Scarpa's triangle vertically to the base formed by Poupart's ligament. The artery rests on the inner border of the psoas muscle, which separates it from the capsule of the hip-joint. Some filaments from the crural branch of the genito-crural nerve are in front of it, and the branch from the anterior crural to the pectineus passes behind it.

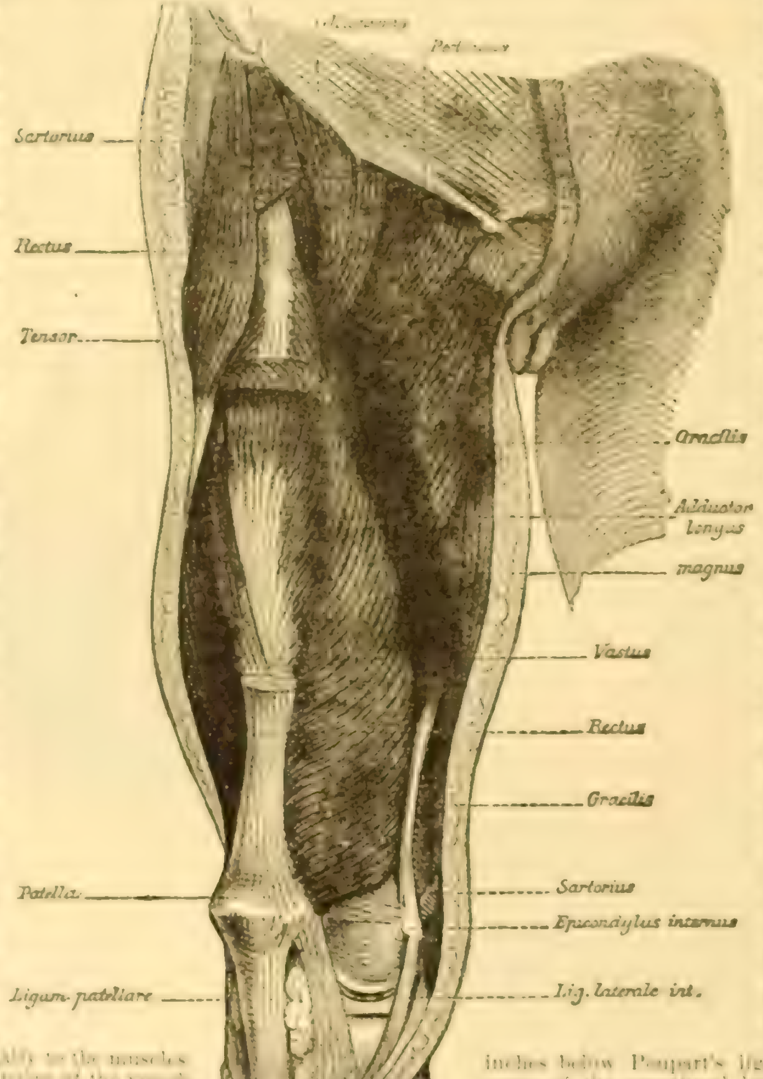

Fig. [illegible].—Anterior View of the Muscles of the Thigh, with the Sartorius and Rectus Removed. (After Henle.)

The relations of the artery to the femoral vein and anterior crural nerve have already been mentioned above.

The artery in this situation gives off its superficial cutaneous branches, and the profunda femoris. The point at which the latter vessel is given off is of considerable importance surgically, as the artery may be tied either before giving off the profunda, or at the apex of Scarpa's triangle (seat of election), or in Hunter's canal. The name of common femoral artery is applied to the vessel from Poupart's ligament to the point of origin of the profunda branch, the continuation of the main vessel being known as the superficial femoral. The first operation would therefore be a ligature of the common femoral, the last two, of the superficial femoral. The profunda arises from the posterior and external surface of the femoral artery one and a half to two inches below Poupart's ligament. Sometimes it is given off higher, or considerably lower, even as low as four inches below Poupart's ligament.

The usual length of the common femoral is one and a half inch, and it may readily be ligated, as it is superficial and of easy access. The operation is, however, not a very successful one, secondary hemorrhage and gangrene of the limb having frequently followed it.

Ligature of the superficial femoral, near the apex of Scarpa's triangle, is the operation most frequently practised. The apex of the triangle is situated about four inches below Poupart's ligament, and on account of the occasional low origin of the profunda branch it has been recommended to tie the artery a little lower than the point indicated. At the apex of Scarpa's triangle the artery is situated behind the inner margin of the sartorius and more or less overlapped by the same according to the muscularity of the subject. The inner margin of the sartorius is therefore the anatomical guide to the artery for ligature in this position. The femoral vein at the apex of the triangle already lies on its posterior aspect.

2. The middle portion of the femoral artery, beneath the sartorius, extends from the apex of Scarpa's triangle to the upper opening of Hunter's canal. At the upper part of this segment of the femoral artery the main mass of the sartorius lies somewhat to the outer side, the inner margin of the muscle covering the artery. In the middle the muscle lies directly in front, and at the lower part more to the inner side. The femoral vein lies behind

and to the outer side. The internal saphenous nerve lies in front of the artery, and in ligature of this portion requires careful separation. In this operation the sartorius must be displaced or divided.

3. The inferior portion of the femoral artery is contained in the adductor canal. The internal saphenous nerve lies superficial and internal to the artery. Behind the artery, and more to the outer side, is the femoral vein. The anastomotica magna is frequently given off in Hunter's canal.

Branches of the Femoral Artery.—In Scarpa's triangle the femoral artery gives off the following small branches:

1. *Superficial epigastric,* ascending to the superficial fascia and integument of the abdomen, after having passed through the saphenous opening.

2. *Superficial circumflex iliac,* to the integument of the groin as far as the crest of the ilium.

3. *The superficial external pudic* (subcutaneous), to the integument of the lower part of the abdomen, penis, and scrotum.

4. *The deep external pudic* (subaponeurotic), passing beneath the fascia lata, on the pectineus and adductor longus, to the external genitals.

FIG. 5094.—Surgical Anatomy of Femoral Artery. (After MacCormac.)

The largest branch of the femoral artery is:

5. *The Profunda Femoris.*—This vessel, as already stated, arises from the external and posterior aspects of the femoral artery in Scarpa's triangle, from one and a half to two inches below Poupart's ligament. It passes downward and slightly outward upon the psoas tendon and upper part of the crureus, and then curves inward behind the femoral artery, separated from the same by the profunda and femoral veins. Arrived at the upper or external border of the adductor longus, quite close to its insertion into the bone, the artery passes beneath the muscle, running between it and the adductor magnus, and finally perforating the latter—as the fourth perforating artery—a little above the adductor foramen.

The upper part of the profunda is accompanied by a single vein which lies to the inner side and joins the femoral vein.

The more important branches of the profunda artery are the following:

a. *The external circumflex* arises from the outer side of the profunda, passes between the two main branches of the anterior crural nerve, and beneath the sartorius and rectus muscles, and divides into an ascending and a descending branch; a few small branches being continued transversely over the crureus and through the vastus externus to the back part of the femur, just below the great trochanter, anastomosing with the internal circumflex, sciatic, and superior perforating arteries. The ascending branch curves around the upper part of the shaft of the femur at its back part, beneath the trochanter major, passing beneath the tensor vaginæ femoris, and anastomosing with the internal circumflex, sciatic, gluteal, and circumflex iliac arteries. The descending branches pass behind the rectus femoris to the outer aspect of the thigh, supplying the quadriceps extensor.

b. *The internal circumflex* arises frequently from the femoral artery, instead of from the profunda. Soon after its origin the vessel gives off an internal superficial muscular branch which supplies the pectineus and the superficial adductors. The main trunk continues backward around the inner side of the femur, between the pectineus and psoas, dividing finally into two branches which pass to the back part of the femur, one above, the other below the quadratus femoris. The artery supplies muscular branches to all the adductors and to the obturator externus, and its terminal branch anastomoses with the sciatic, external circumflex, and superior perforating arteries, forming the so-called "crucial anastomosis."

As the vessel winds around the neck of the femur an articular branch to the hip-joint is frequently given off, which passes beneath the transverse ligament, along the round ligament, to the head of the bone. Other branches perforate the capsule and pass along the neck of the femur, supplying the periosteum. These branches are important in conveying blood to the head of the bone in cases of intra-capsular fracture of the neck of the femur.

c. The *perforating arteries,* usually three in number, are given off from the profunda as this vessel passes in front of and between the adductors. They perforate the adductor muscles close to their insertion into the linea aspera, and pass backward to supply the posterior muscles of the thigh.

The middle perforating artery usually supplies the nutrient artery for the femur.

6. *Muscular branches,* varying in number and size (two to seven), are given off from the superficial femoral, supplying chiefly the sartorius and vastus internus.

7. The *anastomotica magna* (art. articularis genu suprema) arises from the lower portion of the superficial femoral in Hunter's canal, and perforates the anterior wall of this canal formed by the tendinous portion of the adductor magnus. The vessel divides into a superficial and a deep branch.

The superficial branch runs in front of the adductor magnus and beneath the sartorius accompanied by the internal saphenous nerve to the fascia and integument covering the internal condyle.

The deep branch enters the substance of the vastus in-

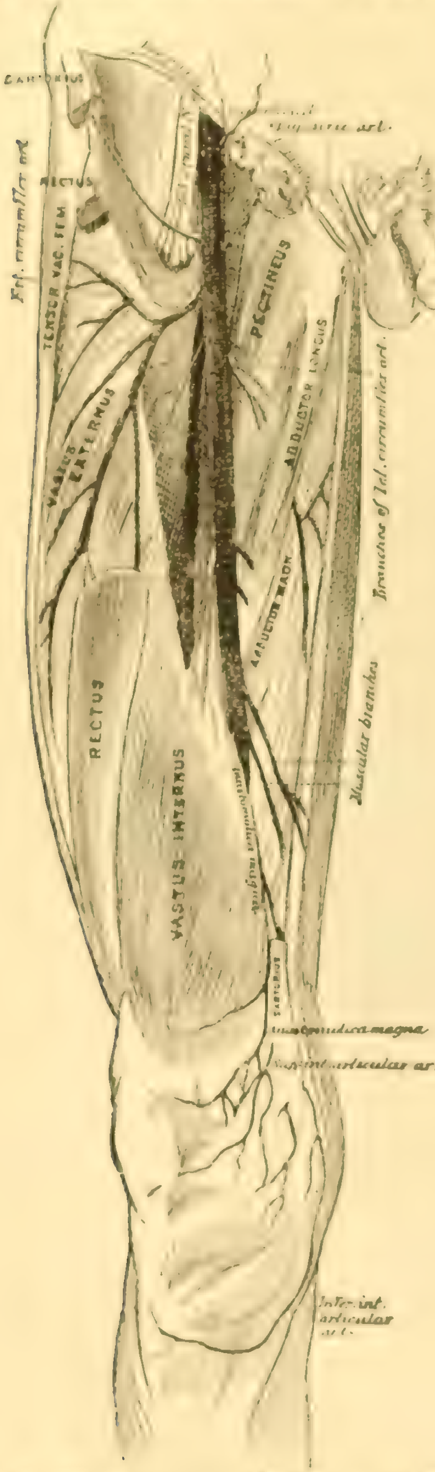

Fig. 4646.—Femoral Artery and Branches. (After Allen.)

ternus, anastomosing with the superior internal articular and anterior tibial recurrent arteries. A branch passes outward above the articular surface of the femur to anastomose with the superior external articular artery.

The *obturator artery* belongs topographically to the pelvic and gluteal regions. A few of its terminal branches pass to be distributed to the structures of the thigh. After emerging from the obturator canal the vessel divides into two branches. The anterior or internal branch passes to the adductors, anastomosing with the internal circumflex artery. The posterior or external branch frequently gives an articular branch to the hip joint and passes to the gluteal region, anastomosing with the sciatic artery. The collateral circulation, after ligature of the femoral artery immediately below Poupart's ligament, is chiefly carried on by means of these anastomoses.

The course and relations of the *femoral vein* have been sufficiently referred to in speaking of the artery. In the lower half frequently two venæ comitantes accompany the artery besides the femoral vein proper, a fact to be borne in mind in applying a ligature to this portion of the vessel.

Nerves.—The deep branches of the anterior crural nerve are:

1. Muscular branches to the pectineus and to the different portions of the quadriceps extensor; the nerves to the vastus externus and internus supply in addition articular filaments to the knee joint.

2. *The internal or great saphenous nerve* accompanies the femoral artery into Hunter's canal, lying in front and somewhat to the outer side of the vessel. Just above the adductor foramen the nerve quits the artery, passing through an opening in the anterior wall of Hunter's canal, usually in company with the anastomotica magna. It then descends vertically beneath the sartorius along the inner side of the knee, piercing the deep fascia and becoming subcutaneous between the tendons of the sartorius and the gracilis.

The *obturator nerve* is derived from the second, third, and fourth lumbar nerves and supplies the obturator externus and adductor muscles, the hip and knee joints, and occasionally the integument of the thigh and leg.

The branch to the obturator externus is usually given off within the pelvis and emerges with the main trunk through the obturator canal.

Immediately after its exit from the pelvis the nerve divides into a superficial and a deep branch.

The superficial branch descends beneath the pectineus, which it occasionally supplies, and gives branches to the adductor longus, brevis, and gracilis.

This anterior or superficial branch usually furnishes a cutaneous filament which descends along the inner margin of the adductor longus, and communicates opposite Hunter's canal with the internal saphenous and internal cutaneous nerves. The deep or posterior branch perforates the obturator externus, supplies this muscle and the adductor magnus and minimus.

Deep lymphatics, five to six in number, accompany the femoral artery, passing between the popliteal and the deep crural glands of the inguinal region.

B. Posterior Region of Thigh.—The *integument* and *fasciæ* have already been described with the general anatomy of the thigh. Beneath the fascia lata is found the *small sciatic nerve*, a branch of the sacral plexus, which, after emerging from the pelvis through the great sacro-sciatic foramen below the pyriformis muscle, descends beneath the gluteus maximus, supplying the same, and then beneath the fascia lata along the back of the thigh to the popliteal space. The nerve in its course gives off several cutaneous filaments, which pierce the fascia lata and supply the integument of the posterior part of the thigh and gluteal region.

The *arteries* of the back of the thigh are: 1. The *sciatic artery*, a branch of the internal iliac, giving off the comes nervi ischiadici, inferior gluteal branches to the gluteus maximus, muscular branches to the muscles on the posterior aspect of the hip, a coccygeal branch to the coccygeal region, and an articular branch to the hip. 2. Terminal branches of the *external* and *internal circumflex arteries*; and 3. Terminal branches of the *perforating arteries* already described with the profunda femoris.

The veins accompany the corresponding arteries.

III. MUSCLES OF THE POSTERIOR GROUP.—1. *The biceps* arises by two heads. One, the long head, arises, together with the semitendinosus, from the posterior and external portion of the tuberosity of the ischium. The short head arises from the middle third of the outer lip of the linea aspera. The two portions unite, forming the outer hamstring tendon, and are inserted into the head of the fibula.

2. *The semitendinosus* arises with the long head of the biceps from the tuberosity of the ischium, and passes around the internal condyle of the femur to the inner aspect of the shaft of the tibia.

3. *The semimembranosus* arises from the anterior portion of the tuberosity of the ischium, behind the quadratus femoris, above and to the outer side of the biceps and semitendinosus, and is inserted into a groove on the inner and back part of the inner tuberosity of the tibia, gaining its median position by passing in front of the biceps and semitendinosus.

FIG. 5096.—Posterior Region of Thigh and Gluteal Region. (After MacCormac.)

The *great sciatic nerve* emerges from the lower border of the glutæus maximus and passes down the back of the thigh between the trochanter major and the tuberosity of the ischium, under cover of the biceps. At about the lower third of the thigh the nerve divides into the external and internal popliteal nerves. This division may, however, take place at any point between the sacral plexus and the lower third of the thigh.

The nerve supplies articular branches to the hip-joint and muscular branches to the biceps, semitendinosus, and semimembranosus, also a branch to the adductor magnus, in its course along the back of the thigh. After emerging from the lower border of the glutæus maximus, the nerve rests on the adductor magnus with the biceps externally, and the semimembranosus and semitendinosus internally. The nerve is imbedded in a layer of loose areolar tissue which extends between the muscles named from the great sacro-sciatic foramen to the popliteal space. This loose cellular tissue is a favorite site for deep abscesses, and abscesses which form within the pelvis may descend with the nerve along this route to the popliteal space.

The great sciatic nerve is accessible for operation in the middle line of the thigh, just below the gluteo-femoral crease, midway between the trochanter major and the tuberosity of the ischium. The muscular guide is the biceps, immediately beneath which muscle the nerve is found.

George S. Huntington.

THYROIDECTOMY. The history of the operations for disease of the thyroid gland dates from the time of Celsus, who spoke only of cysts of the gland and recommended either extirpation or incision.

Cl. Galenus, Paulus of Ægina, and Albucasis wrote of the extirpation of cysts and of small and completely movable strumata. They called especial attention to the injury to the recurrent laryngeal nerves, as well as to the larger vessels in the neck.

In the thirteenth century Rulandus recommended the employment of the seton or of the hot iron, as well as the extirpation of the capsule, as the best means against a return of the struma.

In 1652 Fabricius Hildanus mentions a case of extirpation which was followed by immediate death.

In 1716 Gottfried Purmann advocated, as the best means of arresting the growth of strumata, the double ligature of the afferent vessels.

In the eighteenth century more attention was paid to the internal treatment and to the use of ointments than to operative measures. It is scarcely probable that any formal operation was performed, as we find the word "struma" was a collective term for a variety of tumors in the neck. It is safe to say that until the middle of the eighteenth century no true thyroidectomy (in the sense in which we use the term) had been performed. With Laurentius Heister (1682–1758) came a new era in the treatment of strumata. He mentions several methods, such as ligature of the pedunculated variety, cauterization of solid nodules, incision and cauterization in cystic nodules, and the shelling or peeling out of solid ones. At this time, 1750, Albert Haller first referred to the compression of the trachea in strumata.

In 1770 Benjamin Gooch first described an extirpation of the thyroid gland, and in 1771 A. T. Vogel described the first typical partial extirpation of the thyroid gland with ligature of the afferent vessels. In 1791 Desault reported the first typical half extirpation with recovery, and in 1800 J. A. W. Hedenus performed the first total extirpation with recovery. Haussleuthner, in 1810, called attention to the mental disturbance following destruction of the thyroid gland.

V. Walther recommended, in 1814, the ligature of the superior thyroid arteries in the treatment of aneurismal strumata.

In 1834 K. J. Beck gave a very succinct account of the method of extirpation, with all the surgical and anatomical details, including a description of the ligature of the thyroid arteries.

From 1850–1875 von Bruns, Schuh, Billroth, Luecke, Kocher, Rossander (1874–1875), and Greene (1871) contributed mostly to the advancement of the operation.

From 1875 to 1886 Luecke, Kocher, Hopmann, Kuster, Albert, Billroth, Wölfler, Rose, Liebrecht, Reverdin, and Socin were the most prominent in advancing the operative measures for the relief of strumata. We can thus see how slowly the operation has advanced from an incision for cysts to what we now consider a safe and thoroughly studied operation, such a method of operation as is practised by Mikulicz, Kocher, Rose, Billroth, or Lebrecht.

Although we must admit that the good results to-day are largely due to the care which we bestow upon the treatment of the wound, we must not overlook the fact that the "technique" of the operation is important and is to be ruled by two principles: the one, complete control of bleeding; the other, the avoidance of any injury to the recurrent laryngeal nerve. Both principles depend upon an accurate knowledge of the anatomy of this region. In no other region are the irregularities in the blood supply so great as in this very organ. As a general rule the vessels can be followed regularly.

The superior horns of both lateral lobes are supplied by the superior thyroid artery from the external carotid artery, which, when the isthmus is present, anastomoses with the artery of the opposite side along its upper border, forming a superior communicating branch. The inferior horns of the lateral lobes are supplied by the inferior thyroid arteries from the subclavian.

In addition to these we have the arteria thyroidea ima from the aorta, the innominate, or branches of either, which supplies when present (in about ten per cent. of the cases) the lower portion of the isthmus and the inner surface of the inferior lobes. The veins are, however, more numerous, larger, and of more importance than the arteries, and an exact knowledge of them is necessary in order to carry out a bloodless operation.

After division of the skin and the platysma muscle we find the venæ subcutaneæ colli. They lie in the superficial fascia and form an irregular plexus between the vena maxillaris externa (facialis anterior) and facialis communis above, and the jugularis externa below. Of these, three branches require special mention. The jugularis externa, beginning above from branches communicating with the vena facialis posterior and vena occipitalis, and ending below at the junction of the vena jugularis interna or subclavia, or either one of them, lies upon the outer border of the sterno-cleido-mastoideus muscle and comes into notice only when the superior horns are greatly enlarged and the oblique incision has been used for the extirpation of the tumor. If such be the case, it must be divided between two ligatures. The venæ jugulares anteriores, a pair of veins united by a transverse branch near the hyoid bone, and receiving branches from the venæ submentales, pass downward along the median line, gradually diverging until they reach the anterior border of the sterno-cleido-mastoid muscle, where they join the venæ jugulares obliquæ, and with them pass beneath this muscle, emptying into the vena subclavia or vena jugularis interna or externa. The vena jugularis obliqua, beginning above from branches of the vena facialis communis, or vena thyroidea superior, runs along the inner border of the sterno-mastoid muscle until it meets and joins the vena jugularis anterior. It also continues by a branch across the median line, which unites with a similar branch from the opposite side. This transverse branch occurs at a variable distance above the incisura sterni. After division of these subcutaneous veins and their ligation the sterno-hyoid, sterno-thyroid, and omo-hyoid muscles are to be divided upon a director, especially in all strumata of any size. The struma is now exposed, with its large veins upon and within its external capsule. Without disturbing the tumor one proceeds to ligate the arteries and veins of the thyroid itself. Of these the first is the vena thyroidea superior, which has the position and course of the artery of the same name. It can be ligated with the artery in one ligature. A second branch which should be ligated is the branch of this vein which communicates with a branch from the opposite side along the upper border of the isthmus, forming the superior thyroid communicating branch. This branch does not communicate with that of the opposite side when the isthmus is wanting. Its ligation is necessary, for it often receives a branch from the vena jugularis anterior. A third branch requiring ligation is the vena thyroidea superior accessoria, which is found upon the external border of the lateral lobe at a variable distance below the vena thyroidea superior. It empties into the vena jugularis interna and its branches receive the blood from the anterior surface of the superior horn of the lateral lobes. When the veins in any struma are marked, we generally find some important veins at the lower surface of the struma. These are the venæ thyroideæ imæ. The left is often small, and ends in the vena anonyma sinistra. The right is larger, and ends in the vena anonyma dextra or sinistra. They receive the blood from the lower border of the isthmus and from the inner and anterior surface of the inferior horns. They often form a large plexus in front of the trachea and communicate with the venæ thyroideæ inferiores. Their ligation is necessary, and is to be done below the isthmus in front of the trachea.

The next veins of importance are the venæ thyroideæ inferiores. They receive the blood from the posterior surface of the inferior horn of the lateral lobe. They are often wanting, and when this is the case the venæ thyroideæ inferiores accessoriæ are correspondingly enlarged.

The venæ thyroideæ inferiores accessoriæ correspond to the venæ thyroideæ superiores accessoriæ, and are situated at a point above the venæ thyroideæ inferiores, having a more transverse course in the neck. They receive the blood likewise from the posterior surface of the inferior horns of the lateral lobes and join the lower portion of the venæ jugulares internæ. This vein is always very large when the vena thyroidea inferior upon the same side is wanting. Moreover, both of these veins may be wanting, and the whole mass of venous blood from the inferior horns may be carried through the venæ thyroideæ imæ, which latter are by far the most important of the venous branches found in this region of the neck. The next important step after the ligature of the arteries and veins is the avoidance of any injury to the recurrent laryngeal nerve. Wolfler first drew attention to this point, and it is not difficult to avoid the nerve, if one remembers the relation of the inferior thyroid artery to the nerve at the time of ligation. Before ligation one must secure its complete isolation, and must not ligate near the trachea.

From the aorta, or the innominate artery, the nerve advances laterally parallel to, and slightly in front of, the posterior end of the tracheal rings toward the venous plexus of the inferior thyroid, and accessory inferior thyroid veins on the posterior surface of the struma. Here it is very necessary to avoid the nerve, and in order to accomplish it, one must keep close to the capsule of the gland. This is especially demanded in the neighborhood of the isthmus, for it is just here that the union is very intimate, and any unguarded incision or ligation of arteries may be attended with injury to the nerve. This is the reason why in the operation one secures at first a completely bloodless wound before attempting a separation of the struma from the trachea. The relation of the inferior thyroid artery to the nerve is that, in its course from the thyroid axis, it passes transversely and slightly ascending in the neck, lying at first upon the outer side of the nerve, then behind it, and when it reaches the tracheal rings ascends upon its internal surface and divides there into its branches to supply the posterior surface of the lateral lobe. When the artery divides into its branches early in its course, some of them will pass over the nerve, while the rest pass behind it. On this account one must tie the artery either close to the gland at its point of division, or with a double ligature on the lateral surface of the lobe before it has come in close relationship with the nerve. All haste or tearing of the tissue in this neighborhood must be avoided, for in such a procedure one runs great risk of injuring the nerve.

Having gone over the more important points in the anatomy of the venous, arterial, and nervous supply, we will describe the operation, dividing it into three steps:

1. Exposure of the struma, *i.e.*, the mode of incision and the tissues cut.
2. Isolation of the lateral lobes with the ligature of the vessels.
3. Separation of the lateral lobes and isthmus from the trachea or œsophagus.

Of the various incisions used in the operation of thyroidectomy, we prefer that of Kocher to the median incision or to that carried along the anterior border of the sterno-mastoid muscle. The advantages gained by Kocher's incision are that it allows a more perfect and complete survey of the whole field of the operation, and an excellent chance to ligate the veins and arteries without difficulty.

This incision commences at the manubrium sterni in the median line, and ascends as far as the cricoid cartilage. This portion of the incision divides the skin and superficial fascia, and avoids the veins, with the exception of the smaller anastomoses between the oblique jugular veins, which, as a general thing, lie just above the incisura sterni. The upper portion of the incision passes from the cricoid cartilage upward and outward toward the anterior border of the sterno-mastoid muscle, until one arrives at the upper limit of the lateral lobe. The advantages offered by this mode of incision over the median and that along the anterior border of the sterno-mastoid muscle are the more perfect exposure of the trachea where the thyroid gland is attached, and of the inner surface of the inferior horn of the lateral lobe where the large veins are present, which, in *goître plongeant* (struma substernalis), must be rendered free for ligature. In addition, the upper oblique portion of the incision, besides dividing the skin and platysma muscle, crosses the anterior, oblique, or external jugular veins transversely, or at least obliquely, so that they may be easily secured with double ligatures before proceeding further with the operation. The sterno-hyoid, sterno-thyroid, and omo-hyoid muscles are now divided upon a director in the line of the oblique portion of the incision.

By the use of blunt hooks in the outer portion of the wound these muscles, together with the sterno-mastoid muscle, are drawn outward, and the lateral lobe is completely exposed, so that the veins and arteries supplying it may be easily secured before proceeding to the isolation of the tumor from the surrounding parts.

To do this we at first follow the inner border of the lateral lobe to its highest portion, so as to ligate with a double ligature the superior thyroid artery and vein as near to the main trunk as possible. They can be ligated together and need not be isolated from one another for the ligature. From this portion we descend upon the outer border of the lateral lobe until we meet with the accessory superior thyroid vein, when it is present, and, after the application of a double ligature, divide it. The superior communicating thyroid vein upon the upper border of the isthmus is next ligated, together with the artery, should the latter be present. The upper half of the lateral lobe is now free from all vascular connection, and with the finger one can easily strip from it the loose connective-tissue capsule in which it lies. It is now raised as much as possible with the fingers alone, or when, as in substernal strumata, dyspnœa is impending, with a strong pair of blunt forceps. We have thus a perfect view of the venæ thyroideæ imæ, which are often large and must be ligated with double ligatures in more than one place so as to shut off all blood from the inferior communicating thyroid vein. This is easily accomplished, and we follow the lower border of the lateral lobe, meeting the inferior thyroid vein, which we ligate with double ligatures. Proceeding along the outer border of the lobe, we meet the inferior accessory thyroid vein, which we likewise ligate. The struma is at this stage attached only at its pedicle, *i.e.*, at the isthmus on the upper tracheal rings. It is raised completely from the underlying tissues, and turned upon itself toward the median line of the neck and held in this position by the hand of an assistant. We proceed to look for the inferior thyroid artery, which we find in the lower angle of the wound. It is secured by a double ligature as near as possible to the point where it is passing behind the common carotid artery. This is not difficult, for from its transverse or oblique course it is readily distinguished. Its isolation must be carefully done, and the ligatures must enclose only the artery itself. This being accomplished, we proceed to separate the tunica propria of the gland from the tissue covering the posterior surface until we reach the isthmus. It is necessary in this region to keep close to the gland in order to avoid the recurrent laryngeal nerve as well as the vessels entering the posterior surface of the gland. Having ligated such arteries as bleed in this neighborhood, we have only the isthmus left to manage. This we do in one of two ways. Either the isthmus is completely separated from the trachea with the knife, and such arteries as bleed are caught with clamps, or we keep out of the way of the nerve, the artery, and the trachea by making use of Mickulicz's method of avoiding any injury to these structures. This method consists in fastening the struma with a clamp, and by squeezing out the glandular portion of the struma he leaves a pedicle which consists only of the tunica propria of the gland. This pedicle, which is made at a point where the gland is not attached to the trachea, can be subsequently treated just as in the case of ovarian tumors.

By either procedure the nerve is safely avoided. Kocher had in 1883 twenty cases, of which sixteen showed no paresis of the nerve by laryngoscopic examination. In one case the nerve was paralyzed before the operation. In two cases, though no hoarseness remained after the operation, the patients were not subjected to a laryngoscopic examination. In one the voice remained weak, though otherwise perfect, after the operation. In this case, also, no laryngoscopic examination was made. In the 322 cases reported by Liebrecht, section of the recurrent laryngeal nerves was certain in 9 cases and doubtful in 4 cases.

This incision (Kocher's) suffices in many cases of total extirpation. Should it not be sufficient, one can add a second similar to the upper portion of the first incision, making a **Y**-shaped incision. This is to be preferred to the **V**- or **T**-shaped incision, as it produces less injury to the skin with a more perfect exposure of the field of operation. Should tracheotomy be performed in this operation ? Rose prefers it in order to avoid the mediastinitis, in cases of dyspnœa, for the orthopædic treatment of the deformed and softened trachea, and to render the operation easier. Wölfler raises as an objection to this the fact that of 48 cases in Billroth's Klinik just those cases did badly in which tracheotomy was performed. Of these, 43 were not tracheotomized, and all lived ; 5 were tracheotomized, and 3 of them died. Kocher adds also 43 cases, in which tracheotomy was performed in 4 cases ; 3 of these 4 died. It is impossible, when tracheotomy has been performed, to keep the wound aseptic. The air and mucus from the trachea escape easily beneath the dressing and infect the wound. On the other hand one must, when tracheotomy has been performed, prevent the escape of the discharges from the wound into the trachea, where, decomposition occurring, a septic bronchitis and broncho-pneumonia will certainly result. If one must perform tracheotomy, it is better to make use of the open treatment. The mediastinitis for the avoidance of which the tracheotomy (Rose) is performed occurs only when sepsis is present in the wound. The best means of avoiding this or, at least, of avoiding a factor in its production, is not to open the trachea. Moreover, it is not yet thoroughly determined whether the tracheal cannula is able to restore the trachea to its proper shape. Rose has certainly obtained the honor of calling attention to the inflammatory softening of the tracheal rings and the consequent scabbard-shaped (säbelscheidenförmig) contour, as well as the angular bend in the wall of the trachea resulting from atmospheric pressure or from movements of the head and neck, when the struma has been removed.

This condition he explains by showing how, when the trachea and larynx are removed from the body and suspended, the larynx being downward, the softened trachea will form a sharp angle at the point of softening while the healthy trachea hangs straight or with a gentle curve. Kocher has shown that the same will occur in the healthy trachea at the point where tracheotomy has been performed, and says that as the cartilages will only unite by connective tissue, the same conditions and dangers will exist after tracheotomy as are present in a trachea softened by strumata. Tracheotomy is to be avoided in this operation, and performed only where immediate danger of suffocation exists. Such danger is generally due to stenosis of the trachea from the pressure of bilateral strumata, or to severe tracheitis or a double paralysis of the recurrent nerves. In all cases it is best to delay the tracheotomy as long as possible, allowing an assistant to press with the finger upon the trachea from before backward, maintaining thus an oval or round lumen and giving a free ingress to the air. This procedure is continued until the operation is finished, when, if the rings are not softened to the last degree, and if the lumen is kept, the danger will not recur. It is proposed also to sew the walls of the trachea to the adjoining muscles or soft parts in order to give the necessary support to the trachea and thus secure more perfect asepsis in the wound, rather than to tracheotomize the patient with the necessary danger of subsequent infection.

During the operation many complications can occur, and of these the hæmorrhage deserves attention. This takes place if, during the isolation of the struma, we omit to tie all veins and arteries with a double ligature. Excessive bleeding occurs if we accidentally injure the capsule of the gland with sharp hooks or forceps. It is best not to use such instruments, but to confine oneself to blunt instruments and the finger for raising or turning the struma.

If hæmorrhage does occur from the extracapsular vessels they are to be compressed immediately by the finger, and subsequently caught with artery clamps beyond the finger. They can then be tied or the forceps can be left hanging in the wound until the operation is completed. The possibility of the entrance of air into the vein is thus best avoided. Another complication liable to occur during the operation is a sudden asphyxia. This is due either to a paralysis of the recurrent laryngeal nerves as the result of injury from the knife or forceps (some maintain that the same result will occur when too strong or too long-continued solutions of carbolic acid are used upon the wound), or to a sudden closure of the trachea either from torsion or from compression of its wall due to too forcible dragging, raising or turning of the whole struma or one lobe during its isolation, or to deformation of the trachea by which its walls are approximated to one another and its lumen is diminished in size as a consequence of the long-continued pressure of the struma. Lastly, as a cause we have the softening and disappearance of the cartilaginous rings (Rose), in which case the trachea is practically a membranous tube whose walls collapse from atmospheric pressure as soon as the support given them by the struma is removed. Some deny this complete absorption of the tracheal rings, yet preparations show it sufficiently well to demand a belief in its existence.

More frequently, however, the compression of the walls of the trachea occurs, and in this case the slightest lateral deviation of the head and neck results in an angular bend in the wall and a complete closure of the lumen.

Such deformity in the trachea occurs more frequently from approximation of the lateral than from that of the anterior and posterior walls, or from a sinking in on one side only. Should such an accident occur it is not absolutely necessary to perform tracheotomy, for we can make use of Kocher's method for re-establishing the form of the trachea. This method consists in passing a suture through one lateral wall of the trachea without injuring the mucous membrane, then over the anterior surface of the trachea and through the lateral wall of the opposite side. The ends of the suture are then drawn tightly and tied over the anterior surface. In this way the lateral walls are drawn away from one another, the sharp anterior angle is pushed backward, and the rounded form of the trachea re-established. In cases of complete absorption of the tracheal rings and in bilateral paralysis of the recurrent nerve, tracheotomy is demanded. Unilateral paralysis produces only a hoarseness in the voice or breathing, and according to Wölfler, in addition to these symptoms there occur frequent attacks of choking, as a result of the oblique position of the epiglottis and the insufficient closure of the aditus ad laryngem. Other than this it does not demand our attention. Injury to the œsophagus may occur in the extirpation either of malignant strumata or of retro-œsophageal strumata in case the operation is not carefully done. The separation of the struma from the œsophagus is generally easily accomplished, but where the capsule is closely adherent to the œsophagus the struma must be divided near it and the parenchyma scraped out, leaving the capsule intact and attached to the wall of the œsophagus.

The indication for the operation of thyroidectomy, either partial or complete, can be said to exist in cases in which most therapeutic measures cannot be used, or in which such remedies have been shown to be of no avail, and when the symptoms demand speedy measures for their relief. Formerly the cosmetic effect was considered an indication for the operation. Julliard, Reverdin, and Kocher, however, have shown that the extirpation of this gland is followed by after-effects upon the general organism, that in young people a condition of cretinism with cachexia strumipriva, as well as tetany (Billroth), is often observed. Complete extirpations are reserved for those cases which give dangerous symptoms of impending strangulation, and in this group are classed sarcomatous or carcinomatous strumata, and struma cystica with numberless disseminated pus cavities in the gland. Further we may include struma retro-pharyngea, retro-œsophagea, retro-sternalis, and struma circularis, which surrounds both trachea and œsophagus. Finally we include also struma lateralis, which by its pressure upon the trachea deforms it, narrows it in its lateral diameter, softens its rings, or so twists it upon its axis as to deform and diminish the size of its lumen, and partly through this mechanical pressure and partly through the pressure paralyses of the recurrent nerves causes the danger of suffocation.

In all cases of partial involvement of the thyroid the removal should be partial so far as concerns the gland. In this way the sequelæ are more completely and effectually excluded.

The mortality following the operation of thyroidectomy has been steadily lowered since 1850.

According to Süskind and Wölfler the mortality of all cases operated upon prior to 1850 was forty-one per cent. Kocher gives as the death rate up to the year 1877, comprising 146 cases, a percentage of 21.2 per cent. From 1877 to 1888 there were 28 cases of malignant struma with 16 fatal cases, giving a mortality of 57.1 per cent, and 240 non-malignant cases with 28 deaths, a mortality of 11.6 per cent.

In 1888, in the clinic at Berne, there were 43 cases in which thyroidectomy was performed, with 3 deaths; mortality, 6.9 per cent. Of these 43 cases 4 were malignant strumata with 1 death; mortality 25 per cent. The remaining 39 were non-malignant in nature, with 2 deaths; mortality, 5.1 per cent. Zesas reports 50 cases from 1880 to 1887, with 2 deaths; mortality, 4.1 per cent. Liebrecht gives a table of 422 thyroidectomies for benign goitre, with a mortality of 7.92 per cent. Bruns and Rotter together report 50 cases with 30 deaths, a percentage of about sixty.

Kocher, in summing up his cases for the last five and one-half years, gives 250 cases with 6 deaths; 2.4 per cent. Of these there were 3 in 20 cases of malignant disease, and 1 in 5 cases of Basedow's disease. Leaving these out, we have for simple goitre 0.8 per cent. Of the two remaining, one was a death from chloroform poisoning, the other was in the last stage of asphyxia when operated upon.

As to the development of cachexia strumipriva, we find that the largest collection of cases was made by the Clinical Society of London. This report comprises 277 cases of total thyroidectomy in all. In 22 cases the goitre returned, or hypertrophy of the accessory thyroid glands followed. In these no symptoms occurred. In 186 cases no symptoms of cachexia strumipriva were present, although no such recurrence of the goitre took place, nor was there any observable compensatory hypertrophy of accessory thyroid glands. In 69 cases there were symptoms present suggestive of cachexia strumipriva. We have thus 69 cases in 186 in which no recurrence of the goitre nor any hypertrophy of accessory glands was found, and yet in these there were symptoms of cachexia strumipriva in thirty-three per cent. In partial thyroidectomy we find that in 550 cases symptoms were present 6 times; one per cent.

These symptoms appear clinically in two forms. The first form comprises all those cases in which the symptoms are well marked. The second form embraces those cases in which only a few of the symptoms are present and these symptoms are not permanent, but disappear in from three to four months. Such cases have been observed by Julliard, Reverdin, Baumgärtner, and Zesas. Such symptoms are seen mostly in the mental sphere. The patients become inattentive, falling asleep when talking to anyone, and showing slowness in all mental actions.

If we seek for a cause of these transitory symptoms following the operation, we shall most probably find it in the fact that the portion of the gland remaining after the operation was not sufficient to carry on the function of the gland, and only when it hypertrophied did we find any diminution in the symptoms. Such an office might be carried on by the accessory thyroid glands, and Streckheisen, Zuckerkandl, and Gruber have shown that these accessory glands are by no means uncommon. These are divided, according to their position, into superior and inferior median, lateral, and posterior glands. Of these, careful observations have been made on the median glands only. The superior median arise from the processus pyramidalis, either being connected directly with it or without any connection, or they occupy its place entirely. The processus pyramidalis, which often occupies the position over the thyroid cartilage as far as the hyoid bone, is much more frequently present than was formerly suspected. This processus pyramidalis was present in from sixty-eight to seventy-four per cent. of the cases examined.

Of the superior accessory thyroid glands, *i.e.*, those situated in the space between the isthmus of the thyroid gland and the hyoid bone, Streckheisen found them 33 times in 153 cases; twenty-one per cent. Of these 33 cases, 16 times there was also present a processus pyramidalis. Of the glands above the hyoid bone (the suprahyoid accessory thyroid glands) Zuckerkandl found 57 in 200 cadavers examined for this purpose; twenty-eight per cent.

In 130 cases examined by Streckheisen for accessory thyroid glands, 36 times glands were found, either præhyoid, suprahyoid, epihyoid, or intrahyoid; *i.e.*, twenty-seven per cent. Gruber found the superior accessory glands to occur in one case in thirteen, and the lateral accessory glands once in ten times. Madelung has shown that the lateral accessory glands occupy very irregular positions in the lateral portion of the neck, but are generally close to the lateral lobes of the thyroid glands between the lower jaw and the clavicle and sternum. The inferior glands are situated below the isthmus upon or beside the trachea. Sometimes they lie deeply within the thorax, upon the superior or posterior surface of the aorta (Carle). The posterior accessory glands are situated at the junction of the pharynx and œsophagus and close to the posterior surface of the lateral lobes, or between the trachea and œsophagus, or between the œsophagus and vertebral column. In four cases accessory thyroid glands have been found within the trachea. We may thus compute, from the frequency with which these glands have been found, that in about one-half of the cases there will be accessory glands present. It is very probable that with a more intimate knowledge of these glands their frequency will be found to be greater.

The pathogenesis of this cachexia has been variously explained.

1. The theory is that it results from a diminished amount of oxygen on account of the atrophy of the trachea, which latter was due to the ligature of the thyroid arteries (Kocher).

2. Baumgärtner seeks the cause in an imperfect opening of the glottis due to disturbances of innervation, and later to changes in the sympathetic nerves as the result of mechanical or chemical injury in the wound, which produce an ascending neuritis extending to the cervical ganglia and central organs.

3. Gussenbauer, Mikulicz, and J. Wolff ascribe the cachexia to the injury to the nerves during the operation.

4. L. and A. Reverdin believe the cause to reside in vaso-motor disturbances dependent upon a centre situated in the thyroid gland.

5. .Bircher states that the cause is not the removal of the thyroid gland, but that there is a general infection of the system, whose first stage is the development of the goitre and whose second stage is seen in the symptoms characterizing cretinismus.

6. P. Bruns ascribes to the thyroid gland the function of aiding certain metabolic processes, which are indispensable to the normal activity of the central nervous system.

We may compare these various views with the results of the experiments upon animals. The latter show us that: 1, The total removal of the thyroid gland with the accessory glands produces death; 2, in the removal of one-half of the thyroid gland, with hypertrophy of the remaining half, no symptoms follow; 3, with atrophy of the remaining half, symptoms do follow; 4, in the removal of one-half of this half, with hypertrophy in the portion remaining, no symptoms are observed; 5, in the removal of the whole gland, with hypertrophy of the accessory glands, *i.e.*, superior, lateral, or aortic thyroid, no symptoms have followed (Halsted). We may also add to these experiments the clinical observations as collected by the Clinical Society of London, and the exact physiological investigations of Horsley and Fuhr. As a result of all these, we are led to the belief that the symptoms following the loss of the thyroid, either from operation or as a result of disease, should be ascribed not to any injury to nerves or vessels in the neck, nor to any general disease existing before the operation, but to the loss of a function which is indispensable to proper activity of the nervous system.

Dependent upon the observations that the cachexia will not occur if a portion of the gland remains, Mikulicz has recommended his so-called *resection* of the thyroid gland, in order not only that a portion of the gland may be left, but also that any injury to the nerves or vessels may be avoided. Instead of this mode of operation, but for the same reasons, Wölfler recommended the ligature of the thyroid arteries in order to produce an atrophy of the gland. Such a method might be of advantage in the vascular or aneurismal variety, but certainly not in the colloid or cystic forms. Rydygier has lately reported sixteen cases, in fifteen of which all four arteries were tied, in one case two arteries. They were observed by him for one and one-half year, with no symptoms of cachexia strumipriva following. He recommends the ligature of the arteries for recent cases of parenchymatous goitre. The method of ligation for the superior thyroid artery is the usual one along the anterior border of the sterno-mastoid muscle. The inferior thyroid artery is ligated either by an incision along the anterior border of the sterno-mastoid muscle (Velpeau) or in the cleft between the sternal and clavicular portions of the same muscle (v. Langenbeck). On account of the many difficulties both in the topography and in the depth at which one must work, Drobeck has devised a somewhat easier method. An incision is made beginning one or two centimetres above the clavicle on the lateral border of the sterno-mastoid muscle and ending at the level of the thyroid cartilage. The subclavian triangle is exposed, and the contents pushed aside until one finds the scalenus anticus muscle. Here are seen the phrenic nerve and the ascending cervical artery. The phrenic nerve and muscle are covered by the deep fascia. The internal jugular vein, carotid artery, and vagus nerve are held to the inner side by a blunt retractor. The carotid tubercle is felt. The artery lies below it 1 ctm. in old people, and 2 to 3 ctm. in younger people, on the inner border of the scalenus anticus muscle. Care must be taken that no injury occurs to the vertebral vein and artery. The cervical fascia must be divided before ligation. Rydygier prefers an incision situated 2 ctm. above the clavicle and parallel to it and about 6 to 8 ctm. long, which crosses the sterno-mastoid muscle so that a little less than one-half lies over the muscle. In other respects the method is similar to that of Drobnik. He claims for this a cosmetic effect, as the cicatrix lies beneath the collar and is not seen. Rydygier also prefers, for the same reason, i.e., a better cosmetic effect, in the ligation of the superior thyroid artery an incision at a right angle to the inner border of the sterno-mastoid muscle. The intra-capsular or intra-glandular enucleation of the struma, as recommended by Julliard and Socin, however, seems to be the most certain and radical of the methods for partial extirpation, with the slightest possible danger from hæmorrhage or injury to important nerves. For cystic strumata the intracapsular enucleation, first recommended by Julliard, seems to be the safest and least dangerous of all methods. It requires the shortest time for healing and is easily accomplished. In the parenchymatous strumata the intraglandular enucleation recommended by Socin and Garrè is applicable to those cases in which small or moderately large nodules are present, and are distinctly circumscribed. The bleeding is more abundant than in the cystic variety, in which it is very slight, as the vessels of the capsule are already obliterated.

This intracapsular or intraglandular enucleation is, moreover, less liable to be followed by tetany or cachexia strumipriva than other modes of partial thyroidectomy. In fifty cases Socin saw no case of tetany or cachexia. Should the parenchymatous goitre involve the whole or one half of the gland, or be composed of a large number of cysts and nodules, not covered with the parenchyma of the gland, a partial extra-capsular enucleation is to be preferred to the intra-capsular, as the bleeding is much less by the former and the time required for the operation is less. In just such a case, P. Bruns lost his first case in seventy consecutive operations.

If we thus consider the methods of operation for strumata, we should select when possible the intra-capsular or glandular enucleation; when this is not possible, partial or total thyroidectomy. We may thus hold to the general rule, that when the disease is circumscribed we are to make use of some form of intra-capsular operation, and when we have to do with a diffuse disease we must use the extra-capsular operation.

Of the first variety, we may include Socin's method of enucleation. This is especially applicative to all cases of cysts, and small or moderately large and distinctly circumscribed nodules in which the vascular supply is not excessive. Kocher's evidement or evacuation differs from the enucleation in that, instead of dividing the glandular capsule down to the struma and shelling it out, he incises immediately through the strumatous nodule, and removes it either with the fingers, or with a sharp spoon. This method Kocher himself recommends where the separation of the strumatous nodule from its surrounding tissue is too difficult and bloody, or where during an operation dangerous symptoms of suffocation are present.

It is to be recommended especially for those cases consisting of large and soft, but circumscribed, nodules with abundant vascular supply.

Of the second variety we may include the resection of Mikulicz or Kocher, and the extirpation.

Kocher's resection has been recommended to supersede Mikulicz's operation, simply on account of the possible danger of injury to the nerves in the application of the ligature to the stump. Such a result, however, has not been present in those cases reported by Mikulicz. This method, which is to be considered the one applicable to the greater number of cases of struma, except in the malignant, diffusely infiltrated, and the diffuse hypertrophic strumata for which extirpation is alone suitable, consists in two principal steps:

1. If we wish to preserve as much as possible the function of the gland, we omit the ligature of the superior and inferior thyroid arteries, if not, this is done as in the case of extirpation, early in the operation. 2. After the exposure of the anterior surface of the struma, the isthmus is ligated. A vertical incision in the thyroid gland is now made at the base of the struma, down to the middle of nodules, and with the scissors or knife the gland is separated from the inner and posterior surface of the struma (all bleeding being stopped as one advances), until one arrives upon the outer edge of the posterior surface, where there is no danger of injuring the recurrent nerve. Here the glandular capsule is again divided upon the outer side of the struma. This is practically an enucleation with a circular division of the gland.

This operation has the advantage that as much healthy glandular tissue may be left as is possible. It is a safe method so far as concerns the injury to the recurrent nerve.

Mikulicz's method is equally advantageous, but requires some care in the clamping and ligature of the pedicle, so as not to include the nerve. In his hands this difficulty has not been present, and it thus recommends itself for adoption in the same class of cases.

Extirpation, either partial or complete, must be reserved for cases of malignant, diffusely infiltrated, or hypertrophic and diffuse strumata. *Frank Hartley.*

TOBACCO HABIT. The term tobacco habit is employed to designate the custom of using tobacco in any form, whether by smoking, by chewing, or by snuffing; but the phrase has also acquired a more restricted sense, meaning the over-indulgence in tobacco, which is characterized by definite symptoms of poisoning, mainly of a dyspeptic and neurotic character. Since there are all degrees of this habit, it is best to consider, first, briefly the properties and physiological action of tobacco; secondly, the general effects of its use; and finally, the special symptoms of severe tobacco poisoning.

Tobacco is made from the dried leaves of an annual plant called *Nicotiana Tabacum* Linné (Nat. Ord. Solanaceæ). It was found, on the discovery of America, to be used by the natives as far north as Virginia. Its consumption did not become general among civilized people for some time thereafter. M. Jean Nicot, a French ambassador to Portugal, first brought the attention of scientific men to it in 1560, and made it fashionable in France; hence the name Nicotiana. It was introduced into England in 1565, by Sir John Hawkins. The plant grows from three to eight feet high, and bears light greenish, funnel-shaped flowers.

The valuable properties of tobacco reside only in the leaves, which are from fourteen to twenty-four inches long, six inches wide, oval or ovate, lanceolate, acute, entire, thick, heavy, pubescent, friable, bright green if fresh, mottled brown, if dried. As the plant grows they become oily and semi-resinous, and when dried and "cured," by partial sweating, the aroma increases and the flavor improves. They have a nauseous, bitter taste and strong, peculiar odor. The darker leaves are the stronger.

Tobacco contains: 1. Nicotine, an alkaloid which is the most active principle. 2. Nicotianin—"tobacco camphor"—got by distillation of the leaves (fresh or dry) with water. It is a fatty matter, occurring in minute acicular crystals. It has little taste, but a tobacco odor. 3. Albuminous bodies. 4. Resinous matter. 5. A large amount—sixteen to twenty-seven per cent.—of inorganic salts. The ash contains about twenty-five to fifty per cent. of lime, and thirty per cent. of potassium salts. The principal acids represented are nitric, phosphoric, and malic. The unusual proportion of inorganic matter makes a tobacco crop very exhausting to the soil.

NICOTINE (nicotia) was first isolated by two German chemists, Posselt and Reimann, in 1828. It occurs in tobacco as a malate, in proportions varying between two per cent. and eight per cent. Good Havana contains two per cent., and Virginia 6.9 per cent. (Orfila). The cultivation of tobacco aims at the increase of the aromatic principles and the diminution of the nicotine. Nicotine contains nitrogen in greater proportion than any other product of its class. Pure nicotine is a volatile, inflammable, oily liquid, soluble in water, alcohol, ether, and oils. Exposed to light, it turns red-brown. With acids it crystallizes. It has a hot, sharp, bitter taste, and an alkaline reaction. The odor is feeble if cold, irritant if the alkaloid is heated. It is obtained by distillation with an alkali.

Nicotine, when injected into an animal, at first slows the heart without enfeebling the force of contraction. It may even stop the beats for a few moments, after which the heart regains its normal rhythm, but stimulation of the vagus is without effect. Experiments with other alkaloids, like muscarine, assist in determining the mode of action of nicotine. When the heart has resumed beating after nicotine poisoning, muscarine, which is a known cardiac muscle poison, will bring it to rest permanently. It is, therefore, shown that nicotine does not poison the heart muscle, but it first excites the terminal filaments of the vagus and slows the heart; it then exhausts them (Foster), preventing other alkaloids from affecting them, and allowing the heart to beat faster under the influence of sympathetic or of intrinsic stimulation. This disturbance, in greater or less degree, of the balance of nerve forces acting upon the heart, accounts for the palpitations which characterize the tobacco habit; and the fact that nicotine does not destroy the heart muscle power makes it rarely fatal as a cardiac poison.

Nicotine injected into warm-blooded animals causes excitement, dyspnœa, muscular tremors, evacuation of urine and fæces, staggering, clonic convulsions, paralysis, and death. It affects all classes of animals, but does not particularly injure plants; tobacco fumigations are therefore used in green-houses to destroy insect life. Some animals, like goats, can eat tobacco leaves with impunity, but they are severely poisoned by the fumes (Richardson). Nicotine in man causes vomiting, purging, "sinking" at the epigastrium, vertigo, muscular tremor and weakness—all the symptoms of acute tobacco poisoning. Nicotine is far more active than tobacco itself, and it causes death quicker than any other poison except prussic acid (Stillé). One drop kills a rabbit in three and a half minutes. A thirty-second of a grain causes toxic symptoms in man, and one-sixteenth of a grain has produced muscular spasm and other effects lasting for three days.

One case of death in three minutes has occurred (Taylor), and another in five minutes, in man. With large doses animals utter a loud cry, fall, and pass at once into convulsions, which soon terminate in paralysis and coma

Tobacco Smoke consists of aqueous vapor, nicotine, free carbon soot in minute particles, and if it be passed through a strong solution of potassium hydrate, and afterward through dilute sulphuric acid, the KOH separates CO_2, CO, acetic, formic, butyric, valeric, and other acids, including a trace of prussic acid, with creosote and some hydrocarbons. The H_2SO_4 fixes ammonia and a series of oily bases parallel to the aniline series. Of these pyridine, C_5H_5N is the lightest, and viridine, $C_{12}H_{19}N$ is the heaviest (Eulenberg and Vohl). The former is more abundant in pipe tobacco, the latter in cigar smoke. Collidine is formed from cigars when smoked with free access of air, and it is far less active than pyridine. These various bases are not all formed in ordinary smoking, for a more rapid and complete combustion is required to decompose the resin into new products. Dry distillation yields a volatile empyreumatic oil ("oil of tobacco") which collects in old pipes and, if inhaled, gives a sense of oppression, and an unpleasant odor to the breath. The odor of "stale" tobacco which clings to clothing and to smoking-rooms, and which is exhaled by the skin, is due to this oil.

In common combustion the nicotine and empyreumatic oil are always developed and inhaled, and the effects of smoking are due to them.

Prevalence.—It is impossible to estimate the number of cases of the tobacco habit. Every physician repeatedly encounters patients with whom he must restrain or interdict the use of tobacco. Laymen generally acquire for themselves a knowledge of the "poison limit" of tobacco, and after one or two experiences in slightly overstepping, learn to avoid it. Tobacco, however, in common with other stimulants and with narcotics, often enslaves the user to a degree which is wholly unsuspected, until through some reason it is suddenly withheld, when the craving for it becomes intolerable. The symptoms of tobacco poisoning from excessive smoking are so well understood by laymen, and for the most part so easily recognized by them, that they can usually control them without resorting to a physician's aid. The physician has therefore to deal chiefly with, first, those cases in which the habit has so undermined the will power as to make the patient a helpless victim of grave functional disorder; and secondly, with milder cases in which the symptoms are obscure, or the concurrence of cardiac or other disease renders the use of tobacco in any quantity most deleterious. Attempts have been made by Anti-Tobacco Societies to summarize statistics regarding the prevalence of the tobacco habit in its various degrees. It is customary in hospitals to refer to it in the case histories. But for the reasons above given, it is seen that such statistics are often useless, and they may be even harmful in exaggeration. A few figures from the Report on Tobacco of the U. S. Census of 1880, will give a better idea of its widespread use. In 1880, there were made in the United States alone over two billion cigars, over four hundred million cigarettes, and over one hundred and thirty-six million pounds of "manufactured tobacco," *i.e.*, tobacco prepared for smoking in pipes and for chewing. There were 638,841 acres under tobacco cultivation, producing 472,661,158 pounds, and attempts were being made in every State and nearly every Territory to cultivate it. The value of tobacco exported yearly from the United States varies between twenty-five and forty-five million dollars.

It is futile to attempt to compute the total number of those who use tobacco in the community. Many who would smoke are deterred by the expense involved, or by chronic maladies, or through fear of yielding themselves uncontrollably to the "Tobacco Habit." In some countries, particularly in the East, nearly every adult male smokes, and many women do so also. In the United States, about all that can be said is that the majority of men, and especially a large majority of the male laboring population, use tobacco in one or other form. Its use among native American women is almost unknown (except among the lowest classes in the South), and wholly unknown among the best classes of society. Indian women and many foreign laboring women, especially the Irish, make occasional use of a pipe. Cases of tobacco-poisoning among women are therefore extremely rare.

The extent to which the tobacco habit (in its general sense) prevails among all civilized and many uncivilized peoples, supplies an easy means for supporting governments by taxation. In England and Ireland attempts were early made to cultivate tobacco, but this has been prohibited by law, in order to enable the government to derive a more certain income by taxation of the imported article. In France there exists a government monopoly of the sale of tobacco, which amounts to 300,000,000 francs per annum. In the United States, in 1885, the receipts for internal revenue, from the tobacco tax alone, amounted to $26,407,088. The North American Indians attach great formality to the smoking of tobacco upon all state occasions, and the "pipe of peace" has become a universal emblem.

Influence of Different Forms of Tobacco—Cigars.—Nearly one-half of all the tobacco grown is made into cigars. They vary greatly in quality and strength, and therefore the effects produced by them cannot be classed as especially differing from other forms of tobacco. Probably a mild, light, good cigar is the least likely, of all the kinds of tobacco, to produce ill effects. Partly smoked cigars which have been relighted, are more bitter in flavor, and the nearer the butt, the stronger the effect produced.

Pipe Smoking.—Many smokers find that they can smoke pipes with less injury than cigars. Much, however, depends upon the mode of use. The pipe-stem should be long enough to cool the smoke, and the bowl should be made of some porous material, like meeramount, with a small reservoir beneath it. The reservoir absorbs the nicotine in products somewhat (which cause it), and the reservoir collects an oily material, one or two drops of which, if worked in through a dirty pipe and taken into the stomach, produce most violent toxic effects. Mild tobacco should be used, and the pipe kept carefully cleaned. In both pipe and cigar smoking the last portion of tobacco smoked is the strongest, because of the absorption by it of some of the products of earlier combustion.

Cigarettes are, upon the whole, the most injurious form of tobacco. Not, however, because they are at all harmful if smoked in moderation, but because they are particularly affected by the youth of the country. Small boys, even under the age of puberty, are sometimes seen smoking them, and youths of sixteen to twenty years are very apt to smoke them to the detriment of their health. Many men actively employed have the leisure for only one or two cigars a day, but they smoke cigarettes in excess because, if interrupted, it is easy and inexpensive to light a fresh one. In this way the taste for tobacco is greatly fostered, until it becomes an abnormal craving. Cigarettes are made of all grades of tobacco, but they are usually inferior to cigars. The best are rolled by machinery, which secures perfect cleanliness, and they should be covered with good French linen paper of delicate texture. There is no such thing as "rice paper" used, as is claimed, for wrappers. The smoke of inferior grades of paper is somewhat irritant to the respiratory mucous membrane, but it is not otherwise especially poisonous. Many prefer to roll their own cigarettes to insure better qualities of tobacco and of paper. A certain number of cigarettes are rolled in tobacco leaves to obviate the objections raised against paper, but they are less popular. The practice of inhaling cigarette smoke, that is, attempting to draw it into the bronchi, retaining it as long as possible, and exhaling it through the nose or mouth, is highly pernicious.

Chewing Tobacco produces constitutional effects similar to those observed from smoking, but it occasions far less local irritation. It is very often the cause of dyspepsia.

Snuff is prepared by rubbing dry tobacco leaves to a fine powder in a mortar. It is then flavored by various aromatics, and is used in the nose by inhalation. In some localities it is placed directly on the palate by a wooden spoon, and the process is called "dipping" (Basiger). Snuff was first introduced to civilization by the Spanish. Of late years Scotch snuff is the favorite. A century ago, and even early in the present century, the habit of snuff-taking was very prevalent in good society among both sexes. Much formality and exchange of courtesy attended its use, and lavish expenditure was made upon jewelled snuff-boxes. The snuff habit rarely produces the neurotic symptoms acquired from smoking and chewing, but it tends to deform the nose by causing congestion of the Schneiderian membrane, and dilatation of the superficial capillaries, and the particles of tobacco dust which find their way into the upper air-passages are highly injurious irritants. The reflex nasal irritation stimulates the cerebral circulation, produces a feeling of comfort, and enables one to think more clearly: it "clears the head" (Brunton). The use of snuff in polite society is now obsolete in America, and almost entirely so in European countries. A comparatively small amount is sold annually for use among the poorer classes.

Tobacco has been used medicinally in the form of fumigations, stupes, and as an infusion or smoke injected per rectum for the purpose of killing intestinal worms, (ascaris and oxyurides). Before the introduction of anæsthetics it was employed as an enema to relax spasm of the muscles during surgical operations, such as reduction of hernias or dislocations. None of these usages are now justifiable, for the drug has several times caused death. Thirty grains by enema have been fatal (Copeland). Tobacco diminishes the venereal appetite when used as a drug, and checks chordee and priapism. It has also been used to promote diuresis in dropsy. It has been used in tetanus, and as an antidote in strychnine poisoning (Haughton). Spasmodic asthma has been relieved by inhaling tobacco (Trousseau) but its action is unreliable. There are no officinal preparations of tobacco. Tobacco leaves have also been applied to the skin as a poultice, and the oil as an ointment for various ailments, such as erysipelas, scabies, gout, etc. Soldiers have been known to apply them in the axilla to produce vomiting and other constitutional effects, in order to escape from duty. Several deaths have occurred from application of tobacco to the abraded skin (Bürger).

It has long been a popular idea that tobacco smoke was a germicide, and therefore an antidote for contagious diseases. Professor Tassinari, of Pisa, has lately shown that tobacco smoke does retard the development of certain bacilli, and prevents the growth of others, especially those of cholera and typhus fever.

Adulteration of tobacco, and especially of cigarettes, with opium and other deleterious ingredients, is frequently assigned as a potent cause of the ill effects of excessive smoking. It is claimed that cigar butts are collected and ground for use as cigarettes and pipe tobacco. In England there is far more adulteration of tobacco than elsewhere, and stringent laws have been enacted to suppress it. In the United States, although much inferior tobacco is sold, it is probably very seldom adulterated, for the simple reason that it is far cheaper to use more tobacco than to put in foreign substances. One stale cigar stump added to a few pounds of smoking tobacco so destroys the flavor, as to require relatively great expense to make it palatable again. It is well known that inferior grades of tobacco are flavored with liquorice to disguise the bitter taste, and that syrups and pure glycerine are added in small amounts for the same reason, and also to maintain a proper degree of moisture; but these substances are not to be regarded as adulterants, and they are certainly not injurious to health.

Effect of Tobacco upon the System. Circulation.—In almost all cases of the tobacco habit the heart action is functionally affected. Long-continued over-excitement of the heart and disturbance of its rhythm may be predisposing causes of cardiac hypertrophy, dilatation, and valvular insufficiency. In the milder cases the heart action becomes irregular only for a little while after each use of tobacco, and is normal in the intervals of smoking. In other cases the patient suffers from palpitation whenever the least exertion or excitement stimulates the heart, and in the worst cases the heart rhythm becomes constantly irregular; every fourth or fifth beat may be omitted or very feeble, and the pulse-rate as a whole may be increased fifteen or twenty, or even more, above the normal. The patient may be annoyed by the sensation of his heart-beats, and his attention being directed to his pulse, he is apt to increase the palpitation by nervous anxiety. Sometimes the pulse beats at the normal rate per minute, but there is irregularity in the force or in the succession of beats. Bruits are rare, but they may occur as a result of (1), altered tension of the heart muscle or valves; (2) altered force of impact of the heart against the lungs and chest wall; (3) anæmia due to general debility. They are purely functional, and disappear with improvement in the heart action.

Attacks of angina pectoris have been attributed to the tobacco habit. Such cases are rare, although patients often complain of precordial "oppression," dull pains, etc., probably the result of dyspepsia.

If tobacco is well borne, and if used in moderation, it has a tonic effect upon the circulation, increasing slightly both the frequency and the force of the cardiac pulsation, and, therefore, raising temporarily the arterial blood-pressure. In larger doses the pressure falls considerably.

The Blood may become anæmic in the course of the tobacco habit, but this is due rather to impairment of digestion and of the general health than to any specific action. In cases of fatal acute tobacco poisoning the blood does not readily coagulate after death. The same is true of many poisons. Crenated red corpuscles are found in abundance (Banfield), and the hæmoglobin is diminished (Richardson). The blood absorbs many of the ingredients of tobacco with great rapidity, and distributes them so as to quickly produce constitutional effects.

Alimentary Canal.—The mouth, tongue, and fauces usually become dry, or at least feel so to the patient, although abundant watery saliva may be secreted. Their mucous membrane becomes congested. In bad cases of the habit from pipe smoking the heat of the pipe, combined with the irritation of the ammonia, nicotine, etc., may produce ulceration of the mucous membrane of the lips, gums, or tongue adjacent to the pipe-stem. The mouth may become lop-sided from continually carrying a pipe or "quid" upon one side. Rarely, syphilis has been transmitted by smoking pipes used by syphilitic persons, or cigars which have been moistened by rolling their wrappers in the mouth. In this way inoculation occurs through any abrasion of the mucous membrane of the mouth.

The tongue may be heavily coated as a result of dyspepsia, or it may be dry and red. Not infrequently, after first smoking two or three pipes, the tongue feels exceedingly dry, and there is a sharp burning pain at the tip. This is due rather to the ammonia evolved with the smoke than to its heat. The tongue soon becomes inured to this in habitual smokers.

Carcinoma of the mouth and throat has often been attributed to smoking. Certainly smoking affords no immunity from it, but the worst cases of tobacco habit may occur without it, and there is no scientific ground for the belief that smoking, *per se*, produces cancer. It is, however, true, with regard to epithelioma of the mouth, that when it occurs in persons having a decided tobacco habit it is prone to affect the lower lip, and the side of it where the pipe or cigar commonly presses. This is said to be the case especially where a short-stemmed pipe, constantly saturated with nicotine, has been long in use. It is known that where the carcinomatous or epitheliomatous diathesis exists, the disease is often focussed at the site of some constant local irritation or injury. Given, then, a predisposition to epithelioma, and the irritation of smoking may focus the disease in the mouth or throat. It is worthy of note that both the mouth and throat are far more injured by smoking than by chewing. Much smoking leaves a black or brown deposit of carbon on the teeth, and the gums become pale and unduly firm and contracted. Chewing stains the tongue and mucous membrane of the mouth, and the beard if there is careless expectoration. The sense of taste is not impaired by smoking. Great smokers may be good judges of the flavor of wines, but the appetite, especially for sweets, is often, not always, diminished. The fact that tobacco smoke so readily gives constitutional symptoms after inhalation, affords an admirable physiological illustration of absorption by the mucous membranes of the mouth and pharynx. Nicotine is a highly diffusible crystalloid. The flow of *gastric juice* and of *intestinal secretion* is stimulated by tobacco in moderation. *Peristalsis* is decidedly increased at first, but, later, constipation ensues from excessive stimulation. Gastric catarrh may result from excessive smoking.

The Pupils are contracted when tobacco is introduced in the eye, or taken by the stomach. In severe cases of tobacco habit there is an abnormally long retention of images by the sensorium when the eye is withdrawn from them (Richardson). Photophobia, muscæ volitantes, etc., are said to occur. Tinnitus aurium has been noted, probably due to the disturbed circulation.

The sense of smell, unless snuff be used, is little, if at all impaired.

Secretory System.—Constant irritation of any gland tends for a certain time to increase its functional activity, with the effect of producing a more watery ("paralytic") secretion with fewer of the normal solid ingredients. Tobacco affects the salivary glands in this manner. Many persons expectorate a great deal while smoking, and all do so while chewing tobacco. In this way the body loses a large amount of water, thirst is increased, and the composition of the saliva is so altered as to impair its usefulness as a digestive agent. There is an increase in the deposit of tartar (salts of lime) on the teeth. Nicotine, like physostigmine, acts on the peripheral ends of secretory nerves, also on the nerve centres. Section of the chorda tympani therefore greatly diminishes, but does not stop, the secretion. Nicotine is less active in these respects than pilocarpine. The practice of expectorating while smoking is wholly unnecessary. It is claimed by some that the saliva, if swallowed, carries more of the noxious ingredients to the stomach, but the difference effected by expectoration, if any, is very slight.

The *perspiration* is increased by the use of tobacco in excess, and the odor of tobacco is perceived in the skin of persons who, without smoking themselves, have inhaled for some time the atmosphere of a smoking-room. Many cannot smoke even a single cigar without exhaling the odor of tobacco by the skin for several hours. Those having a diminished area for pulmonary exhalation, asthmatics *et al.*, retain this odor for a much longer time (Richardson). Nicotine and the resinous body are eliminated by the kidneys (Biddle). It is said that tobacco has a diuretic action, but the effect is not marked.

Respiratory System.—Habitual smokers almost invariably have more or less congestion of the pharynx. Catarrh and hoarseness are so frequent as to give rise to the name "smoker's sore throat."

The mucous membrane is thickened and engorged; there is profuse watery secretion of the mucous glands, succeeded by dryness, with soreness and exfoliation. Speaking, singing, and swallowing are all interfered with. The tonsils are enlarged, soft, and tender. The chronic laryngitis, and pharyngitis, and post-nasal catarrh are exceedingly rebellious to treatment so long as the habit continues. They are more easily acquired from cigars and cigarettes than from pipes. A cough following a simple cold often remains obstinate until smoking is stopped. Pulmonary lesions are not often to be traced to the tobacco habit; but when they are produced in other ways they are fostered by it. Phthisical patients are especially in need of pure air and of a normal heart-action, and therefore tobacco is injurious. Fortunately, persons having severe pulmonary disease seldom care for tobacco. When tobacco of poor quality is used and inhaled deeply in the bronchi, it may give rise to subacute or chronic bronchitis, or to bronchorrhœa, and the functional weakness of the heart, produced at the same time with impaired digestion, tends to retard recovery. The carbon soot from smoke inhaled discolors the bronchial secretion.

Nerves and Muscles.—Tobacco expends its action upon the peripheral nerves and cord, and does not, except indirectly as the result of severe poisoning, affect the brain. Nicotine, like curare, abolishes first the conductivity of motor nerves, and then of motor paths in the spinal cord, without impairing the response of muscles to direct local irritation. As a result of the failure of the nerves to excite muscular contraction there are weakness, inability to stand, great depression of the respiratory movements, and finally death from failure of the muscles of respiration. The heart may continue beating after the respiration has ceased. Tobacco smoke inhaled by a rabbit through the nostrils, or blown up the nose from a tracheal cannula, arrests breathing in expiration, from irritation of the vapor upon branches of the fifth nerve; but it has no such effect if blown into lungs (Kratschmer).

Methyl and ethyl, derivatives of nicotine, have no paralytic action upon the nerves (Brunton). In the case of a patient, who smoked in one day forty cigarettes and fourteen cigars, paralysis of both legs occurred, with bronchorrhœa (Richardson). All motor depressants act as synergists to tobacco. Brunton claims that the stimulus to mental work derived from smoking comes in great part from the warmth of the smoke, which acts on the sensory nerves of the mouth and reflexly stimulates the vaso-motor centre which dilates the vessels of the brain.

Injurious Effects.—Tobacco in any form is highly injurious to children and youths. It impairs digestion, checks nutrition, stunts the growth, and produces serious nervous disorder. It is said to induce premature puberty. The writer has seen chorea in a child of nine years, with violent exacerbations, caused by the habit of chewing tobacco. In military and naval academies, etc., stringent rules are enforced against the use of tobacco. In Germany its use by youths is prohibited by law, and in several of the United States it is illegal to sell tobacco to any one under sixteen years of age.

It is injurious to those who are subjected to severe mental strain, or severe physical training. Athletes, boating crews, prize-fighters, *et al.*, are obliged to temporarily abstain from tobacco, as are those who are employed in very delicate manual work, such as hand section-cutting for the microscope. It is injurious to those who are of a highly neurotic temperament, or who suffer from either functional or organic affections of the heart and lungs. If sudden abandonment of the use of tobacco causes discomfort, restlessness, and craving, it indicates the degree of influence which it has upon the system. If the odor of tobacco lingers long in the breath or perspiration, it is an indication that the system is saturated with it.

Some forms of tobacco are more harmful than others. Generally only the leaves of the tobacco plant are used, but Latakia (Syrian) tobacco has the buds and flowers added. The dark, rich color of Cavendish is produced by sprinkling the leaves with an infusion made from the midribs, stalks, and other waste parts. They are then fermented a second time, dried, and pressed by machinery into cakes. Cavendish, pig-tail, etc., yield more fluid residue than Turkish tobacco. The latter dries the tongue from excess of ammonia, but upsets digestion less. Cigars which are "good" cause dyspepsia more readily, for nicotine is more readily formed from them. Most men can smoke much more at sea, or in the open air, where elimination is freer, and an extraordinary degree of toleration for tobacco is acquired by many, after long practice.

Lesions of varied character have been attributed to the tobacco habit, such for example as atrophy of the auditory and optic nerves, apoplexy, and the like. Such cases, however, are without foundation.

SYMPTOMS OF A MILD CASE of tobacco poisoning, such as may result from smoking the first cigar, are these: Vertigo, headache, and faintness are soon followed by nausea and an indescribable feeling of oppression in the epigastrium; and general prostration, palpitation, pallor, and possibly dyspnœa and vomiting result. The state of the stomach and the time of day modify these symptoms. Tobacco always has more effect upon an empty stomach and if smoked early in the morning. The ill effects may last for a day or two after the first smoke. If depression occurs at once on attempting to smoke, it is an indication that even the smallest quantity of tobacco is injurious (Anstie).

SYMPTOMS OF SEVERE CASES.—The appetite fails, especially in the morning, the tongue is coated, the bowels constipated, the breath foul, and a train of nervous symptoms follow: restlessness, nightmare, insomnia, hyperæsthesia, irritability of temper, and great hypochondriasis. Attacks of nausea, and even continued vomiting, may occur. The emesis resembles that produced by antimony in the depression which follows. In the worst cases there is malnutrition, loss of weight, the skin has a sallow, yellowish hue, it is cold and bathed in profuse perspiration; often violent cramps and colicky pains accompany the constipation; there are tremors, decided muscular weakness, inability to exert the mind. The throat is congested and sore, the mouth feels parched, the tongue burns, and hot or acid foods increase the discomfort. Rarely there are superficial ulcers in the mouth. There is increased vertigo, and there may be disturbed vision. There may be slight fall of temperature owing to the perspiration and the general depression.

TREATMENT OF MILD CASES.—Temporary suspension or limitation of the use of tobacco is frequently all that is required in mild cases of functional disorder produced by its use in excess. Frequently patients need no further warning than the experience they have had. All cases, however mild, should be carefully examined as to the coexistence of possible causes or preliminary organic disease, anæmia, etc.

TREATMENT OF SEVERE CASES.—It is best to interdict entirely the use of tobacco for several months or even years. This is usually easier for the patient after the first day or two, than any attempt to abandon the habit by lysis. The diet should be regulated, the digestion aided by appropriate medicaments, and the functions of the liver stimulated. Blood and nerve tonics, as iron, strychnine, arsenic, etc., are particularly indicated. The palpitations are best controlled by heart tonics, such as digitalis, strophanthus, caffeine, cactus, and convallaria. In the experience of the writer the combination of two or more such tonics in moderate doses (*e.g.*, strophanthus with digitalis or with caffeine) is far more prompt in controlling the great irritability of the heart than is either remedy used alone. The insomnia and restlessness, which are often prominent symptoms, are frequently cured through the general improvement in circulation and digestion which follows the treatment above suggested, and without recourse to anodynes. The latter are to be avoided, if possible, because of the ease with which one "habit" may be grafted upon another in any crisis of the nervous system. Over-indulgence in strong black coffee often complicates the tobacco habit. The physician should always bear in mind the frequency with which alcoholism is associated with the tobacco habit. There is danger that in suddenly withdrawing the additional stimulus of tobacco, the craving for drink may be exaggerated, and precautions should always be taken to control both habits together.

TREATMENT OF THE WORST CASES.—In the gravest form of chronic tobacco poisoning, if the drug be suddenly withheld entirely, there may be some danger of collapse from withdrawal of the accustomed stimulus to the nerve centres, as occurs similarly in the opium habit. Fatal cases resulting from the sudden deprivation of tobacco have not been recorded. The worst cases require active treatment by means of diffusible cardiac stimulants, application of warmth, proper nourishment, etc., to guard against collapse.

TREATMENT OF ACUTE TOBACCO POISONING.—There is no definite poisonous dose. There is no reliable chemical antidote. If the drug has been swallowed, evacuate the stomach, give tannin, and observe the general rules for alkaloidal poisoning and the prevention of collapse by heat, friction, artificial respiration, and cardiac stimulation. Acute and even fatal poisoning sometimes occurs when habitual smokers on a wager smoke sixteen to twenty pipes or cigars at a sitting. Gmelin reports two such cases. In these cases very prompt treatment is necessary. Strychnine and iodides have been given as antidotes, but with doubtful benefit. Ergot, digitalis, alcohol, atropine, and ammonia antagonize the effect upon the heart and circulation.

THE HISTORY of the use of tobacco is remarkable for the violent opposition which attended its introduction and the first century of its use in Europe. James I. of England wrote a tirade against it, and Pope Urban VIII. a bull. Its use was prohibited by law in the seventeenth century in Turkey and Persia—countries where the habit is now almost universal. The literature of satire and denunciation against smoking, and more especially against the dirty habits of chewing and snuff-taking, would fill many volumes. Yet to-day there is no other one article of greater value than tobacco (unless it be alcohol) to nations as a source of governmental revenue, and the active opposition to its use is confined to a few anti-tobacco societies and an occasional enthusiast. It is difficult to believe that the use of tobacco, or the tobacco habit, will ever be abandoned, or that it will ever become less prevalent. In regard to the question so often asked every physician, "*Is smoking injurious?*" no brief answer can be truthfully given, but the following summary of the facts may be stated:

1. Both individuals and nations have attained the highest intellectual and physical development without the use of tobacco in any form.

II. Tobacco is in nowise essential for the welfare and progress of mankind.

III. Tobacco, like alcohol, is positively injurious: 1, to the young; 2, to those suffering from certain maladies, notably cardiac and pulmonary diseases; 3, to those who have a marked idiosyncrasy against it, or who have a highly neurotic diathesis; 4, to those who have not sufficient will-power and force of character to enable them to restrict its use properly; 5, to everyone, if used to great excess.

IV Many inveterate smokers have lived to be over ninety or even one hundred years of age, without having their health affected by the use of tobacco.

V. All nations and all races ascribe value to the use of tobacco as a sedative for the relief of fatigue and ennui. Smoked in moderation after meals, it stimulates secretion, aids digestion, and increases peristalsis.

Many find in it a soothing influence, it promotes reverie, overcomes weariness, and as a moderate stimulant, in a limited degree, it takes the place of scanty food (like coca, Anstie).

VI. Those who have passed middle life, and whose physical, emotional, or intellectual faculties are overburdened with the activities of modern civilization, often find that tobacco favors mental and physical calm, and counteracts nervousness and exhaustion.

VII. An enormous number of persons do use tobacco constantly without any ill effects whatever; although the tobacco habit is seductive, and, once thoroughly established, it tends to grow beyond easy control.

William Gilman Thompson.

TOES, DEFORMITIES OF THE. Many of the deformities to which the toes are liable are similar in their nature to those of the fingers.

Syndactylism in the lower extremity is less rare than is the same affection in the hand, and it is not uncommon to see two of the toes united as far as the first interphalangeal joint. As, however, the deformity does not seem to interfere in any way with the function of the foot, and as it is concealed by the shoe, it seldom calls for treatment. If in any case it be deemed advisable to release the toes it may be accomplished in the same manner as the separation of webbed fingers (see Vol. III., p. 498).

Polydactylism in the foot is frequently seen in connection with the same deformity of the hand. Amputation of the extra digits is usually needful to restore the shape of the foot, though this measure is not as imperative here as it is in the upper extremity.

Clubbing of the toes is sometimes observed along with a similar condition of the fingers in phthisis and other diseases of the thoracic organs. As the condition is merely an indication of defective hæmatosis, it calls for no special treatment.

The other non-painful deformities of the toes need no special mention, since they cause no inconvenience to the patient and seldom are brought to the notice of the surgeon. It is otherwise, however, with certain other affections which, though seemingly insignificant, are often the cause of much suffering and inconvenience, and may even interfere so seriously with locomotion that the patient becomes practically bedridden. The gouty and rheumatic deformities of the toes, as also hallux valgus and ingrowing toe-nail, have been discussed in other portions of this work, and we have to consider here only that condition known as hammer-toe.

HAMMER-TOE (Fr., *orteil en marteau*; Ger., *Zehenverkrümmung*) is an affection characterized by a permanent flexion at the first interphalangeal articulation of one or more of the toes. The second toe is the one most commonly, though not exclusively, affected. Not infrequently the deformity is seen in both feet. The third phalanx may be extended or flexed, or in a line with the second, and some French writers have accordingly distinguished three forms, named, from the fancied shape of the toe, respectively, **Z** form, **C**-form, and **L**-form. The affected joint is seldom actually anchylosed, except occasionally in the later stages, but it is simply restricted in extension; additional flexion is not interfered with, but it is impossible to straighten the toe. Not infrequently, when the deformity has existed for some time, there is a subluxation of the second phalanx upon the first.

The affection is usually the cause of a great deal of annoyance, and often of acute suffering. The impact of the tip of the toe on the sole of the shoe in walking causes pain, and sometimes an acute subungual inflammation. The pressure of the shoe upon the prominent angle formed by the flexion of the digit produces considerable irritation, which leads in time to the formation of a very troublesome corn. Sometimes a bursa develops at this point and then becomes inflamed, resulting in the production of a bunion. This may subsequently suppurate and give rise to the formation of an obstinate ulcer. Dubreuil has described this latter condition under the name of *mal dorsal des orteils*, and regards it as analogous to perforating ulcer of the foot. If neglected, this ulcer may increase in depth, and finally open into the joint, setting up an arthritis with exfoliation of the cartilage and necrosis of the phalanges.

The causation of hammer-toe is obscure. It has been attributed to ill-fitting shoes which are either too narrow or too short, and in support of this view it is stated that the deformity is never seen among Eastern peoples who do not wear European shoes. A fact which would seem to argue against this theory is that men are somewhat more frequently affected than women, although the latter are more prone to confine their feet in closely fitting shoes. It is probable that defective shoes are seldom the exciting cause of the deformity, though they undoubtedly play an important rôle in the production of the later troubles which have been described above. In many cases there seems to be an hereditary predisposition to hammer-toe, the condition being frequently present in several members of the same family. The deformity appears usually during childhood, and has even been seen in infants, and is, perhaps, due to some vice of development.

According to Shattock, who bases his views upon the results of dissection in several cases of recently amputated hammer-toe, the flexion of the toe is due to a shortening of the lateral ligaments, and not, as has been supposed by some, to a contraction of the flexor tendons or of the plantar fascia. After the deformity has existed for some time, changes take place in the articular ends of the bone similar to those occurring in knock-knee and lateral curvature of the spine. There is a wearing away of the lower half due to pressure, and an overgrowth of the upper half from which the normal pressure has been removed. When subluxation has occurred early these alterations are not so marked. When these changes have taken place, little can be hoped for from any measure except resection of the joint.

In the treatment of hammer toe little can be effected in the majority of cases by mechanical apparatus, and the same may be said of massage, though either of these measures may be useful in the earliest stages of the deformity. Mr. William Adams, who looks upon the condition as one of contraction of the lateral ligaments, advises and practises the subcutaneous division of these ligaments. After the operation the toe is bandaged to a light metal splint for some weeks to prevent a return of the flexion. Terrier makes a V-shaped resection of the joint, removing a small wedge from each articular surface, excising at the same time the callosity or bunion that has formed on the convexity of the joint. Anderson performs a somewhat similar operation, resecting the articular surface of the first phalanx. In the severest cases, in which the deformity has existed for a considerable length of time and inflammatory changes have taken place in the joint and peri-articular tissues, amputation of the toe is often the only recourse left to the surgeon. This operation, indeed, is recommended by some in all except the mildest cases, but, in view of the successful results of resection and of syndesmotomy, so radical a measure as amputation seems hardly called for.

HALLUX FLEXUS (hallux rigidus, hallux dolorosus). This is a condition allied to, and perhaps in many instances identical with, hammer-toe, in which there is flexion of the first phalanx of the great toe. The second phalanx is usually extended upon the first, and there is more or less rigidity of the metatarso-phalangeal joint. Walking is more or less painful, and the patient generally rests his weight upon the outer edge of the foot. The occurrence of the deformity is variously attributed to compression from an ill-fitting shoe, to traumatism (as from stubbing the toes), and to a breaking down of the plantar arch. Possibly any one of these factors is sufficient to produce the deformity, and in some cases it may result from the combined action of all of them. Doubtless it is often nothing else than hammer-toe affecting this digit instead of its next neighbor. All the cases hitherto reported have been in men, but this fact is probably without significance, as the number of recorded cases is not large. The only cases which the writer has seen, two in number, were in young women.

When the deformity is secondary to flat foot it will disappear upon the restoration of the plantar arch. In other cases, if massage, splints, and mild measures fail, resection will be indicated. *Thomas L. Stedman.*

UNDERWOOD SPRING, Falmouth-Fore-Side, Me., on the shore of Casco Bay, six miles from Portland.

This water is remarkable as being one of the purest known.

ANALYSIS.—One U. S. gallon contains (Bartlett):

Sodium chloride	[illegible]
Silica	[illegible]
Lime carbonate	[illegible]
Magnesium carbonate	[illegible]
Potassium sulphate	[illegible]
Organic matter	[illegible]
Total	[illegible]

A glance at the above table reveals this striking feature. Every precaution has been taken to guard the well against contamination. There are as yet no accommodations for guests, though the exceeding beauty of the locality and the unquestioned value of the water should render this spot invaluable as a health-resort. The supply seems inexhaustible; 20,000 gallons are used per day for commercial purposes, while many times that amount are allowed to run to waste.

The Indians appreciated this spring, as is revealed by the presence of huge mounds of partially burned shells in the immediate vicinity.

The well is only a few hundred feet from the waters of Casco Bay, which, with its many islands and rock-bound shore, offers a constant feast in the way of picturesque surroundings.

Its purity renders this water the best solvent for the contents of mucous cavities. It is readily absorbed and excreted, thus perfectly performing that office for which pure water only is adapted.

Therapeutically it is indicated in chronic catarrhal diseases of the alimentary canal and urinary system, rheumatism, and gout. *George B. Fowler.*

URETERS. Simple and uncomplicated disease of these tubes, outside of their pelves, is quite rare.

PYELITIS.—The most important diseased condition of the ureters is that which implicates chiefly their expanded and superior portion. It is an inflammatory or catarrhal process of the pelves of the kidneys and of their calices. It may attack one or both organs at a time.

Etiology.—Sometimes, though rarely, it may occur after exposure to cold, but its most frequent cause is the irritation of renal calculi in the pelvis, or some obstruction in the urethra, bladder, or ureter itself. When the urine is acrid or unduly acid, it excites a hypersecretion of an alkaline mucus from the muciparous glands of the pelves of the kidneys, and the presence of this mucus, together with the unduly acid urine, acts as a constant irritant to the mucous membrane of the renal pelves. In this way there is developed, first, a catarrhal condition of the mucous membrane, which is shown in the discharge of acid urine containing pus. Later, the hyperacidity is overcome by the abundant hypersecretion of mucus, a true inflammatory process is excited, and all the symptoms of a typical pyelitis are finally developed.

This is the mode of development of many of the apparently idiopathic cases. A mild form is sometimes excited by any of the varied forms of renal disease, and occasionally it occurs during pregnancy. It may also result from cystitis, ureteritis, gonorrhœal urethritis, and, in fact, from any inflammatory conditions of the urinary tract, by an extension of the same to the pelvis. With gonorrhœa, the inflammatory process in the renal pelves may develop suddenly, without any apparent involvement of the intervening portion of the urinary tract. Pyelitis may be excited by turpentine, cantharides, squills, and the many forms of irritating balsams, resins, etc., as well as by all acrid substances excreted by the kidneys.

A mild form of this disease is sometimes developed in the typhoid stage of cholera, in typhus fever, diphtheria, and in any of the exanthemata. In these instances the superacidity of the urine and increased amount of effete material eliminated, together with the general deterioration in the nutritive conditions, both general and local, are important factors in exciting the pyelitic inflammation.

A hæmorrhagic variety has been described by some writers, in which there are frequent, and sometimes extensive, hæmorrhages into the renal pelves. This condition occurs in connection with scurvy, purpura hæmorrhagica, pernicious anæmia, and chronic syphilis.

Pathological Anatomy.—The mucous membrane is very much congested and dotted with ecchymotic extravasations, and in places the epithelial surface is completely destroyed. In the most acute stage there is little or no discharge, but as the disease advances and becomes more chronic a muco-purulent secretion occurs and the membrane is relaxed and swollen. As the inflammation advances, the pelves and infundibula become enlarged and their walls thickened; the color of the mucous membrane changes to a grayish-white or slate color, and its surface is traversed by delicate capillaries. Should there be much irritation, ulceration is liable to take place, which may cause rupture of the wall and extravasation of the urine into the surrounding tissue, the peritoneal cavity, or into some of the surrounding organs, inflammation having been excited and previous adhesions formed.

The walls of the pelves may be very much distended by the retained urine and accumulated pus, and the kidneys may undergo atrophy, as in hydronephrosis. Occasionally the fluid may be entirely absorbed, the pelvis of one kidney becoming contracted into a hard capsule around its own inspissated contents, while the ureter is converted into a fibrous cord, its lumen having been obliterated. In certain cases where the inflammation has been very severe, a fibro-plastic exudation is thrown out upon the surface of the mucous membrane; this has been termed a diphtheritic pyelitis.

Symptoms.—In studying the symptoms it must always be remembered that those of the pyelitis are often masked by those due to the exciting cause. The disease usually begins, however, with a chill, sometimes a series of rigors, followed by a rise of temperature of about three degrees Fahrenheit, pain in the back, increased on pressure, and often radiating down along the course of the ureter. There is often nausea and vomiting, together with a continual desire to micturate, and pain on attempting to do so. As the disease progresses and becomes more chronic, the lassitude from which the patients suffer increases. Hectic is finally developed, and death ensues, either from exhaustion or from a form of septicæmia, or from the combined action of both.

In those cases which are due to a renal calculus, the pain in the loins is the most prominent symptom.

Another quite diagnostic symptom is the alternating discharge of clear or normal urine, and of urine charged with pus.

Urinary Examination.—The urine is usually increased in quantity, owing, perhaps, to the moderate hyperæmia of the kidneys always associated with this disease. The specific gravity is somewhat above normal, from 1.025 to 1.030, and the reaction is alkaline. Under the microscope the urine is found to contain blood, pus, and epithelial cells.

Great stress has been laid upon the character of the epithelial corpuscles in the urine and their diagnostic significance in reference to pyelitis. It, however, is well known that there is a great variety in the form of the epithelial elements found in the urine, some of which are derived from the urinary tract, and others from the generative organs, while a smaller number may come from the air-passages, the mouth, or the skin. But, of all these, the variety known as flat or pavement epithelium, the tailed cells, and the small angular cells commonly called "renal," have given rise to the most discussion.

Naturally, epithelial cells from the urinary tract are found in either sex. On the other hand, the urine of the female is almost invariably said to contain a peculiar sort of large and angular cells that have been regarded as peculiar to the sex. But all varieties, sizes, and forms of epithelial cells may come from the bladder, the ciliated form excepted. The structure of the mucous membrane of the bladder distinctly explains this, because it is divisible into three separate layers. The innermost, or deepest, is composed of several rows of small cells, varying in size and shape, but usually cuboidal or round in outline. When these cells are shed rapidly they increase in size and have a more irregular form, especially in catarrhal conditions or where the mucous membrane is inflamed in any way. The intermediate plane is made up of a single or in part double layer of pyriform cells. Their tail-like prolongations are either single or double, but in the majority of instances single, and fitted in between the epithelial cells of the deeper layer. Their round ends fit into depressions in the inferior face of the superficial cells.

The third or outer layer is composed of a form of flattened cells called transitional. These cells are made up of large masses of protoplasm which usually appears to have two or more nuclei, but often this phenomenon is an optical illusion, and one at least of the apparent nuclei is produced by the fossa on their lower surface, where it rests upon the underlying corpuscles. In case of an ordinary catarrhal condition or inflammation, the epithelial membrane may be cast off in separate layers, or with its three layers adhering together, and appearing as such under the microscope.

A careful examination of the mucous membrane of the renal pelves, of the ureters, of the bladder, and of the vagina, demonstrates that in all these regions the membrane is composed of three layers of cells similar to those found in the urine as illustrated by Figs. 5097 and 5098, and from the bladder, ureters, renal pelves, and vagina, as in Fig. 5099. Although the epithelial cells known as flat, or vaginal, do not concern us directly in the study of pyelitis, they do indirectly in giving a more complete knowledge of all the kinds of epithelial cells that may be found in the urine, and the varying circumstances under which they may be present. A few words, therefore, in relation to them is quite admissible at this point.

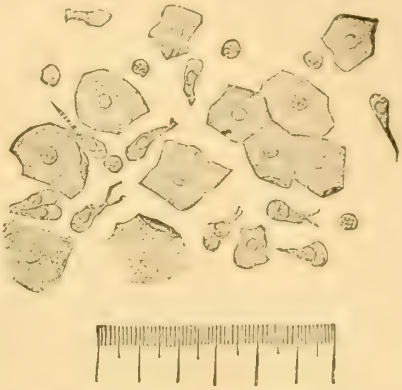

FIG. 5097.—Cells found in Urine. Each division of the scale equals 0.0033 mm., or 3.3 μ, roughly, 3⅓ μ. The large flat cells average, probably, from 40 to 55 or 60 μ in their greatest diameter. Fifty cells, measured carefully by the author, averaged 49 μ in their greatest diameter, and 37 μ in the diameter at right angles to the long one.

The so-called vaginal epithelial cells have been found, on investigation, to be quite as likely to come from the female bladder, and even from the ureters or the pelves of the kidneys, as from the vagina. There is also another quite interesting point of medico-legal interest in connection with these cells, some alleging that they are always absent in the virgin. The writer's attention was especially called to this subject when making a necropsy upon a female patient, aged eighteen, who had died twenty-four hours after a fracture of the skull. When the kidneys were examined they unexpectedly gave every evidence of a chronic parenchymatous metamorphosis. The urine was examined to see if it contained evidence of the renal lesion, which it did in every particular. It was also found to contain an abundance of large flat cells identical with those commonly called vaginal, and single and

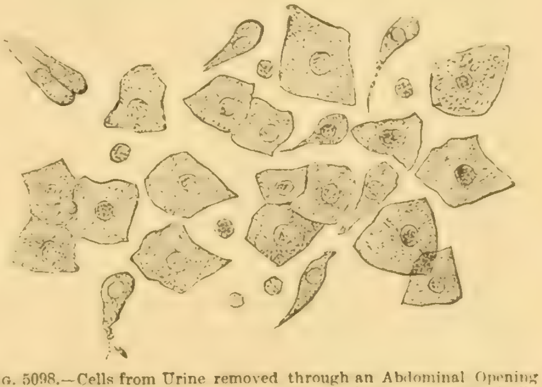

FIG. 5098.—Cells from Urine removed through an Abdominal Opening into the Bladder. The measurements for this figure are practically the same as in Fig. 5097.

bifid-tailed cells also were abundant. In this case the urine was not withdrawn through the urethra, but the bladder, which happened to be distended, was opened from the abdominal cavity, and its contents were withdrawn through a clean syringe. Further, there was no evidence of the existence of an acute or chronic inflammation of the pelves of the kidneys. Excluding the vagina, and tracing the origin of these flat cells to the bladder, it becomes necessary to explain the fact of their frequency in the female and rarity in the male; this can be done as follows: From the loose attachment of the bladder to the movable anterior wall of the vagina there is of necessity greater mobility in the female than in the male. The frequent motion and tendency to pouching of the trigonum vesicæ, and the more frequent over-distention in the female, naturally tend to excite a mild catarrh, which damages the epithelial cells, loosens their attachments, and easily accounts for their frequent and abundant desquamation. On the other hand, the firm attachments of the male bladder to the surrounding tissue, and its less mobility and distensibility, tend to hold the epithelial cells in their proper relations. In either sex, when this desquamation does occur from the bladder only, it is quite clear from the accompanying cuts that not only flat epithelial cells, but single and bifid-tailed epithelial cells, will also be found in goodly numbers.

This point of depending upon the tailed cells or any special form as diagnostic of pyelitis, appears to be quite conclusively overthrown by the following observations, made by Dr. Creedon, now of Globe Village, Mass., while working in the laboratory of Professor Satterthwaite. He prepared with great care specimens of the epithelial cells from the different portions of the urethra, bladder, ureters, pelves of the kidneys, and renal tubules. He made accurate measurements and also drawings of the cells removed from the various regions. The result of his researches was, that single and bifid tailed epithelial cells were present throughout the mucous membrane of the urinary tract, from the meatus urinarius to the papillæ of the kidneys. He further found that the renal epithelial cells, and those from the deeper layers of the urinary tract and from the uriniferous tubules of the kidneys, also corresponded exactly in size and shape in all the specimens and in the different regions. Of course, various shapes and sizes existed throughout, but the general average was uniformly the same. This careful observation was strong evidence in favor of the impossibility of locating with certainty the source of any given variety of epithelial cells when found in the urine. These experiments were made upon subjects in whom the membrane was free from any inflammatory process at the time of death. If the membrane examined was the seat of any inflammatory action, the rapid metamorphosis, subdivision, and desquamation of the cells would tend to make the similarity still greater.

In the instance already cited by the writer, the tailed epithelium, both single and bifid, was abundant, but there was no evidence of pyelitis or of any inflammatory condition of the urinary tract at the necropsy. There was, however, catarrh of the bladder. To establish more certainly the close similarity in the shape and size of the epithelial cells in the various regions of the genito-urinary tract, the writer and his assistants made a large number of similar examinations. Specimens were carefully prepared from the pelves of the kidneys, the ureters, the fundus and trigonum of the bladder, and from the vagina. Drawings and measurements were made of the various kinds of cells from the different regions, also of the cells found in the urine taken from the bladder through the catheter at the time when the necropsies were made. In all the different regions and in all the cases examined, the size and shape so closely corresponded that no apparent difference could be made out, as is well illustrated by the drawings (Fig. 5089). The various specimens were also carefully measured, and the figures corresponded. The only variation that could be detected in the flat cells was a slight difference in size, those from the vagina and bladder being a little larger than those from the ureters and pelves of the kidneys.

The middle layers of the vagina contained cells that approached more closely typical spindle-shaped cells than the pyramidal type of the other regions.

The results obtained by Dr. Creedon, together with the writer's observations, are strong proof of the untrustworthiness of the statement of Professor Ebstein in von Ziemssen's "Cyclopædia of Medicine," vol. xv., p. 574, that the occurrence of tailed epithelial cells in purulent urine is the most positive indication that the patient has pyelitis. By reason of the above facts it becomes absolutely impossible to base any positive diagnosis of pyelitis upon anything found in the urine with the microscope. Albumin will always be found on account of the pus.

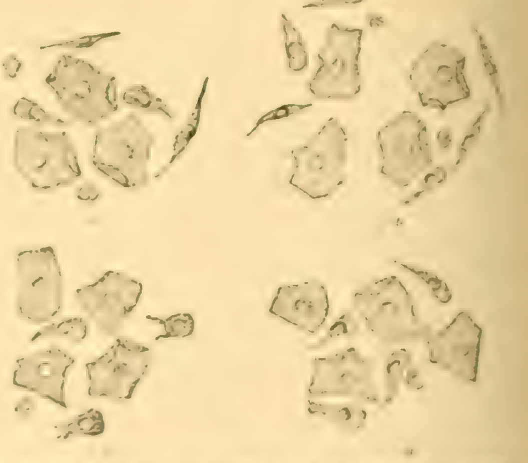

FIG. 5089.—a, Cells from the vagina; b, the six cells on the left came from the trigonum vesicæ, and the six to the right from the fundus of the bladder; c, cells from the ureters; d, cells from the renal pelvis.

In some cases the urine and pus may be retained in the pelvis of one kidney for a time, and the urine excreted by the other kidney will then appear normal.

In other instances the urine is permanently retained in the pelvis of one kidney; under such circumstances there will often be found a pyelonephritic tumor in the lumbar region, which will produce a bulging of the side between the crest of the ilium and the twelfth rib. There will be deep-seated fluctuation, which can be detected upon palpation, with tenderness upon pressure, and dulness upon percussion, except where the tumor is crossed by the colon containing gas. If tapped, a seropurulent fluid may be obtained, but with all the above symptoms the urine may remain normal and free from pus.

A mild form of pyelitis is far more frequent than the severer type just described. It is often mistaken for and treated as a cystic catarrh or inflammation.

This variety is often quite chronic, when it unquestionably acts as an exciting cause for the development of intrinsic renal lesions. Its characteristic symptoms are the passing of pale *acid* urine, which usually has a low specific gravity, and contains albumin and pus corpuscles. The urine from a case of chronic pyelitis contains a fair amount of pus, while the reaction remains strongly acid; in cystitis the urine contains pus in varying quantities, but the reaction is alkaline.

From the study of a large number of these cases this conclusion has been formulated: When the patient has increased micturition, and has to rise several times during the night to empty the bladder, and the urine passed is strongly acid, with a considerable quantity of pus-corpuscles and some albumin, but no casts, the catarrhal or inflammatory condition is located in the pelves of the kidneys.

These cases are frequently kept up by an undue acidity of the urine. This high acidity also prevents the alkaline fermentation that otherwise would occur, and explains the irritability of the bladder, and the symptoms simulating a catarrhal or inflammatory state of this viscus.

In other cases this superacidity induces such a copious discharge of mucus from the pelves of the kidneys, that an alkaline fermentation is speedily developed, and the urine which escapes from the urethra is at all times alkaline in its reaction.

This has led to the supposition that the primary cause was an undue alkalinity of the urine, and when the cases have been treated as such, the results have proved to be unsatisfactory. When, however, the true cause, the superacidity of the urine, is recognized and treatment for it instituted, a rapid disappearance of the alkalinity occurs, and an improvement or complete recovery is soon effected.

The *diagnosis* in many cases of pyelitis is exceedingly difficult to make with certainty. If the patient has, along with the above symptoms, alternating intervals of purulent and clear or normal urine, the diagnosis of pyelitis is pretty certain to be confirmed at the necropsy. This phenomenon occurs in connection with those cases which are due to renal calculi, or plugging of the ureter with mucus or inspissated pus. On the other hand, it should be remembered that this fluctuation is not always present. The continuous discharge of acid urine containing pus, especially in the absence of marked bladder symptoms, is positively diagnostic of pyelitis.

The *prognosis* depends in a great measure, if not wholly, upon the exciting cause. When it is a complication of chronic cystitis, enlarged prostate, urethral stricture, and operations upon the genito-urinary tract, the prognosis is very unfavorable, to say the least. When pyelo-nephrosis occurs the tumor may disappear, the sac be obliterated, and the patient recover, but it ruins one kidney; if this does not take place, and no rupture follows, death may be expected from exhaustion or septic toxæmia. Should the sac rupture, the prognosis will depend upon the seat of the extravasation; if it is into the peritoneal cavity, or the retroperitoneal areolar tissue, death will ensue from shock, peritonitis, or septicæmia; if externally or into the alimentary tract, the patient may, and not infrequently does, recover. If both kidneys are the seat of a pyelitis, the case is almost always certain to terminate fatally, but when only one is implicated there is always a chance for recovery.

Treatment.—At the onset of the disease, wet or dry cups to the loins, followed by warm poultices, should be employed, and morphine should be injected hypodermatically if the pain be very severe and unbearable; considerable care, however, must be exercised in the use of opium in any form, for in some it excites a fatal uræmia. Alkaline and demulcent drinks should be administered freely, as they render the urine less irritating.

The combination of damiana, hyoscyamus, and bicarbonate of potassium is a most valuable mixture not alone in inflammations of the renal pelvis, but in all forms of catarrh and inflammation involving any portion of the mucous membrane of the urinary tract. This statement is especially true in regard to the bladder. For it is quite clear that a large proportion of the inflammatory conditions of this canal, not due to a calculus or some mechanical obstruction, are in a great measure dependent upon a depressed and overworked condition of the lumbar portion of the spinal cord, and to a similar condition of the abdominal sympathetic system, and especially of the hypogastric, renal, and vesical plexuses, in connection with an over-acid condition of the urine.

If we overcome these difficulties, restore the cord and sympathetic system to their normal state, and remove the irritant properties of the urine, the inflamed mucous membrane will, by nature's intrinsic reparative powers, be speedily restored to its normal condition.

The combined use of the fluid extract of damiana and hyoscyamus and bicarbonate of potassium fullfis these three indications, and their administration is usually followed by immediate relief.

The damiana is one of the most powerful tonics to a depressed or overworked spinal cord; while in health it has but little, if any, influence. The so-called antispasmodic action of hyoscyamus is due to its power to stimulate a weakened sympathetic system, and in these cases acts by its stimulating properties, and raises the depressed and irritable hypogastric plexuses to their normal standard and activity. The alkali renders the superacid urine less irritating and more nearly normal in reaction.

The hyoscyamus and potash are not new agents, but the damiana is, and one greatly needed in many of these cases, for they are frequently excited by venereal excesses. Hot baths, especially hip-baths, and perfect rest must be insisted upon. One of the best methods for a medicated sitz-bath is to put a bunch of wormwood in a chamber or other receptacle in a closed water-closet chair, and then pour on it some boiling-hot water, and have the patient sit over the steaming infusion.

If the disease becomes chronic, with the excretion of large quantities of pus, astringents, especially gallic acid, will be found useful, and in all a nutritious nonstimulating diet must be enforced.

In case pyonephrosis makes its appearance, aspiration is the only mode of treatment at first, both to prove the correctness of the diagnosis and to lessen the immediate danger from rupture into some locality, when a fatal result would be almost certain to ensue; later, if the tumor reappears, it may be expedient to make a free and permanent opening through the abdominal wall.

Counter-irritation to the lumbar region, in the form of actual cauterization, is often followed by a great improvement.

As an undue acidity of the urine often exists and keeps up the inflammatory action, it should be regarded as indicating a digestive disturbance which requires attention, in order that the quantity of uric acid produced may be diminished. By a careful attention to this condition, as well as to the local disease, the nutritive powers of the system will be increased, and the amount of irritating excretory products passing out through the urinary tract will be greatly decreased. The accomplishment of these two ends will insure recovery in many instances when all local measures have failed, but when both are judiciously combined a favorable result is almost certain.

In addition to the means already enumerated, the operation of kolpo-uretero-cystotomy,[1] as practised by Dr. Nathan Bozeman, may be successfully carried out in some cases. This operation consists in the establishment of a temporary vesico-vaginal fistula, by cutting through the anterior wall of the vagina into, and through, the posterior wall of the bladder, in such a direction that the superior extremity of the wound will terminate just anterior to the vesical opening of the ureter to be treated. In this way the ureter can be easily catheterized, the pelvis of the kidney drained, and local medication readily applied. By using Dr. Bozeman's utero-vesical drainage support, all the inconveniences from incontinence of the urine will be avoided and the patient will be made perfectly comfortable. As all the discomfort from the vesico-vaginal fistula has been overcome, it can be kept open until the diseased condition of the ureter or renal pelvis has been cured. When the disease of the renal pelvis or that of the ureter has been subdued, the opening between the bladder and vagina should be closed by the ordinary operation commonly employed for vesico-vaginal fistulæ.

RENAL CALCULI.—The condition which stands next in importance to pyelitis is that known as renal calculi.

A renal calculus is a concretion formed in the tubules of the kidneys, or in the renal pelves, by a deposition of one or more of the solid constituents of the urine. Calculi may form at any time during intra- or extra-uterine life.

The precise cause of renal calculi is unknown, and although many theories have been advanced to account for their development, none is entirely satisfactory.

It is known, however, that every calculus has a nucleus of some foreign substance, such as pus, inspissated mucus, blood, pigment granules, or crystals of some sort; often uric acid, as this is the most insoluble substance found in the urine. The uric acid is also very frequently produced in abnormally large amounts. Further, renal calculi are usually composed of uric acid, but other kinds occur, such as those composed of oxalate of lime, phosphate of lime, carbonate of lime, cystine, xanthine, and still others composed of several of these ingredients.

In cases in which there has been a deposition of crystals without the formation of large calculi, the kidneys upon post-mortem section have a streaked appearance, usually of brick-red color, owing to the presence of the uric acid in the tubules. If the concretion be large and yet retained in the substance of the kidney, it becomes the source of much irritation; congestion and inflammation are excited, and often followed by suppuration and abscess; in fact, it acts as a foreign body would elsewhere. If, on the other hand, it passes from the kidney and remains in the pelvis of the organ, it becomes a fruitful source of pyelitis. By blocking up the opening to the ureter it may produce hydronephrosis. In case the calculus becomes large, it may of itself press upon the renal substance and in this way cause marked atrophy of the kidney. Passing from the renal pelvis down to the bladder through the ureter, it may there become the nucleus for the formation of a vesical calculus.

Symptoms.—Renal calculi which are retained in the pelvis of the kidney may increase to a very large size, and even completely destroy the renal substance, without having given rise to any sign of their presence during the life of the patient.

But usually there is pain in the lumbar region, which shoots down the groin, and is aggravated by exercise or any jolting of the body. In the urine blood, pus, epithelial cells, and often crystals, usually of uric acid or oxalate of lime, are discovered. Sometimes a calculus may pass from the pelvis through the ureter to the bladder, and so on out through the urethra, without the patient's knowledge; but, as a rule, the symptoms are painfully severe.

When attacked by renal colic the patient complains of intense shooting pains in the loins, radiating over the hypogastrium and down the inner side of the thighs. The testicle and the scrotum of the affected side are often retracted, and there is sharp pain there, as well as in the head of the penis. In the female the labia are affected in like manner, but women seldom suffer from renal calculi.

There is often nausea and vomiting, the patient is covered with a cold perspiration, the respiration is rapid and shallow, the pulse small, hard, and rapid, with great anxiety of countenance.

An attack may last for a few minutes only, or there may be remissions followed by recurrences, each one appearing to the patient more serious than the one which preceded; but if the calculi become lodged in the ureter, the symptoms gradually subside and hydronephrosis is developed.

Prognosis.—The presence of a renal calculus in the pelvis of the kidney is variable in its consequences. No danger is to be feared so long as complications are not developed. When they occur the prognosis rests upon the nature of the complication, and not upon the presence of the calculus. A fatal result from renal calculi rarely occurs, unless by the induced suppression of urine, secondary to nervous exhaustion excited by nature's efforts to expel the stone.

Treatment.—Under the head of treatment many different ways have been proposed, with the view of dissolving the calculus *in situ*, but none of them has been found reliable. The very great insolubility of uric acid in water renders it almost impossible to pass enough of any safe solvent through the system to dissolve it after it has once been deposited in its crystalline form. Perhaps a hygienic mode of life, by which the food-stuffs are most perfectly oxidized, and urea instead of uric acid is produced, is as near a safeguard as anything in the way of a prophylactic. In renal colic, baths as hot as the patient can bear, or hot applications over the abdomen and loins, relax the tissues and lessen the pain, but they do not arrest the muscular contraction on the part of the ureters as much as does the administration of ether or chloroform. In conjunction with the heat, the internal administration of full doses of belladonna and strychnine will diminish the irregular and spasmodic contraction of the muscular coat of the ureter, while the normal and even peristaltic action will be intensified, and its expulsatory power increased.

Opium and anæsthetics are to be avoided, if possible. The anæsthetics tend to diminish the peristaltic action of non-striated muscle-fibres, and hence prevent the movements of the calculus along the ureter. They will, of course, if given in sufficient quantities, relieve the pain, but when the patient recovers from their influence he is no better, and the stone has made little or no progress in its descent. They are, however, of service in relaxing the tissues and giving the patient a rest.

Opium is usually inefficient, for the same reason as the anæsthetics, and besides it has a dangerous element. To completely alleviate the suffering in these cases, enormous doses of the drug may be required. If now, for any reason, the calculus should slip through into the bladder, the necessity for the opium at once disappears, and the patient may become suddenly narcotized, which might prove both a troublesome and a serious, if not a fatal, complication. For this reason great care should be exercised in reference to the quantity of opium administered, either by the mouth or hypodermatically.

In cases in which a calculus is retained in the pelvis of the kidney, and complications make their appearance, nephrotomy is probably the only treatment that will afford relief. But in those cases in which the stone becomes lodged in the ureter, the method described by Mr. Reginald Harrison, in a paper entitled "On the Possibility and Utility of Washing out the Pelvis of the Kidney and Ureters through the Bladder," may be of service. Mr. Harrison narrates the following case in his paper: A middle-aged man was under observation for acute renal pain, which was assumed to be due to a renal calculus. Nephrotomy was suggested, but the patient would not submit. The stone finally was believed to be lodged in the ureter. The previous passage of renal calculi led to the supposition that the ureter was dilated. Acting upon this theory, and after washing out the bladder, the organ was filled with tepid water, upon which pressure was exercised by the evacuator usually employed in litholapaxy. The patient at once became conscious of something moving in the back, and subsequently half a teaspoonful of phosphates and uratic debris was removed. This process was repeated on several occasions with a similar result, and gave much relief. Clinical facts such as these, taken in connection with pathological specimens, show that it is possible to reach the kidney in this way, and that the escape of calculi may thereby be facilitated.

This method of treatment, however, can only be of service when the ureters have previously been dilated. In the primary attack of a calculus, or in other diseased conditions of the ureters, it would not be wise, even if it were possible, to distend the bladder with the view of secondarily dilating the ureter.

URETERITIS.—A simple uncomplicated ureteritis probably never occurs. Inflammation of the ureter is usually, if not always, due to the passage of a calculus, the extension of an inflammatory process from the renal pelvis downward, or from the lower portion of the urinary tract upward and backward. Whatever the local symptoms are, they are so masked by those of the exciting cause that they in themselves become unrecognizable. If there is pain and irritation along the course of the genito-crural nerve, with retraction of the scrotum in the male, or of the labia majora in the female, it is reasonable to suppose that the ureter is involved in the diseased process.

RUPTURE OF THE URETER followed by recovery has been reported in a few cases. As there are no necropsy records in connection with ruptured ureters, it is impossible to say with accuracy what the pathological phenomena are in such instances. The probability is that rupture acts like an occlusion or ligature of the ureter, and causes an arrest of the functional activity of the kidney, followed by an atrophy of the gland and a complete collapse and obliteration of the ureter.

New Growths in the Ureters.—Various neoplasms have been found to invade the ureters, but in almost every instance the new growth in the ureters has been secondary to a primary disease in the kidney or bladder. All the symptoms present will be more directly traceable to the primary condition, and this renders it almost, if not absolutely, impossible to locate any diseased condition in the ureter alone.

The two new growths most frequently found invading the ureters are carcinomatous and tubercular neoplasms, secondary to a similar condition existing in the bladder.

The writer has found but one instance of a new growth in the ureter at the post-mortem table, during an extensive experience of more than ten years. In this case there was a general tubercular infiltration of the membranous and prostatic portion of the urethra, of the prostate, of the wall of the bladder, and of both ureters up to the pelves of the kidneys. This extensive development of new tissue had not occluded the lumen of the genito-urinary tract, nor in any way impeded the discharge of urine; and, so far as known, had not given rise to any marked symptoms during life.

The patient from whom the specimen was obtained was a laboring man, who was accidentally killed while at work, and the necropsy revealed this extensive diseased condition of the genito-urinary tract.

Congenital Malformations in the shape of two or more ureters arising from a common pelvis are very frequently found. As a rule they join to form a common ureter before entering the bladder, but in a few rare instances they have been found to pass separately through the vesical wall. The presence of valve-like folds, causing partial or complete occlusion of the ureter, is not infrequently recorded among the malformations of the ureters. *William Henry Porter.*

UTERUS: EPITHELIOMA OF THE CERVIX. Pathological Anatomy.—No more fitting introduction to a description of the various forms of carcinoma of the cervix uteri could be found than the following words of Lusk: "The old familiar division of uterine cancer into scirrhus, medullary cancer, colloid cancer, and epithelioma, has at the present time ceased to be tenable. It was based upon tactile impressions, physical appearances, and peculiarities of growth. It represented not distinct varieties, but accidental conditions, or successive stages of development. It served to introduce into the subject an element of confusion detrimental to progress, as rarely two observers were found in agreement as to the classification of the disease in the same patient. A true pathology is necessarily based upon minute structure, modes of development, and variations due to site."

The general acceptation of the views of Ruge and Veit has materially altered not only the hitherto entertained opinions as to the origin and early development of cancerous disease of the neck of the womb, but the whole nomenclature of the subject, so that it is no longer expedient or correct to speak, for example, of epithelioma, of scirrhous, or medullary carcinoma of this locality, but it becomes necessary to class all of these forms under the generic term cancer, and to establish new subdivisions in accordance with "minute structure, modes of development, and variations in site."

For the purpose of elucidating the subject under discussion Ruge and Veit divide the neck of the uterus into two parts, the portio vaginalis, extending from the external os uteri to a point a little above the vaginal fornix, and the cervix proper, that is to say, all that part of the collum lying above the vaginal portion. In the first of these locations—the vaginal portion,—while the malignant disease may appear under various forms, the nodular and cauliflower varieties are the most distinctly marked and the most commonly observed. Cancerous nodules may appear near the superficies, which, breaking down, leave ulcers behind of varying depths; or a pre-existing benign papillary erosion gradually changes its character, presenting at first a sharply bounded, finely granular, slightly depressed, and faintly yellowish area, and, subsequently, as the malignant process advances, a pronounced fungous or cauliflower-like excrescence, which may ultimately attain such dimensions as to fill the entire vagina.

In all forms of cancer of the vaginal portion the tendency of growth is downward, and if other tissues become involved by direct extension of the disease, or by metastasis, they are such as lie below the level of the external os, a point that is respected in the early development of carcinoma of the portio vaginalis.
